Quantum correlations between parts of a composite system most clearly reveal themselves through entanglement. Designing, maintaining, and controlling entangled systems is very demanding, which raises the stakes for understanding the efficacy of entanglement-free, yet quantum correlations, exemplified by quantum discord. Discord is defined via conditional mutual entropies of parts of a composite system and its direct measurement is hardly possible even via full tomographic characterization of the system state. Here we design a simple protocol to detect and quantify quantum discord in an unentangled bipartite system. Our protocol relies on a characteristic of discord that can be extracted from repeated direct measurements of certain correlations between subsystems of the bipartite system. The proposed protocol opens a way of extending experimental studies of discord to electronic systems, but can also be implemented in quantum-optical systems.

DOI: 10.1103/PhysRevA.100.022321

I. INTRODUCTION

While quantumness of correlations between the parts of a system in a pure state is fully characterized by their entanglement (see Ref. [1] for reviews), mixed states may possess quantum correlations even if they are not entangled. The quantumness of the correlations is properly described in terms of quantum discord [2–4], which is a discrepancy between quantum versions of two classically equivalent expressions for mutual entropy in bipartite systems (see Refs. [5–7] for reviews). Any entangled state of a bipartite system is discorded, but discorded states may be nonentangled. Although it is entanglement which is usually assumed to be the key resource for quantum information processes, it was suggested that quantum enhancement of the efficiency of data processing can be achieved in deterministic quantum computation with one pure qubit which uses mixed separable (i.e., nonentangled) states [8–11]. In such a process, which has been experimentally implemented [12], the nonclassical correlations captured by quantum discord are responsible for computational speedup [13]. Quantum discord was also shown to be the necessary resource for remote state preparation [14] and for the distribution of quantum information to many parties [15,16]. Unlike entanglement, discord is rather robust against decoherence [17]. Thus, along with entanglement, quantum discord can be harnessed for certain types of quantum information processing.

Despite increasing evidence for the relevance of quantum discord, quantifying it in a given quantum state is a challenge. Even full quantum state tomography would not suffice since determining discord requires minimizing a conditional mutual entropy over a full set of projective measurements. Moreover, even computing discord is very difficult (it has been proven to be NP complete [18]). An alternative, geometric measure of discord [19–22] has been successfully implemented experimentally [23–25]. However, geometric discord also faces serious problems. For example, it can increase, in contrast to the original quantum discord, even under trivial local reversible operations on the passive part of the bipartite system [26] (note, though, the proposal of Ref. [27] to mend this deficiency). Most seriously, being a nonlinear function of the density matrix \( \rho \), geometric discord can only be quantified via (full or partial) reconstruction of \( \rho \) itself. This severely limits its susceptibility to experiment in the many-body context.

In this paper, we propose an alternative discord quantifier which would overcome these fundamental difficulties and render quantum discord to be experiment friendly for many-body electronic systems. We present a protocol to detect and characterize quantum discord of any unknown mixed state of a generic nonentangled bipartite system, implemented in either an electronic or photonic setup. The protocol is based on direct repeated measurements of certain two-point correlation functions (which are linear in \( \rho \) as any direct quantum mechanical observable). While discord cannot be detected by a single linear measurement [7,28], we show how repeated measurements allow one to both detect a discorded state and build its reliable quantifier.

In the next section, we describe the principal steps of the proposed protocol. In Sec. III, we demonstrate how to implement our protocol in an electronic bipartite system built on integer quantum Hall devices and prove that it provides a reliable discord witness. In Sec. IV, we illustrate how the protocol works by applying it to a few specified states and propose a discord quantifier based on this protocol. Finally, in Sec. V, we explain how the protocol should be applied to an unknown state.

II. PRINCIPAL STEPS OF THE PROTOCOL

Here we describe how to detect quantumness in unentangled states of a bipartite system via correlations. A generic nonentangled bipartite system in a mixed state is described by
the density matrix [29]

\[ \rho_{AB}^{\delta} = \sum_{\nu=1}^{M} w_{\nu} \rho_{\nu}^{A} \otimes \rho_{\nu}^{B}, \]

(1)

where the classical probabilities \( w_{\nu} \) add up to 1, and each \( \rho_{\nu}^{A,B} \) describes a pure state of the appropriate subsystem, so that they can be parameterized as \( \rho_{\nu}^{A} = |A_{\nu}\rangle\langle A_{\nu}| \) (and similarly for \( B \)). It turns out [5,19,30] that the mixed state (1) is a discord of this state. The proposed protocol can be applied to any bipartite system made of two Mach-Zehnder interferometers, MZI\(^A\), with the phase difference \( \phi_A \), and MZI\(^B\) with \( \phi_B \). The light-blue (light-brown) area represents the state-preparation (the state evolution and discord measurement) part of the protocol. Electrons from sources \( S^A \) and \( S^B \) enter beam splitters \( BS^A_0 \) and \( BS^B_0 \), whose random transparencies are synchronized by a classical computer, allowing the creation of mixed states of the form given by Eq. (1). The final state is controlled by transparencies of beam splitters \( BS^A_0 \) and \( BS^B_0 \) and phases \( \phi_{A,B} \), and is recorded at any pair of detectors \( D^A_0 \) and \( D^B_0 \) (with \( i = 1 \) or 2). Varying the phase difference \( \phi_A \), we can identify a state with no A discord as one for which the interference pattern is suppressed for certain parameters of subsystem \( A \) and remains suppressed for any tuning of subsystem \( B \) (without adjusting \( A \) any further), as illustrated below in Fig. 2.

FIG. 1. Proposed setup of the bipartite system made of two Mach-Zehnder interferometers, MZI\(^A\), with the phase difference \( \phi_A \), and MZI\(^B\) with \( \phi_B \). The light-blue (light-brown) area represents the state-preparation (the state evolution and discord measurement) part of the protocol. Electrons from sources \( S^A \) and \( S^B \) enter beam splitters \( BS^A_0 \) and \( BS^B_0 \), whose random transparencies are synchronized by a classical computer, allowing the creation of mixed states of the form given by Eq. (1). The final state is controlled by transparencies of beam splitters \( BS^A_0 \) and \( BS^B_0 \) and phases \( \phi_{A,B} \), and is recorded at any pair of detectors \( D^A_0 \) and \( D^B_0 \) (with \( i = 1 \) or 2). Varying the phase difference \( \phi_A \), we can identify a state with no A discord as one for which the interference pattern is suppressed for certain parameters of subsystem \( A \) and remains suppressed for any tuning of subsystem \( B \) (without adjusting \( A \) any further), as illustrated below in Fig. 2.

III. PROTOCOL IN DETAIL FOR QUANTUM-HALL-BASED SETUP

It is well known [7] that a separable state can be prepared by local operations and classical communications. Here we propose a particular way of preparing such a state in a solid-state setup and explain in detail how the protocol described in the previous section works in this setup.

A two-qubit bipartite system with a mixed state of Eq. (1) can be implemented with the help of two Mach-Zehnder interferometers, MZI\(^A\) and MZI\(^B\), corresponding to subsystems \( A \) and \( B \) (cf. Fig. 1). Such a system can be realized as an electron-based setup in a quantum-Hall geometry, where the arms of the MZIs are constructed via a careful design of chiral edge modes, and quantum point contacts (QPCs) act as effective beam splitters (BS) [32–34]. It can also be realized as a photonic device using standard interferometry.

Each interferometer is in a quantum superposition of up \( \uparrow \) and down \( \downarrow \) states corresponding to a particle transmitted through the upper or lower arm of the appropriate MZI. Such a superposition in subsystem \( A \) can be parameterized as

\[ |A_\nu\rangle = |\theta_\nu, \phi_\nu\rangle = \cos \frac{1}{2}\theta_\nu |\uparrow\rangle + e^{i\phi_\nu} \sin \frac{1}{2}\theta_\nu |\downarrow\rangle, \]

(2)

with \( |0, 0\rangle = |\uparrow\rangle, \) \( |\pi, 0\rangle = |\downarrow\rangle, \) and \( |\pm \frac{\pi}{2}, 0\rangle = |\pm\rangle = |[\uparrow\downarrow] \pm |\downarrow\uparrow]/\sqrt{2}. \) Notations for subsystem \( B \) are similar (we suppressed indices \( A, B \) for now). The coefficients in each superposition are determined by the gate-controlled transparency and reflection of the appropriate BS (with the corresponding amplitudes parameterized as \( t = \cos \frac{1}{2}\theta_\nu \) and \( r = e^{i\phi_\nu} \sin \frac{1}{2}\theta_\nu \), where index \( \nu \) labels the states defining density matrices \( \rho_{\nu}^{A,B} \) in Eq. (1). Such a mixed
state can be created with the help of a classical computer that simultaneously and randomly switches transparency and reflection of BS_0 and BS_1^B between two values. The probabilities w_v in this equation are now proportional to the time of the pair of BS_0 having the appropriate transparencies, provided that the output on the detectors D_{1,2}^B and D_{1,2}^A is averaged over time intervals much longer than the switching time. This implements the first step of the protocol described above.

Step (ii) of the protocol is a unitary evolution of the prepared mixed state through the system, \( \tilde{\rho}_{AB} = S \rho_{AB} S^\dagger \). Here each of the scattering matrices \( S^A, B \) through MZI_{A,B} in \( S = S^A \otimes S^B \) includes first a phase difference \( \phi_{A,B} \) between the \( |\uparrow\rangle \) and \( |\downarrow\rangle \) arms of the appropriate MZI, which is controlled by the Aharonov-Bohm flux (measured in units of the quantum flux, \( h/e \)), and scattering through the second set of beam splitters, BS_1^B and BS_1^A. We can parametrize these scattering matrices as the product of that corresponding to the beam splitter and the phase difference accumulated on the opposite arms,

\[
S^A = \left( \begin{array}{cc} r_A & t_A \\ -t_A^* & r_A^* \end{array} \right) e^{i \sigma^A \phi_A},
\]

and likewise for \( S^B \). The transmission (and thus reflection) amplitudes could be represented similarly to those in the input MZIs as \( t_A = \cos \frac{1}{2} \alpha \) and \( t_B = \cos \frac{1}{2} \beta \) (with the phase factors in \( r_{A,B} \) absorbed by the Aharonov-Bohm phase in phase). In repeating measurements with the same input state of Eqs. (1) and (2), one can accumulate statistics by varying parameters of the scattering matrices.

Step (iii) of the protocol is to test, as described below, whether or not the basis \( \{|A_v\rangle\} \) of the A part of input state (1) is orthogonal, i.e., whether the system does not or does have A discord. To this end, we allow the active subsystem A to further evolve through the third, detecting MZI^d attached to it (see Fig. 1), so that the full unitary matrix describes independent evolution of the mixed in-state Eq. (1) through subsystems A, B can be represented as

\[
S = S^B \otimes (S^d \otimes S^A).
\]

Matrix \( S^d \) has the same structure as \( S^A \), given by Eq. (3). However, it is sufficient for the testing to choose a 50:50 beam splitter in MZI^d, so that

\[
S^d = \frac{1}{2}(I + i \sigma_z)e^{i \phi_d \sigma_z/2},
\]

with the Aharonov-Bohm phase \( \phi_d \) remaining the only tunable parameter of the detecting MZI.

In step (iv), we choose a cross-correlation function that describes a simultaneous detection of particles injected into A and B at the detectors D_{1,2}^A and D_{1,2}^B, so that the corresponding projector operators are \( \Pi_{A,B} = |\uparrow\rangle \langle \uparrow| \) in the appropriate space. Hence, with the output density matrix \( \tilde{\rho}_{AB} = S \rho_{AB} S^\dagger \) and \( S \) matrix defined by Eqs. (4), we have

\[
K_{\phi_d} = \text{Tr}[\Pi_A \rho_{AB} \tilde{\rho}_{AB}] = \frac{1}{n} \text{Tr}_A e^{i \sigma^A \phi_d} \tilde{\rho}_{AB} e^{-i \sigma^A \phi_d},
\]

\[
\tilde{\rho}_{AB} = S^A \rho_{AB} (S^A)^\dagger.
\]

Here, \( \tilde{\rho}_{AB} \) is the conditioned output density matrix of the active subsystem A. The corresponding input density matrix \( \rho_{AB} \) resulting from tracing over passive subsystem B can be written as

\[
\rho_{AB} = \frac{1}{W_B} \sum_v w_v \rho^A_v, \quad w_v = w_v \text{Tr}_B[\Pi_B \rho^B_v (S^B)^\dagger], \quad W_B = \sum_v w_v^2.
\]

Steps (v) and (vi) of the proposed protocol are exactly as described in Sec. II. Due to interference between the \( |\uparrow\rangle \) and \( |\downarrow\rangle \) states in MZI^d, correlation function (5) oscillates with the phase difference \( \phi_d \). By changing \( \phi_d \) in repeated measurements of \( K_{\phi_d} \), one accumulates statistics to get the interference visibility function \( V \), measured in units of the phase difference \( \phi_d \). The visibility vanishes when \( K_{\phi_d} \) becomes \( \phi_d \) independent. This happens when \( \tilde{\rho}_{AB} \) in Eq. (5) is diagonal, i.e., \( S^A \rightarrow S^A_0 \), the diagonalizing matrix for \( \rho_{AB} \). Such a diagonalization is always possible so that the zero-visibility lines exist for any input state.

The central point of the proposed protocol is that such zero-visibility lines are independent of the parameters of passive subsystem B only if the A discord vanishes. Now we prove this for the setup under consideration.

We begin with parametrizing input states \( |A_v\rangle \) in subsystem A, given by Eq. (2), via the unit vector \( a_v \) on the appropriate Bloch sphere,

\[
a_v = (\sin \theta_v \cos \phi_v, \sin \theta_v \sin \phi_v, \cos \theta_v),
\]

so that \( \rho_A^v = |A_v\rangle \langle A_v| = \frac{1}{2}(1 + a_v \cdot \sigma) \) in the up-down basis where \( \uparrow \equiv |\uparrow\rangle \langle \uparrow| + |\downarrow\rangle \langle \downarrow| \). Then we represent the conditioned density matrix \( \rho_{AB} \) in Eq. (6) as

\[
\rho_{AB} = \frac{1}{2} \text{Tr}_A \rho_A^v (c - W_B) \|, \quad a \equiv \frac{1}{c} \sum_v w_v a_v.
\]

via auxiliary unit vector \( a_v = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta) \) (with \( c \) being the normalization constant), corresponding to the state \( |A_v\rangle = \frac{1}{2}\sqrt{\theta} |\uparrow\rangle + e^{i \phi} \sin \frac{1}{2} \theta |\downarrow\rangle \). From this representation follows that \( \tilde{\rho}_{AB} \) in Eq. (5) becomes diagonal when the diagonalizing matrix \( S^A_0 \) obeys, up to a phase factor, the following equation that defines zero-visibility lines:

\[
S^A_0 |A\rangle = |\uparrow\rangle \text{ or } |\downarrow\rangle.
\]

Since the unitary matrix \( S^A \) rotates vectors on the Bloch sphere, the solutions to this equation that correspond to the rotations to the north \( |\uparrow\rangle \) or south \( |\downarrow\rangle \) pole are given by the angles \( \phi_A = \varphi \) and \( \alpha = \varphi \), or \( \phi_A = -\varphi \) and \( \alpha = \pi - \varphi \), in the parametrization of Eq. (3).

The angles \( \theta \) and \( \varphi \) are to be found from the definition of \( a_v \), given by Eq. (8). It follows from this definition that if the unit vectors \( a_v \) are either the same (so that \( \rho_{AB} = \rho_A^v \otimes \rho_A^v \)) or antiparallel (so that the appropriate \( |A_v\rangle \) are orthogonal), then \( a \) does not depend on \( w_v^2 \), i.e., on the state of subsystem B (parameterized by angles \( \beta \) and \( \phi_B \)). It is straightforward to see the converse: if \( a \) is \( B \) independent, then \( a_v \) are either the same or opposite vectors on the Bloch sphere, so that the corresponding states \( |A_v\rangle \) either coincide (up to a phase factor) or are orthogonal. But such groups of states are the only ones when the bipartite system of Eq. (1) has no A discord.
in the state of passive subsystem Eq. (6). Any continuous zero-visibility line in (b) can be chosen for a quantitative characteristic of discord, given by Eq. (11); cf. Fig. 4.

orthogonal whereas for known states. Let us start with specifying simple examples, we demonstrate how to build a discord quantifier based on this sensitivity.

IV. CORRELATION-BASED DISCORD QUANTIFIER

Here we introduce an alternative discord quantifier and show how it works on examples of protocol implementation for known states. Let us start with specifying simple real input states for both subsystems, i.e., choosing \( \phi_v = 0 \) in Eq. (2) so that each of these states can be written as \( |A_v \rangle \equiv |\theta_v \rangle = \cos \frac{\theta_v}{2} |\uparrow \rangle + \sin \frac{\theta_v}{2} |\downarrow \rangle \), i.e., parameterized only via a single parameter, \( \theta_v \equiv \theta_v \). Similarly, each \( |B_v \rangle \) is parameterized only via a single parameter \( \theta_v^B \). Next choose \( \phi_{A,B} = 0 \) in the evolution matrices \( S^{A,B} \), given by Eq. (3). In this case, lines of constant visibility for a given in-state are functions of \( \phi_d \) and the two parameters, \( \alpha \) and \( \beta \), describing quantum evolution through the subsystems \( A \) and \( B \). As the auxiliary state \( |A \rangle \) in Eq. (8), and hence diagonalizing matrix \( S^A \) in Eq. (9), are also real, the zero-visibility lines correspond to \( \phi_d = 0 \).

For real in-states, there could be no more than two linearly independent sets for each subsystem. Choosing these sets to be “symmetric,” \( \theta_v^B = \theta_v \), leads to the parametrization \( \rho^{AB} = \sum_{i=1}^{2} w_i |\theta_v, \theta_v; 0 \rangle \langle \theta_v, \theta_v; 0 | \), i.e., each in-state is defined by only three parameters, \( \theta_1, \theta_2, \) and \( w_1 \) (with \( w_2 = 1 - w_1 \)). Here and elsewhere, we use the following notations for partial states of the composite system [35]:

\[
\rho_v^B \otimes \rho_v^A = |A_v B_v \rangle \langle A_v B_v |, \quad |A_v B_v \rangle \equiv |\theta_v^A, \theta_v^B, \phi_v \rangle.
\]  

(10)

In Fig. 2, we present the visibility landscape for two particular choices of the parameters; \( \theta_1 = 0, \theta_2 = \frac{\pi}{2} \) for state (a) which has the maximal \( A \) discord, and \( \theta_1 = \frac{\pi}{4}, \theta_2 = -\frac{\pi}{4} \) for state (b) which has zero \( A \) discord, with \( \phi_v = 0 \) and \( w_1 = \frac{1}{2} \) in both of these cases.

The dependence \( a_0(\beta) \) corresponding to the zero-visibility lines in the landscapes of Fig. 2 reveals a striking difference between the nondiscorded and discorded states: the latter show a strong dependence on \( \beta \), while the former are \( \beta \) independent; this certainly works not only for the chosen but for generic mixed states.

The eye-catching signature of discord in Fig. 2(a) is a high nonmonotonicity of the zero-visibility lines, \( a_0(\beta) \). However, a \( \pi \) periodic in the \( \alpha \) pattern of the zero-visibility lines implies that vertical \( \pi \) jumps in zero-visibility curves happen for nondiscorded states. Hence, nearly \( \pi \) jumps in zero-visibility curves over a small interval of \( \beta \) [Fig. 3(a)] signify weak sensitivity with respect to changes in the passive subsystem similar to that in curves with a small nonmonotonicity over a large interval; see Fig. 3(b). To treat both cases on equal footing, we employ the standard deviation of \( f_\alpha(\beta) \equiv \cos^2[a_0(\beta)] \) from its average over the period as a quantifier of such a sensitivity, which plays the role of a discord quantifier:

\[
\Delta_a^2 = \int_0^{2\pi} \frac{d\beta}{2\pi} |f_\alpha(\beta) - \bar{f}_\alpha|^2, \quad \bar{f}_\alpha = \int_0^{2\pi} \frac{d\beta}{2\pi} f_\alpha(\beta).
\]  

(11)

This quantifier gives similar results for the two sets of symmetric in-states in Fig. 3. Both have the density matrix \( \rho_v^{AB} = \frac{1}{2} (|\uparrow \uparrow \rangle \langle \uparrow \uparrow | + |\theta \rangle \langle \theta |) \), with different \( \theta \). For \( \theta = 0, \rho_v^{AB} = |\uparrow \uparrow \rangle \langle \uparrow \uparrow | \) is a pure state with no discord,
FIG. 3. The visibility plots for $\rho^{AB} = \frac{1}{2}[|\uparrow \uparrow\rangle|\uparrow \uparrow\rangle + \frac{1}{\sqrt{2}}|\theta \theta\rangle|\theta \theta\rangle]$, where (a) $\theta = \frac{5}{6}\pi$ and (b) $\theta = \frac{1}{5}\pi$. These density matrices have similar discord, as can be seen from Fig. 4, yet their visibility landscapes look completely different: (a) an almost $\pi$ jump in zero-visibility lines over a small interval of $\beta$ followed by almost $\beta$-independent zero-visibility lines is equivalent to (b) zero-visibility lines with a small nonmonotonicity over a large interval; both signify weak sensitivity with respect to changes in a passive system for the states with a relatively small discord.

and likewise discord is absent for $\theta = \pi$ when $\rho^{AB}_0 \rightarrow \frac{1}{2}[|\uparrow \uparrow\rangle(\uparrow \uparrow\rangle + |\downarrow \downarrow\rangle(\downarrow \downarrow\rangle)$. Thus, discord is small for $\rho^{AB}_0$ with $\theta$ approaching either 0 or $\pi$; cf. Fig. 4.

This suggested quantifier is convenient and, although it is by no means unique, it works remarkably well: its similarity to quantum discord in its original definition is quite appealing, as illustrated for $\rho^{AB}_0$ of the above example in Fig. 4. It is straightforward to prove that this measure is reliable: it vanishes for any nondiscorded state and does not change with a unitary transformation on passive subsystem $B$.

In Appendix B, we give further examples of discorded and nondiscorded states, including that with nonzero phases and that where the density matrices in Eq. (1) are spanned by more than two states. We also describe there a useful generalization of the discord quantifier for in-states with nonzero phases.

FIG. 4. The standard definition of discord $D_A$ (dashed blue line) vs the alternative quantifier of Eq. (11) $\Delta^2_\alpha$ (solid red line) for the in-state with the density matrix $\rho^{AB}_0 = \frac{1}{2}[|\uparrow \uparrow\rangle(\uparrow \uparrow\rangle + |\theta \theta\rangle|\theta \theta\rangle]$. 

V. EMPLOYING THE PROTOCOL FOR UNKNOWN STATES

Experimentally, any in-state, given by Eq. (1), is repeatedly generated in the scheme given in Fig. 1 by random simultaneous changes of transparencies of beam splitters BS$^B_0$ and BS$^A_0$ with fixed probabilities $w_{\nu}$. A set of raw data for the generated in-state should be obtained by varying the phase difference, $\phi_d$, in the detecting MZI$^d$ and measuring the appropriate particle cross-correlation function, given by Eq. (5). From this data set, one extracts the visibility $V$ defined in step (vi) of the protocol; see Sec. II. Fixing the phase difference $\phi_B$ in the passive subsystem $B$ makes $V$ a function of three parameters that experimentally control the in-state evolution through the system: $\alpha$ and $\phi_A$ characterizing the scattering matrix $S^A_0$ [Eq. (3)], and $\beta$ characterizing $S^B_0$.

By also fixing $\beta$, one represents the data as lines of constant visibility in the $\alpha - \phi_A$ plane, thus producing the visibility landscape. From this, one finds $\phi_{A0}$ and $\alpha_0$ that correspond to zero visibility for this value of $\beta$. Repeating this for different values of $\beta$, one derives the parametric representation of the zero-visibility lines as $\alpha_0(\beta)$ and $\phi_{A0}(\beta)$. This step was not required in the example of Fig. 2, as in such a case a single real in-state one expects $\phi_A = 0$. Indeed, from the visibility landscape (where visibility lines are drawn as functions of $\alpha$ and $\phi_A$) for the in-states used in this example (Fig. 5), one clearly sees that zero-visibility points correspond to $\phi_{A0} = 0 \mod(2\pi)$ as expected. Hence, $\alpha_0(\beta)$ dependence alone is sufficient for quantifying discord for such states; see Eq. (11) and Fig. 4.

For a generic (unknown) in-state characterized by arbitrary phases, one should first build a visibility landscape in the $\phi_A - \alpha$ plane in order to determine the values of the phase $\phi_A$ corresponding to the zero visibility. Fixing these values,
one then builds the corresponding visibility landscape on the \( \alpha - \beta \) plane and uses this for the discord detection and its full characterization via the correlation discord quantifier. In Appendix B, we illustrate how this works using known in-states with a nonzero phase.

VI. CONCLUSION

We have proposed an alternative characterization of quantum discord based on measuring cross correlations in nonentangled bipartite systems and thus linear in density matrix \( \rho \), in contrast to other quantifiers, notably geometric discord, that require full or partial quantum tomography for reconstruction of \( \rho \). The linearity of the proposed quantifier opens a path to extending experimental research of discord into electronic condensed-matter systems. We have considered in detail one possible implementation via devices built of Mach-Zehnder interferometers in quantum-Hall systems, where our quantifier is quite robust against external noise and fluctuations: as long as the Aharonov-Bohm oscillations are resolvable [32], the appropriate interference pattern may serve as a pictorial discord witness, as illustrated above in Figs. 2 and 3. Finally, our discord quantifier is qualitatively consistent and quantitatively very close to the original measure.

The relative simplicity of this protocol and the fact that it is based on presently existing measurement technologies and available setups (electronic Mach-Zehnder interferometers) is bound to stimulate experiments in this direction. While the present analysis addresses discord of bipartite systems, an intriguing generalization of our protocol to multiple-partite systems is possible by introducing a number of coupled interferometers. Extension of our protocol to anyon-based states (employing anyonic interferometers) or other topological states may open the horizon to the topology-based study of discord.

FIG. 5. The raw visibility landscape for the two in-states used in Fig. 2 as a function of parameters \( \alpha \) and \( \phi_A \) controlling, respectively, the transparency of BS\(^1\) and the phase difference in MZI\(^B\) (see Fig. 1). Here we keep fixed the values of the corresponding parameters in MZI\(^B\) \( (\beta = \pi/3 \) and \( \phi_B = 0 \)). Here, zero-visibility points correspond to \( \phi_0 = 0 \mod(2\pi) \) as expected.

APPENDIX A: QUANTUM DISCORD

Quantum discord [2,3] exemplifies the difference between classical and quantum correlations of two subsystems, \( A \) and \( B \), as quantified by mutual information. The latter, which is a classical measure of correlations between \( A \) and \( B \), is defined as \( I(A:B) \equiv H(A) + H(B) - H(AB) \), where the Shannon entropy \( H(A) \equiv -\sum \rho_{ab} \ln \rho_{ab} \), with \( a \) being the possible values that a classical variable \( A \) can take with the probability \( p_a \), while the joint entropy \( H(AB) \) is that of the entire system \( A \cup B \). An alternative way of writing a classically equivalent expression to \( I(A:B) \) is \( I(A:B) \equiv H(A) - H(A|B) \), with \( H(A|B) \equiv H(AB) - H(B) \) being the conditional entropy which is the uncertainty remaining about \( A \) given a knowledge of \( B \)'s distribution.

The quantum analogues to these expressions can be obtained by replacing the Shannon entropies for the probability distributions with the corresponding von Neumann entropies for quantum mechanical density matrices, \( S(\rho) = -\text{Tr}(\rho \ln \rho) \). The quantum analog of \( I(A:B) \) is then straightforward to define,

\[
I(\rho^{AB}) \equiv S(\rho^A) + S(\rho^B) - S(\rho^{AB}),
\]  
(A1)
where $\rho^A$, $\rho^B$ are the reduced density matrices on either subsystem. However, the straightforward analog to the classical conditional entropy is not that useful: if one defines $S(B|A) = S(AB) - S(A)$, this quantity could be negative, e.g., in the case when subsystems $A$ and $B$ are in a pure state. Instead, the quantum conditional entropy $S(A|B)$ is defined as the average von Neumann entropy of states of $A$ after a measurement is made on $B$.

The result of a measurement depends on the basis picked for the measurement projectors. The postmeasurement density matrix becomes

$$\tilde{\rho}^{AB} = \sum_{\mu} p_\mu \Pi_\mu^A \otimes \rho^B_{|\mu>^A}, \quad (A2)$$

FIG. 6. Visibility as a function of $\alpha$ and $\beta$ for nondiscorded states with $\phi_A = \phi_{1,2}$. (a) $\rho^{AB} = 1/5|++\rangle\langle ++| + 4/5|--\rangle\langle --|$. (b) $\rho^{AB} = 1/2|\uparrow \uparrow\rangle\langle \uparrow \uparrow| + 1/2|\downarrow \downarrow\rangle\langle \downarrow \downarrow|$. (a) The “gridlike” visibility characteristic of a density matrix which is correlated between the $A$ and $B$ subsystems, but nondiscorded, with only the classical correlations between subsystems. (b) The “barcode” graph is a result of a density matrix which is completely uncorrelated between the $A$ and $B$ subsystems.

FIG. 7. The visibility landscapes for the density matrix given by Eq. (B1) with $\phi_2 = \pi/2$. (a) Visibility as a function of $\alpha, \phi_A$ with $\beta = 2\pi/3$. (b) Visibility as a function of $\alpha, \beta$ with fixed $\phi_A = \arctan (\frac{2\sqrt{3}}{3})$ that corresponds to minimal visibility spots in the landscape plot (a).
where $\rho_{B|\Pi^A_\mu}$ is the density matrix conditional on some measurement on $A$ defined as follows:

$$\rho_{B|\Pi^A_\mu} = \frac{1}{p^A_\mu} \text{Tr}_A (\Pi^A_\mu \otimes 1^B) \rho^{AB} (\Pi^A_\mu \otimes 1^B).$$  \hspace{1cm} (A3)

Using this conditional state (A3), one may extract the entropy $S(\rho_{B|\Pi^A_\mu})$ which gives us the amount of uncertainty of the state of $B$ given this projection of $A$ into a measurement basis. Then the conditional entropy after a complete set of measurements $\{\Pi^A_\mu\}$ becomes

$$S(B|\Pi^A_\mu) = \sum_{\mu} p^A_\mu S(\rho_{B|\Pi^A_\mu}).$$  \hspace{1cm} (A4)

Now a generalization of $J(A:B)$ can be constructed,

$$J_A(\rho^{AB}) = \max \{ S(\rho^B) - S(\rho^{AB}) \}.$$  \hspace{1cm} (A5)

where one final ingredient has also been added in order to remove the dependence on the measurement basis: maximizing over all complete measurement bases, essentially equivalent to picking the best measurement basis (that is, the one where the ignorance about subsystem $A$ is reduced the most).

Having defined two quantities which would be classically equivalent, the difference between the two could be thought of as a measure of quantumness. It is the quantity which is termed the quantum discord:

$$D_A(\rho^{AB}) = \min_{\{\Pi^A_\mu\}} [J(\rho^{AB}) - J_B(\rho^{AB})]$$

$$= \min_{\{\Pi^A_\mu\}} [S(A|\Pi^A_\mu) - S(\rho^{AB}) - S(\rho^B)].$$  \hspace{1cm} (A6)

Note that since $J$ is not symmetric about which subsystem the measurement is performed on, neither is discord and, in general, $D_B(\rho^{AB}) \neq D_A(\rho^{AB})$.

**APPENDIX B: FURTHER EXAMPLES OF DISCORD CHARACTERIZATION VIA VISIBILITY LANDSCAPES**

The “gridlike” nondiscorded state of Fig. 2(b) corresponds to the maximal possible classical correlations between the subsystems. In such a case, no information about the correlations between subsystems $A$ and $B$ is lost when one makes the correct choice of measurement on subsystem $B$. Actually, any classically correlated states with no discord would look gridlike. We give another example of a nondiscord in-state of Eq. (1) with $n = 2$, choosing there $w_1 = 1/5$, and define $\rho^{A}_\mu$ via states $|A_1\rangle$, given by Eq. (2), where we put $\theta_1 = -\phi_2 = \pi/4$ and $\phi_1 = \phi_2$. In this case, although the states $|A_i\rangle$ are complex, a relative phase between them is zero. If such a state were unknown, one would find from the $\alpha$-$\phi_A$ plot that the zero-visibility spots correspond to $\phi_A = \pm \pi/2$. Fixing this value of $\phi_A$ results in the gridlike plot on the $\alpha$-$\beta$ plane [Fig. 6(a)], clearly showing the absence of discord. When not only discord but classical correlations between $A$ and $B$ subsystems are also absent, the visibility lines become “barcode like,” i.e., only horizontal [Fig. 6(b)].

If we choose an in-state with the same characteristics as the nondiscorded one in Fig. 2(b) but different phases in subsystem $A$, i.e.,

$$\rho^{AB} = \frac{1}{2} \left[ |+\rangle \langle +| + |0\rangle \langle 0| + \frac{1}{\sqrt{2}} |-\rangle \langle -| + \frac{1}{\sqrt{2}} |\phi_2\rangle \langle \phi_2| \right]$$  \hspace{1cm} (B1)

then such a state is $A$ discorded provided that $\phi_2 \neq 0 \mod \pi$, with discord reaching the maximum at $\phi_2 = \pi/2$. However, the quantifier of Eq. (11) is not sufficient for its full description since the values of $\phi_A$ where visibility drops to zero are now $\beta$ dependent themselves. To illustrate this, we build the visibility landscape in the $\alpha$-$\phi_A$ axes for the maximally discorded state for different values of $\beta$, as illustrated in Fig. 7(a) for $\beta = 2\pi/3$. Extracting $\phi_A(\beta)$ corresponding to zero-visibility points [which is given analytically for this particular known state by $\phi_A = \arctan(2/3 - 1/\sqrt{3})$] but can, in general, be...
found from the plot, we build the $\alpha$-$\beta$ visibility landscape shown in Fig. 7(b).

It becomes immediately obvious that the quantifier of Eq. (11) is not at all convenient in this case. Although the state $\rho_{A0}$ is always A discorded for $\phi_2 = \pi/2$, there are regions where the state cannot be diagonalized and zero-visibility lines, on which the quantifier (11) is based, are absent. The reason is that now there are two diagonalizing parameters, $\alpha_0$ and $\phi_{A0}$, and it is their joint dependence on the parameters of passive subsystem $B$ that fully reveals and characterizes discord. For this particular example, it is $\phi_{A0}(\beta)$ dependence alone that describes discord practically in full, as illustrated in Fig. 8. There we have introduced, similar to Eq. (11), the standard deviation of $f_2(\beta) \equiv \cos^2 [\phi_{A0}(\beta)]$ from its average over the period as a quantifier of the sensitivity of diagonalizing parameters to changes in passive subsystem $B$, with the only difference that it is $\phi_{A0}$ rather than $\alpha_0$, which is now the variable diagonalizing parameter:

$$\Delta_2^2 = \int_0^{2\pi} d\beta [f_2(\beta) - \bar{f}_2]^2, \quad \bar{f}_2 = \int_0^{2\pi} d\beta f_2(\beta).$$  \hspace{1cm} (B2)

In general, it is the sum $\Delta_\alpha^2 + \Delta_\phi^2$ that fully characterizes the $A$ discord of a complex in-state. In order to experimentally obtain $\Delta_\alpha^2 + \Delta_\phi^2$ for an unknown state, one builds the full zero-visibility lines in three-dimensional parameter space ($\alpha$, $\beta$, $\phi_A$). The discord quantifier is extracted from this line by calculating $\Delta_\alpha^2 + \Delta_\phi^2$, which is zero only if discord is absent. The separate measures $\Delta_\alpha^2$ and $\Delta_\phi^2$ can be obtained by the projection of the line onto the $\alpha - \beta$ and $\phi_A - \beta$ planes, respectively.

For a final illustration, we present an example of in-state with $n = 3$ in Eq. (1). We choose a real in-state,

$$\rho^{AB} = \frac{1}{2} |\uparrow\uparrow⟩⟨\uparrow\uparrow| + \frac{1}{3} |\downarrow\downarrow⟩⟨\downarrow\downarrow| + \frac{1}{2} |\theta\theta⟩⟨\theta\theta|.$$

As it is real, the diagonalizing value of $\phi_A$ is zero, so that the visibility landscapes as functions of $\alpha$ and $\beta$ allow one to extract the discord quantifier of Eq. (11) strikingly similar to the standard definition of discord; see Fig. 9.
