Abstract. We develop a semi-classical method to simulate the motion of atoms in a dissipative optical lattice. Our method treats the internal states of the atom quantum mechanically, including all nonadiabatic couplings, while position and momentum are treated as classical variables. We test our method in the one-dimensional case. Excellent agreement with fully quantum mechanical simulations is found. Our results are much more accurate than those of earlier semi-classical methods based on the adiabatic approximation.

PACS. 32.80.Pj Optical cooling of atoms; trapping – 03.65.Sq Semiclassical theories and applications

1 Introduction

One of the most spectacular achievements in the field of laser cooling is the discovery of cooling below the Doppler limit in optical lattices, so-called Sisyphus cooling [1]. An optical lattice is a standing wave of laser light, forming a periodic light-shift potential for atoms moving in the laser field [2,3]. In the optical lattices used for cooling the frequency of the lasers are tuned close to an atomic resonance. The atoms thus undergo cycles of absorption followed by spontaneous emission. Under the right experimental conditions, the spontaneous emission causes an overall loss of kinetic energy of the atoms, i.e., cooling.

Optical lattices are also widely used in Bose-Einstein condensation experiments [4] and for quantum state manipulation [5]. These lattices are tuned far from atomic resonances, in order to avoid spontaneous emission which would destroy the coherence of the condensate. Therefore these far detuned lattices do not provide any cooling.

The name Sisyphus cooling comes from the first theoretical model for the process [6,7]. This model is based on optical pumping between the magnetic sublevels of the light shifted atomic ground state. However, at least in its original form it relies on a number of simplifying assumptions, such as a semi-classical approximation, spatial averaging, and a simplified level structure (a ground state with angular momentum \(J_z = 1/2\), and an excited state with angular momentum \(J_z = 3/2\)). Whereas this model correctly predicts some qualitative features of cooling in optical lattices, it is too crude to provide an overall quantitative agreement. Instead, a number of more advanced theoretical methods have been developed. The most accurate of these is the Monte-Carlo wavefunction technique [8], a fully quantum mechanical method based on stochastic wavefunctions.

In this paper, we develop and test a new semi-classical method for simulating the motion of atoms in a near-resonant optical lattice. The most important approximation of our method is the position and momentum of the atoms are treated as classical variables. Other approximations include a classical treatment of the light field, and adiabatic elimination of excited states of the atoms, but otherwise we make as few approximations as possible. In particular, the internal states are treated quantum mechanically, allowing for any kind of coherent superposition between magnetic sublevels.

Even though more exact fully quantum mechanical theoretical methods exist, semi-classical methods are valuable, partly because they are less demanding numerically, but also because they provide a simpler conceptual framework in which it is easy to formulate an intuitive picture of the mechanisms involved in the cooling process. Up to now, all semi-classical methods for laser cooling in optical lattices have been based on atoms that are pumped between definite internal states as they move through the lattice. To this end a basis of so-called adiabatic states, diagonalizing the light-shift potential at every position, has been used instead of the diabatic basis of the magnetic substates [9]. Coherences between adiabatic states have not been included in the description, and neither have so-called nonadiabatic couplings arising from the position dependence of the adiabatic basis. Thus, the motion of the atoms is described by purely classical equations, albeit the various potentials, pumping rates and diffusion coefficients have been derived from a quantum-mechanical origin. These adiabatic semi-classical methods reproduce some of the qualitative features of Sisyphus cooling, e.g. a linear relation between temperature and irradiance at high irradiances [10]. However, we show that even at very high irradiances the slope of this linear dependence does not agree with fully quantum-mechanical simulations. At the
lower irradiances relevant to most experiments the adiabatic semi-classical method deviates even more severely from the fully quantum-mechanical results. Both these problems are solved by the nonadiabatic semi-classical approach.

2 Theory

In this section we develop the basic semi-classical equations of motion, on which our simulations are based. For generality the theory is developed in three dimensions. The angular momenta of the ground and excited states of the lattice transition are denoted by $J_g$ and $J_e$ respectively, and the corresponding magnetic quantum numbers are $M_g$ and $M_e$. Although the derivation is more general, we shall in the end apply the theory to the case $J_e = J_g + 1$.

Also, the light field $\mathbf{\xi}(r)$ creating the lattice could take different forms, but will in the end be assumed to have a linear configuration in one, two or three dimensions. That is, the lattice is created by the interference pattern of light fields, forming lattice sites with alternating $\sigma^+$ and $\sigma^-$ polarizations.

We start from the optical Bloch equations for an atom in a standing wave laser field. They can be derived from the fully quantum-mechanical results. Both these batic semi-classical method deviates even more severely from the ground to the excited state, while $\hat{d}^- = (\hat{d}^+)^\dagger$ is responsible for the reverse process. In the basis of circular polarization vectors

$$\hat{\mathbf{e}}_{\pm 1} = \pm \frac{1}{\sqrt{2}} (\hat{x} \pm \hat{y}), \quad \hat{\mathbf{e}}_0 = \hat{z},$$

they have simple expressions in terms of Clebsch-Gordan coefficients

$$(\hat{d}_g^+) = (J_eM_e \mid J_e1M_g \hat{g}) = (\hat{d}_g^\dagger)^*.$$

In the basis of the magnetic substates $M_g$ the operator $\hat{A}(r)$ is represented a matrix $A(r)$. For the simple model atom with $J_g = 1/2$ and $J_e = 3/2$ $A(r)$ is a diagonal matrix. However, most atoms of interest have a more complicated level structure, including non-diagonal couplings in the potential. Therefore previous semi-classical methods have used adiabatic basis, where the atomic states are the eigenstates of $A(r)$. Whereas $A(r)$ is diagonal in the adiabatic basis, the position dependence of the basis gives rise to nonadiabatic couplings between adiabatic states. In the adiabatic approximation these couplings are neglected. In our method we keep all off-diagonal couplings. The results are then independent of the basis used, and the simplest choice is to stay with the magnetic levels $M_g$, the diabatic basis. Since this basis is the same for all $r$, all couplings are included in $A(r)$, and their functional form can be calculated analytically for a given laser configuration.

The second term on the right-hand side of Eq. \[2\] contains processes associated with spontaneous emission. Writing the matrix elements of $\sigma$ in the position representation, $\langle r \mid \sigma \mid r' \rangle = \sigma(r, r')$, its form is

$$\sigma(r, r')|_{sp} = -\frac{\Gamma'}{2}\left[A(r')\sigma(r, r') + \sigma(r, r')A(r')\right] + \frac{3\Gamma'}{8\pi} \int d\Omega_k \sum_{\epsilon \pm k} B_\epsilon^I(r)e^{-ik \cdot r}\sigma(r, r')e^{ik \cdot r'}B_\epsilon(r'),$$

where $\Gamma' = \Gamma s_0/2$. The matrices $B_\epsilon(r)$ are given by

$$B_\epsilon(r) = \left[\hat{d}^- \cdot \mathbf{\xi}^\dagger(r)\right] \left[\hat{d}^\dagger \cdot \mathbf{\xi}(r)\right].$$

Hence, $B_\epsilon^I$ represents the excitation of an atom by the laser field, and its subsequent return to the ground state via spontaneous emission of a photon with polarization $\epsilon$. The factors $\exp(ik \cdot r)$ represent the atomic recoil from a spontaneously emitted photon with wave vector $k$. The integration is over the directions of the emitted photon, and the summation is over any axis spanning the allowed

$$\hat{d}^+ = \hat{d}^\dagger - \hat{d}^- = \hat{A}^{\dagger}(r).$$

where $\hat{p}$ is the momentum operator of the atom, $r$ its position, $\Delta' = \Delta s_0/2$, and the operator $\hat{A}(r)$ is given by

$$\hat{A}(r) = \left[\mathbf{\xi}^\dagger(r)\right] \left[\mathbf{\xi}(r)\right].$$

Here $\hat{d}^+$ is an operator that promotes an atom from the ground to the excited state, while $\hat{d}^- = (\hat{d}^+)^\dagger$ is responsible for the reverse process. In the basis of circular polarization vectors

$$\hat{\mathbf{e}}_{\pm 1} = \pm \frac{1}{\sqrt{2}} (\hat{x} \pm \hat{y}), \quad \hat{\mathbf{e}}_0 = \hat{z},$$

they have simple expressions in terms of Clebsch-Gordan coefficients

$$(\hat{d}_g^+) = (J_eM_e \mid J_e1M_g \hat{g}) = (\hat{d}_g^\dagger)^*.$$

In the basis of the magnetic substates $M_g$ the operator $\hat{A}(r)$ is represented a matrix $A(r)$. For the simple model atom with $J_g = 1/2$ and $J_e = 3/2$ $A(r)$ is a diagonal matrix. However, most atoms of interest have a more complicated level structure, including non-diagonal couplings in the potential. Therefore previous semi-classical methods have used an adiabatic basis, where the atomic states are the eigenstates of $A(r)$. Whereas $A(r)$ is diagonal in the adiabatic basis, the position dependence of the basis gives rise to nonadiabatic couplings between adiabatic states. In the adiabatic approximation these couplings are neglected. In our method we keep all off-diagonal couplings. The results are then independent of the basis used, and the simplest choice is to stay with the magnetic levels $M_g$, the diabatic basis. Since this basis is the same for all $r$, all couplings are included in $A(r)$, and their functional form can be calculated analytically for a given laser configuration.

The second term on the right-hand side of Eq. \[2\] contains processes associated with spontaneous emission. Writing the matrix elements of $\sigma$ in the position representation, $\langle r \mid \sigma \mid r' \rangle = \sigma(r, r')$, its form is

$$\sigma(r, r')|_{sp} = -\frac{\Gamma'}{2}\left[A(r')\sigma(r, r') + \sigma(r, r')A(r')\right] + \frac{3\Gamma'}{8\pi} \int d\Omega_k \sum_{\epsilon \pm k} B_\epsilon^I(r)e^{-ik \cdot r}\sigma(r, r')e^{ik \cdot r'}B_\epsilon(r'),$$

where $\Gamma' = \Gamma s_0/2$. The matrices $B_\epsilon(r)$ are given by

$$B_\epsilon(r) = \left[\hat{d}^- \cdot \mathbf{\xi}^\dagger(r)\right] \left[\hat{d}^\dagger \cdot \mathbf{\xi}(r)\right].$$

Hence, $B_\epsilon^I$ represents the excitation of an atom by the laser field, and its subsequent return to the ground state via spontaneous emission of a photon with polarization $\epsilon$. The factors $\exp(ik \cdot r)$ represent the atomic recoil from a spontaneously emitted photon with wave vector $k$. The integration is over the directions of the emitted photon, and the summation is over any axis spanning the allowed
polarization vectors. The recoil momentum of the atomic transition is $p_R = \hbar k_R = \hbar |k|$

Our goal is to approximate Eq. (2) by a semi-classical equation where every atom has a definite position and momentum, i.e. every atom follows a trajectory in phase space. This is of course not allowed in quantum mechanics, because of the uncertainty principle. Hence, a quantum momentum, i.e. every atom follows a trajectory in phase equation where every atom has a definite position and semi-classical approximation. According to this approximation 2

In this work the Wigner function is a matrix with dimension $2L_t + 1$. The Wigner transformation of Eq. (2) becomes

$$W(r, p, t) = \frac{1}{\hbar^3} \int dq \left< r + \frac{u}{2} \right| \sigma \left| r - \frac{u}{2} \right> \exp \left[ -ip \cdot u/\hbar \right].$$

In this work the Wigner function is a matrix with dimension $2L_t + 1$. The Wigner transformation of Eq. (2) becomes

$$\left( \frac{\partial}{\partial t} + \frac{p}{m} \cdot \nabla_r \right) W(r, p, t) =$$

$$\frac{i}{\hbar^3} \int dq \sum_{\lambda=1}^{N} \int dq' \sum_{\epsilon=1}^{k} \int dq'' \exp [iq \cdot r/\hbar][W(r, p + \frac{q}{2}, t) \tilde{A}(q) - \tilde{A}(q)W(r, p - \frac{q}{2}, t)]$$

$$- \frac{i}{2\hbar^3} \int dq \sum_{\lambda=1}^{N} \int dq' \sum_{\epsilon=1}^{k} \int dq'' \exp [iq \cdot r/\hbar][W(r, p + \frac{q}{2}, t) \tilde{A}(q) + \tilde{A}(q)W(r, p - \frac{q}{2}, t)]$$

$$+ \frac{3\Gamma'}{8\pi\hbar^6} \int d\Omega_k \sum_{\epsilon=1}^{k} \int dq \int dq' \exp [iq \cdot r/\hbar] \tilde{B}_e(q') W(r, p + \hbar k + \frac{q' + q}{2}, t) \tilde{B}_e(q).$$

Here $\tilde{A}$ and $\tilde{B}_e$ are the Fourier transforms

$$\tilde{A}(q) = \int dr e^{-iq \cdot r/\hbar} A(r),$$

$$\tilde{B}_e(q) = \int dr e^{-iq \cdot r/\hbar} B_e(r).$$

No approximation has been made in going from Eq. (2) to Eq. (10). The Wigner transformation is just another representation of the same physics. Now, we introduce the semi-classical approximation. According to this approximation the momentum distribution varies smoothly and slowly over typical momentum transfers $q$ in Eq. (10). Since $A(r)$ and $B_e(r)$ have the same periodicity as the laser field, i.e. $\lambda = 2\pi/kr$, Eqs. (11) and (12) show that the typical size for $q$ is the recoil momentum. Thus, the semi-classical approximation assumes that the momentum distribution changes little for emission/absorption of a single photon. As long as the atomic momenta are several recoil units large, and the effects of quantization of the atomic states are small, this approximation can be expected to work well.

Invoking the semi-classical approximation we can make a second-order Taylor expansion around $p$ of the Wigner distribution

$$W(r, p + q, t) \simeq W(r, p, t) + q \cdot \nabla_p W(r, p, t)$$

$$+ \frac{1}{2} (q \cdot \nabla_p)^2 W(r, p, t).$$

Using this expansion it is possible to replace $\tilde{A}$ and $\tilde{B}_e$ by their counterparts in position space. The resulting equation for the semi-classical Wigner function, which now can be interpreted as a phase-space distribution, is

$$\left( \frac{\partial}{\partial t} + \sum_{i=1}^{3} \frac{p_i}{m} \frac{\partial}{\partial r_i} \right) W(r, p, t) = i\Delta' \left[ W(r, p, t), A(r) \right]$$

$$- \frac{\Gamma'}{2} \left\{ W(r, p, t), A(r) \right\}$$

$$+ \frac{\Gamma'}{2} \sum_{q=0, \pm 1}^{3} B_q \left( r, p, t \right) W(r, p, t)$$

$$+ \frac{i\hbar \Delta'}{4} \sum_{i=1}^{3} \left\{ \partial_p, W(r, p, t), \partial_i A(r) \right\}$$

$$+ \frac{i\hbar \Delta'}{4} \sum_{i=1}^{3} \left\{ \partial_p, W(r, p, t), \partial_i A(r) \right\}$$

$$+ \frac{i\hbar \Delta'}{4} \sum_{i=1}^{3} \left\{ \partial_p, W(r, p, t), \partial_i A(r) \right\}$$

$$- \frac{\hbar^2 \Delta'}{2} \sum_{i=1}^{3} \left\{ \partial_p, \partial_p, W(r, p, t), \partial_i A(r) \right\}$$

$$+ \frac{\hbar^2 \Delta'}{2} \sum_{i=1}^{3} \left\{ \partial_p, \partial_p, W(r, p, t), \partial_i A(r) \right\}$$

$$- \frac{\hbar^2 \Delta'}{2} \sum_{i=1}^{3} \left\{ \partial_p, \partial_p, W(r, p, t), \partial_i A(r) \right\}$$

$$+ \frac{\hbar^2 \Delta'}{2} \sum_{i=1}^{3} \left\{ \partial_p, \partial_p, W(r, p, t), \partial_i A(r) \right\}$$

$$+ \frac{\hbar^2 \Delta'}{2} \sum_{i=1}^{3} \left\{ \partial_p, \partial_p, W(r, p, t), \partial_i A(r) \right\}$$

In this equation we use the short-hand notation $\partial_i \equiv \partial/\partial r_i$, $\partial_p \equiv \partial/\partial p_i$, where $i = x, y, z$ are the Cartesian coordinates. The constants $\eta_{i,q}$ come from the integration over the direction of the spontaneously emitted photon, and are given by

$$\eta_{x, \pm 1} = \eta_{y, \pm 1} = 3/4, \quad \eta_{z, 0} = 1/2$$

$$\eta_{z, 0} = \eta_{y, 0} = 1, \quad \eta_{z, \pm 1} = 1.$$

Although the equation is somewhat lengthy, it is possible to give physical interpretations to its terms. The left hand side is simply the kinetic term, i.e. the full derivative $d/dt$. On the right, the terms where $W(r, p, t)$ appear without
any derivative represent transfer of population between states, either by couplings from non-diagonal terms of the light-shift potential $\Delta' A(r)$, or by optical pumping. The terms containing $\partial_{p_i} W(r, p, t)$ describe the motion of the atoms due to forces from light-shift potential and the radiation pressure. Terms containing second derivatives of both $W(r, p, t)$ and first or second derivatives of $A(r)$ or $B_q(r)$ describe the momentum diffusion due to fluctuations in the number of photons absorbed. Finally, the term containing $\partial^2_{p_i} W(r, p, t)$, but no other derivatives, contains the momentum diffusion due to the recoil kick from spontaneously emitted photons.

Equation (14) is the most complete semi-classical approximation for the time-dependent distributions of atoms in $r$ and $p$ space. It is classical in the sense that the atoms are assumed to be particles with definite positions and momenta. The internal states, however, are treated fully quantum mechanically, including all off-diagonal couplings and coherences. It is thus not possible to assign an atom to a definite internal state, nor is it described as a classical probability distribution over the different internal states, but as a quantum-mechanical superposition of internal states.

In order to solve Eq. (14) we recast it into a Langevin-type equation. That is, instead of calculating distributions of atoms, we shall calculate phase-space trajectories $\tilde{x}(t)$ and $\tilde{p}(t)$ of individual atoms. In doing this, we still want to keep the quantum mechanical description of the internal states. That is, the probability distribution of an atom is

$$W(r, p, t) = w(t) \delta (r - \tilde{r}(t)) \delta (p - \tilde{p}(t)).$$

Here $w(t)$ is a matrix of dimension $2J_g + 1$ containing the internal-state density matrix of the atom at time $t$. Inserting this form into Eq. (14), and integrating over position and momentum, the evolution equation for $w(t)$ is obtained

$$\dot{w}(t) = iA'[w(t), A(r)] - \frac{\Gamma}{2} \{w(t), A(r)\}$$

$$+ \Gamma \sum_{q=0, \pm 1} B_q^\dagger(r) w(t) B_q(r).$$

(17)

Here and below, we use the simplified notation $r$ for $\tilde{r}(t)$ and $p$ for $\tilde{p}(t)$. It is, however, important to understand that these are now time-dependent functions representing position and momentum of a single atom, which are conceptually very different from the variables in Eq. (14). Using that $\langle x \rangle = \text{Tr} [x w]$ etc., we derive the equations for the evolution of $x$ and $p$ (see, e.g., [12])

$$\dot{x} = \frac{p}{m},$$

$$\dot{p} = f(t) + \chi(t).$$

(18)

(19)

Here $f(t)$ is a force and $\chi(t)$ is a fluctuating force with the properties

$$\langle \chi_i(t) \rangle = 0, \quad \langle \chi_i(t) \chi_j(t') \rangle = 2D_{ij}(t) \delta(t - t').$$

(20)

The force is given by

$$f_i(t) = - \hbar \Delta' \text{Tr} \{\partial_i A(r) w(t)\}$$

$$- \frac{\Gamma}{2} \sum_{q=0, \pm 1} \text{Tr} \{[B_q(r) \partial_i B_q^\dagger(r)$$

$$- \partial_i B_q(r) B_q^\dagger(r)] w(t)\}. \quad (21)$$

The first term above is the force arising from the second-order light-shift potential, while the second term is the radiation pressure. The diffusion coefficient is

$$D_{ij}(t) = \delta_{ij} \frac{\Gamma \hbar^2}{5} \sum_{q=0, \pm 1} \eta_q \text{Tr} \{[B_q(r) B_q^\dagger(r)$$

$$+ \partial_i B_q(r) \partial_j B_q^\dagger(r)] w(t)\}. \quad (22)$$

The first term arises from the recoil from photons spontaneously emitted in random directions, while the second term is connected to fluctuations in the radiation pressure. The latter term is in general anisotropic.

### 3 Numerical implementation

We simulate the equations (17), (18) and (19) in one dimension. The laser field has the form

$$\xi(z) = \cos(k_R z) \epsilon_{-1} - i \sin(k_R z) \epsilon_{+1}. \quad (23)$$

At the start of every time step the system is in a pure quantum mechanical state. For every time step $w, z, \text{and } p$ are evolved using a second-order Runge-Kutta method. The fluctuating force $\chi(t)$ is included as a term

$$r \sqrt{2 D_{ij}(t)} \quad (24)$$

where $r$ is a random number with zero average and unit variance. This term only needs to be evaluated once every time step [13].

At the end of a time step, the system will not be in a pure state anymore. Its internal-state density matrix $w$ can, however, be decomposed into $2J_g + 1$ pure states

$$w = \sum_{i=1}^{2J_g+1} \lambda_i |\Phi_i\rangle \langle \Phi_i|. \quad (25)$$

The coefficient $\lambda_i$ are the eigenvalues, and $|\Phi_i\rangle$ the corresponding eigenvectors, of $w$. Since $w$ is a density matrix, the eigenvalues satisfy the properties $\lambda_i > 0$ and $\sum_{i=1}^{2J_g+1} \lambda_i = 1$, and can be interpreted as classical probabilities of the different states $|\Phi_i\rangle$. Hence, at the end of each time step the system has the probability $\lambda_i$ to make a “jump” into the pure state $|\Phi_i\rangle$. Even though a density matrix in general has an infinite number of decompositions into pure states, the decomposition above is unique.
in the sense that it is the only one into a set of linearly independent pure states.

For numerical efficiency the eigenvalues were obtained using first-order perturbation theory, which is sufficiently exact if $dt$ is short enough. In practice, one of the eigenvalues will be very close to one, while the others are small or zero. Thus, one can interpret the system as either staying in the same state, or jumping to a new state. When the eigenvalues obtained by perturbation theory indicate that the system makes a jump, the accuracy is increased by a full diagonalization of $w$. The expense in computer time for this improvement is modest, since jumps are comparatively rare.

4 Results

In our simulations we used the parameters for the D2 line in cesium, i.e. $J_g = 4, J_e = 5$, and natural width $\Gamma/2\pi = 5.2227 \text{ MHz}$, and recoil energy $E_R = 1.3692 \times 10^{-30} \text{ J}$. The diagonal elements of the diabatic potential for this transition are displayed in Figure 1. We first investigated the steady-state momentum distributions. For potential depths $\hbar |\Delta'| \geq 200 E_R$ the samples contained 5000 atoms, and were iterated for the time $2500/\Gamma'$. To improve statistics the momentum distribution was averaged over the last $1000/\Gamma'$ of the evolution time. For low potential depths convergence is slower. Therefore we used 20000 atoms for $\hbar |\Delta'| < 200 E_R$, and the evolution time $5000/\Gamma'$, with averaging over the last $2000/\Gamma'$. For all runs the time step was $dt = 0.025/\Gamma'$, and the initial state a spatially uniform distribution with temperature of 10 $\mu$K.

![Fig. 1. Diagonal elements of the diabatic potential for the $J_g = 4 \rightarrow J_e = 5$ transition. Each curve corresponds to a magnetic sublevel $M_e$ of the ground state. Curves corresponding to $\pm |M_e|$ share the same color coding, and differ only by the phase $\pi/2$. States with $M_e$ even (odd) are represented by solid (dashed) curves.](image)

Results for $\langle p^2 \rangle$ as a function of potential depth $\hbar |\Delta'|/E_R$ for a detuning $\Delta = -10 \Gamma$ are displayed in Figure 2. Our results are compared to a full-quantum simulation using the Monte-Carlo wave function method. The two methods are in excellent agreement. The relative difference is at most about 20%. It is not clear how much of this deviation can be attributed to the fundamental difference between the two methods, and how much is due to e.g. statistical uncertainties or other numerical errors. For deep potentials both methods give the same linear slope, although with a slight offset. The agreement continues all the way down through décrochage, i.e. the point where the curve turns around and starts to increase again for small potential depths, although statistical fluctuations in the full-quantum data make comparisons more difficult here.

It also evident from Figure 2 that the present method is a substantial improvement of the adiabatic method used in Ref. [9]. The methods do not even agree at large potential depths, where one would expect the nonadiabatic corrections to become small. Improving upon this method by including non-diagonal diffusion terms (for details see Ref. [9]) does not substantially change the situation. We note that even in the limit of vanishing nonadiabatic corrections our method differs from that in Ref. [9] by allowing for coherences between the internal states. In the adiabatic basis the potential does not induce any coherences between internal states, but such coherences are still induced by optical pumping.

![Fig. 2. Semi-classical results for $\langle p^2 \rangle$ (circles) compared to full quantum results (squares). For comparison we also show results based on the adiabatic approximation calculated similarly to the method used in Ref. [9] (crosses), and the same method improved by including also non-diagonal diffusion coefficients (triangles). The detuning is $\Delta = -10 \Gamma$.](image)

The semi-classical method also makes it possible to follow the motion of a single atom as it moves through the lattice. In Figures 3 and 4 we show the position, momentum, energy and internal state distribution as a function of time for a single atom in optical lattices with detunings $\Delta = -10 \Gamma$, and potential depths $\hbar |\Delta'| = 150 E_R$ and $\hbar |\Delta'| = 1000 E_R$, respectively. The energy was calculated as the sum of the kinetic energy and light-shift potential,
Fig. 3. Position, momentum, energy, and internal state populations as a function of time for a single atom moving in an optical lattice. The potential depth is $\hbar |\Delta'| = 150 E_R$, and the detuning $\Delta = -10 \Gamma$. The internal states have the color coding from Figure 1.

\[ E = \frac{p^2}{2m} + \hbar \Delta' \text{Tr}\{A(z)w(t)\}. \] 

(26)

The ratio between the potential, pumping and diffusion terms in Eq. (14) depends on $\Delta/\Gamma$ only, and is hence the same in both graphs. The only difference lies in the inertial term $p/m \partial_t$. Increasing $|\Delta'|$, while keeping the ratio $\Delta/\Gamma$ constant, is equivalent to increasing the mass $m$ by the same factor. This can be seen comparing the graphs, since the atom is less mobile in Figure 3.

At both potential depths the atom shows, after an initial cooling phase, a high degree of localization. While localized the atom populates mostly the extreme magnetic states $M_g = \pm J_g$. The energy is more or less constant, fluctuating around half the potential depth. The amplitudes of the oscillations in momentum and position vary somewhat due to diffusion, but tend to stay within certain bounds as long as the atom remains in the same potential well. We cannot see any clear trend towards smaller oscillation amplitudes while the atom remains trapped in a site, i.e., we see no local cooling.

The periods of localization are interrupted by brief phases where the atom acquires enough energy to travel over many potential wells, before once again getting localized. These excursions are most prominent at lower potential depths. The periods when the atom is untrapped are associated with abrupt changes of the internal state of the atom, usually from odd to even magnetic states. (The light-shift potential only induces odd–odd and even–even couplings between magnetic states. Thus any pure quantum mechanical state is a superposition of only odd or only even magnetic states.) During all periods of localization the atom is in a state with similar internal-state distribution and energy. Even when the energy sometimes drops below this stationary value the atom is soon returned to the same state.

These results are in qualitative agreement with our earlier conclusion that Sisyphus cooling, especially at low potential depths, works through a transfer of atoms between a hot and a cold mode [16]. The cold mode has a momentum distribution, with a width that does not change over time. This mode corresponds to the popu-
lation of atoms in the trapped state. The cooling process is in effect a transfer of atoms from the untrapped to the trapped state.

In Fig. 5 we compare the semi-classical approximation to the time evolution of the momentum distribution \( D(p) = \frac{dN(p)}{dp} \) (where \( N(p) \) is the number of atoms with momentum \( p \)) to the results in [10], for \( |\Delta'| = 130E_R \). The bimodality of the distribution is very clear also in the semi-classical results, and the agreement with the quantum-mechanical results is very good. The distribution of the hot mode is identical to within statistical uncertainties. This shows that the physics of untrapped atoms, including their rate of transfer to trapped states, is well described by our semi-classical method. The semi-classical method gives a slightly more narrow cold mode, in agreement with the results in Fig. 4.

![Fig. 5. Time evolution of the momentum distribution for a potential depth \(|\Delta'| = 130E_R\). The starting temperature was 50\(\mu\)K. The black curve shows the semi-classical results, while the red curve shows results of a fully quantum mechanical simulation.](http://steck.us/alkalidata)

**5 Discussion**

We have developed a semi-classical method to simulate the dynamics of atoms in optical lattices. Our results for the average momentum distribution of the atoms, including its time dependence, agree excellently with those of the fully quantum mechanical method. To achieve an accurate description it is necessary to include both populations of and coherences between the internal states of the atom. The external degrees of freedom may, at least in some situations, be described classically, i.e., as particles with definite positions and momenta.

The semi-classical approximation was introduced as a second order Taylor expansion in \( p/p_R \) of the Wigner function. According to our results \( \langle p \rangle_{\text{rms}} \gtrsim 4p_R \), and hence this expansion should be a fairly good approximation. Nevertheless, there are some situations where the semi-classical description must necessarily break down. One is when effects from the quantization of bound states are important. Such effects will be most prominent when the atoms are localized near the bottom of the potential wells. Another is the coherent splitting of a wave packet. If the atomic wavefunction is, e.g., partially transmitted to the next potential well, the semi-classical method will describe this as a classical probability (some atoms are transmitted, some are not), while any coherence effects between the two parts of the wave packet will be lost.

The conceptual simplicity of the semi-classical descriptions makes it a useful aid in visualizing complex physical processes. It is also a flexible tool, which is relatively easy to adapt to different physical situations. In the near future we plan to extend the method to double optical lattices [17]. Further studies of the cooling process, e.g., to deepen the understanding of the bimodal velocity distributions observed in experiment and full quantum simulations, are underway.
