A high index of suspicion must exist when evaluating adult patients with clinical presentation of chronic neck pain, torticollis, or ‘cock robin’ head positioning, especially in the post-traumatic setting, to avoid overlooking the possible serious diagnosis of atlantoaxial rotatory subluxation.

Abstract

Introduction: Atlantoaxial rotatory subluxation (AARS) is an uncommonly encountered diagnosis within the adult population. The rare nature of this dislocation within the adult population often results in delayed diagnosis and treatment.

Case Report: A 30-year-old male presented following a low-speed motor vehicle accident. The patient had been involved in a work-related accident 1-year prior and had experienced fixed leftward gaze and tenderness of the cervical spine following this incident, but exhibited no focal neurological deficits. Imaging demonstrated a Fielding Type 1 AARS of approximately 45°. The subluxation was reduced; and posterior C1–C2 instrumentation and fusion were performed, with no complications. Post-operative imaging revealed maintained reduction and alignment. The patient regained acceptable alignment and relief from his pre-operative symptoms.

Conclusions: Our case is an illustration of a chronic post-traumatic AARS in an adult patient with delayed diagnosis and definitive management. This diagnosis is rare within the adult population and is frequently overlooked. A high index of suspicion must exist when evaluating adult patients with clinical presentations of chronic neck pain, torticollis, or “cock robin” head positioning as delayed diagnosis.

Keywords: Atlantoaxial, subluxation, rotary, delayed.

Introduction

Atlantoaxial rotatory subluxation (AARS) is a rare diagnosis in the adult patient that is characterized by incomplete dislocation of the inferior atlantal and superior axial articular facets [1, 2, 3, 4]. Patients typically present in the characteristic “cock robin” position with associated painful torticollis. Due to its rarity, AARS is typically overlooked, often resulting in delayed diagnosis and treatment [3, 4, 5]. The current case is an illustration of delayed diagnosis and treatment of post-traumatic AARS in a 30-year-old male.

Case Report

An otherwise healthy 30-year-old male self-presented to the emergency department after being involved in a low-speed traffic collision. He was seeking evaluation of acutely worsening neck pain that had been present for approximately 1 year. Physical examination demonstrated a fixed leftward gaze with midline tenderness about the cervical spine. There were no neurological deficits. He noted to our team that his gaze had been fixed and his neck had been painful for 1 year following a work-related accident. Computed tomography (CT) scan demonstrated a Fielding Type 1 AARS of approximately 45°.
There were no complications related to the procedure. Post-operative CT and X-rays demonstrated maintained reduction and alignment of the atlantoaxial joint (Fig. 2). The patient regained normal head alignment and had relief from his pre-operative symptoms. He was discharged home from the hospital on post-operative day #6.

**Conclusions**

AARS is a relatively uncommon diagnosis in the adult population. It can present acutely after significant trauma, and rarely, patients can present in delayed fashion after remote cervical injury as described in this case. It is critical to keep AARS in mind when assessing patients with chronic neck pain, torticollis, or "cock robin" head positioning as delayed diagnosis can result in catastrophic complications. Our case is an illustration of a chronic post-traumatic AARS in an adult patient with delayed diagnosis and definitive management.

**Discussion**

Unlike children who are predisposed to AARS due to large heads, underdeveloped musculature of the neck, and increased laxity of the joint capsule, adults will typically develop rotatory subluxation secondary to higher energy trauma [2, 3, 6]. Adult patients can also present after remote history of cervical trauma. Symptoms may include painful neck, torticollis, occipital neuralgia, and even vertebrobasilar insufficiency [6]. In addition, initial plain radiographs are exceedingly challenging to interpret for a variety of reasons and are often read as normal studies [7]. Therefore, a high index of suspicion must exist when evaluating adult patients with clinical presentations of chronic neck pain, torticollis, or "cock robin" head positioning as delayed diagnosis can result in catastrophic complications. Our case is an illustration of a chronic post-traumatic AARS in an adult patient with delayed diagnosis and definitive management.

**Clinical Message**

It is a key to pay close attention to history and examination findings of patients presenting with symptoms of neck pain and stiffness, especially those with fixed posturing or loss of neck motion. Careful attention to imaging studies including plain radiographs and CT scan is critical to identification of AARS. Diagnosis allows the clinician to institute proper treatment with closed or operative measures, thus avoiding potentially serious complications related to AARS.
