(Dated: February 5, 2010)

Chiral gravity and cosmological birefringence both provide physical mechanisms to produce parity-violating TB and EB correlations in the cosmic microwave background (CMB) temperature/polarization. Here, we study how well these two mechanisms can be distinguished if non-zero TB/EB correlations are found. To do so, we evaluate the correlation matrix, including new TB-EB covariances. We find that the effects of these two mechanisms on the CMB are highly orthogonal, and can thus be distinguished fairly well in case of a high-signal-to-noise detection of TB/EB correlations. An Appendix evaluates the relative sensitivities of the BB, TB, and EB signals for detecting a chiral gravitational-wave background.

I. INTRODUCTION

Both inflation [1] and late-time cosmic acceleration [2] require new physics beyond general relativity and the standard model (SM) of particle physics. Since the SM violates parity (P) within the weak sector and is presumably only a low-energy limit of a grand unified theory, it is natural to inquire whether there are manifestations of P violation in the new physics responsible for cosmic inflation and/or late-time acceleration.

For example, a coupling of the quintessence field to the pseudo-scalar of electromagnetism would manifest itself as cosmological birefringence (CB) [3], a rotation of the linear polarization of electromagnetic waves as they propagate through the Universe. Parity violation has been introduced in inflation through modifications of gravity that produce a difference in the amplitude of right (R) and left (L) circularly polarized gravitational waves (GWs) in the inflationary GW background. These include the addition of Chern-Simons terms to the Einstein-Hilbert action [4]; chiral gravity, wherein there is a different Newton’s constant for R and L gravitational waves [5]; and gravity at a Lifshitz point [6]. We refer collectively to these inflationary mechanisms as chiral gravity.

Since the CMB polarization can be decomposed into two modes of opposite parity—E modes, or the gradient part, and B modes, or the curl part [7, 8]—a cross-correlation between the E and B modes would, if detected, be a sign of parity violation [9]; and similarly for a correlation between the temperature (T) and the B mode. Chiral GWs induce TB/EB correlations at the CMB last scattering surface (LSS) [4, 5], while CB induces P violation by rotating the primordial polarization afterwards [4, 8].

An early analysis of CMB data suggested a possible CB with rotation angle $\sim 6^\circ$ [10], but current constraints are less than a few degrees [11, 12]. Ref. [13] showed that WMAP does not have enough sensitivity to test chiral gravity and discussed prospects for detection of chiral GWs with Planck and CMBPol.

In this paper, we quantify how well the effects of CB and chiral gravity can be distinguished, in case of a positive detection of EB/TB correlations. We find that the effects of these two mechanisms are orthogonal to a very high degree, and we show that the earlier tentative detections of CB, if true, could not have been attributed to chiral gravity. We perform these forecasts for WMAP [14], SPIDER [15], Planck [16], CMBPol (EPIC) [17], and a cosmic-variance–limited experiment.

The plan of this paper is as follows: In [II] we forecast the sensitivity of CMB experiments to gravitational chirality and in [III] to CB. [IV] calculates how well the two effects can be distinguished, and in [V] we make concluding remarks. In Appendix A, we derive the elements of the power-spectra covariance matrix, and in Appendix B, we evaluate the relative sensitivities of the BB, TB, and EB signals to a chiral gravitational-wave background, finding that the best sensitivity comes from the BB signal, in disagreement with an earlier claim [8].

II. CONSTRAINING GRAVITATIONAL CHIRALITY

A. Effects of Gravitational Chirality on the CMB Polarization

If linearized gravity prefers one handedness (i.e., if it is chiral), then the power spectra of the L and R GWs may have different amplitudes and thus induce non-vanishing TB and EB correlations at the LSS [4, 5]. Measurements of these correlations can provide an estimate of the chiral asymmetry with a variance due to the finite precision of the instrument and cosmic variance (CV).

We first want to quantify the chirality by introducing an appropriate chirality parameter and show how the CMB polarization map depends on this parameter. To
have B modes at the LSS, we need primordial GWs, or in other words, a non-zero tensor-to-scalar ratio,

\[ r \equiv A_t / A_s, \quad A_t = \frac{r}{1 + r}, \]  

(1)

where \( A_t \) and \( A_s \) are, respectively, the fractional contributions of tensor and scalar modes to the GW (tensor) power spectra—TT, EE, BB, TE, TB, and EB—have a tensor component proportional to \( A_t \), while TT, EE, and TE additionally have a scalar component proportional to \( A_s \). The tensor-to-scalar ratio \( r \) is currently constrained to be \( \leq 0.22 \) at a 95% confidence level \[12\].

The TB and EB power spectra are proportional to the difference of the L- and R-mode contributions to the GW (tensor) power spectra, \( P^{t>L}(k) \) and \( P^{t>R}(k) \). These P-violating power spectra are \[13\],

\[ C_{i}^{XX'} = (4\pi)^2 \int k^2 \, dk \left[ P^{t>L}(k) - P^{t>R}(k) \right] \Delta_X^{XX'}(k), \]  

(2)

while the tensor part of the P-conserving correlations are

\[ C_{i}^{XX'} = (4\pi)^2 \int k^2 \, dk \left[ P^{t>L}(k) + P^{t>R}(k) \right] \Delta_X^{XX'}(k), \]  

(3)

where \( P^{t>L}(k) \) and \( P^{t>R}(k) \) are the L- and R-mode power spectra, \( \Delta_X^{XX'}(k) \) is the radiation transfer function for \( X \), and \( X, X' = \{ T, E, B \} \). Following Ref. \[13\], we define a chirality parameter \( \Delta \chi \) as

\[ \Delta \chi = \frac{C_{TB}^{L} / \sigma_{TB}^{L}}{C_{TB}^{R} / \sigma_{TB}^{R}} \]  

where

\[ P^{t}(k) \equiv P^{t,L} + P^{t,R}. \]  

(5)

Maximal P violation occurs when there are GWs of only one handedness: \( \Delta \chi = 1 \) corresponds to fully left-handed, and \( \Delta \chi = -1 \) to fully right-handed GWs. To illustrate, we show BB, TB, and EB power spectra for \( r = 0.22 \) and \( \Delta \chi = 0.2 \) in Fig. 1.

To calculate the uncertainty with which \( \Delta \chi \) can be estimated with different experiments we use a Fisher-matrix analysis \[18\], employing the null hypothesis, \( C_{i}^{EB} = C_{i}^{TB} = 0 \). This ensures that the TB and EB power spectra do not have cross correlations with the other four power spectra. The reciprocal value of the variance \( \sigma_{\Delta \chi}^2 \) is then given by \[7\],

\[ \sigma_{\Delta \chi}^2 = \sum_{l} \sum_{A,A'} \frac{\partial C_{l}^{AA'}}{\partial \Delta \chi} \frac{\partial C_{l}^{AA'}}{\partial \Delta \chi} [\Xi_{i}^{-1}]_{AA'}, \]  

(6)

where \( A, A' = \{ TB, EB \} \), and \( \Xi_{i} \) is the TB-EB part of the power-spectrum covariance matrix;\(^1\) This covariance matrix is derived in Appendix A. The partial derivatives in Eq. (6) can be evaluated by noting from Eqs. (2) and (4) that

\[ (\partial C_{l}^{TB/EB} / \partial \Delta \chi) = C_{l}^{TB/EB} (\Delta \chi = 1). \]  

(7)

We obtain the TB/EB power spectra by modifying CMB-FAST \[19\] using a ACDE model consistent with WMAP-5 \[12\] parameters.

B. Numerical Results: Forecasts for Errors to \( \Delta \chi \)

| Instrument  | \( \theta_{\text{fwhm}} \) [arcmin] | NET [\( \mu K/\text{sec} \)] | \( t_{\text{obs}} \) [years] |
|-------------|-------------------------------------|-----------------------------|-----------------------------|
| WMAP-5      | 21                                  | 650                         | 5                           |
| SPIDER      | 60                                  | 3.1                         | 0.016                       |
| Planck      | 7.1                                 | 62                          | 1.2                         |
| CMBPol      | 5                                   | 2.8                         | 4                           |
| CV-limited  | 5                                   | 0                           | 1.2                         |

TABLE I: Instrumental parameters from Ref. \[15, 20–22\] for the five experiments considered in this paper. The parameters are the beamwidth \( \theta_{\text{fwhm}} \), noise-equivalent temperature NET, and observation time \( t_{\text{obs}} \).

We now forecast the sensitivities to chiral GWs of the following five experiments: (i) WMAP-5, (ii) SPIDER’s 150 GHz channel, (iii) Planck’s 143 GHz channel, (iv) CMBPol’s (EPIC-2m) 150 GHz channel, and

\(^1\) Under the null hypothesis \( \Delta \chi = 0 \), the \( 2 \times 2 \) TB-EB part of the inverted \( 6 \times 6 \) covariance matrix is the same as the inverse of the \( 2 \times 2 \) TB-EB matrix.
(v) a CV-limited experiment. The corresponding instrumental parameters are given in Table I. Note that the noise-equivalent temperature NET is related to the temperature/polarization pixel-noise variances, $\sigma_T^2$, as $\sigma_T^2/N_{\text{pix}} = (\text{NET})^2/t_{\text{obs}}$, where $\sigma_p = \sqrt{2}\sigma_T$. We take $f_{\text{sky}}^0 = 1$ (the fraction of the sky surveyed), and $f_{\text{sky}} = 0.7$ (the fraction of the sky used in the analysis), for all experiments, except for SPIDER, where $f_{\text{sky}}^0 = f_{\text{sky}} = 0.5$.

FIG. 2: 1σ error on the gravitational chirality parameter $\Delta \chi$, for five different CMB experiments, for the fiducial value of $\Delta \chi = 0$. The horizontal dotted line is at $\sigma_{\Delta \chi} = 1$ and represents maximal P violation. In the region above this line, the chirality is non-detectable. The WMAP-5 curve lies entirely above the non-detection line.

Fig. 2 shows the 1σ error of the estimate of $\Delta \chi$ as a function of tensor-to-scalar ratio $r$. The error increases with decreasing $r$, which implies the existence of a critical value of $r$ below which a 1σ-level detection becomes impossible even for maximal P violation (when $\sigma_{\Delta \chi} \geq 1$). This value is far above the current upper limit for WMAP-5 (compare to Ref. [13]), and so WMAP-5 can give no constraints on chiral gravity. Prospects are more optimistic for the next-generation CMB data releases. The critical $r$ is about 0.064 for SPIDER, 0.082 for Planck, 0.0079 for CMBPol, and 0.0025 for the CV-limited experiment. If $r$ is just below the current detection limit of 0.22 [12], $\Delta \chi$ will be detectable at the 1σ level if it is greater than 0.46, 0.51, 0.18, and 0.11 for these four instruments, respectively. If we consider the 3σ confidence level, the corresponding minimum detectable values are larger by a factor of ~ 3.

To conclude this Section, we show how different multipoles $l$ contribute to the sum of Eq. (6), separating the contribution from TB and EB, in Fig. 3. In this plot, only the TB/EB summands of Eq. (6) are plotted against $l$, for $r = 0.22$, for SPIDER, Planck, and CMBPol. The off-diagonal terms that contain the covariance between TB and EB are negligible. The major contribution to $\sigma_{\Delta \chi}^2$ for all five experiments comes from the TB power spectrum, from low multipoles, $l \sim 7$. Thus, large angular scales in TB (at $l \leq 10$) contain most of the information about gravitational chirality.

III. CONSTRAINING COSMOLOGICAL BIREFRINGENCE

Cosmological birefringence rotates the linear polarization at each point on the sky by an angle $\Delta \alpha$, and this rotation induces TB/EB power spectra

$$C_l^{\text{TB,rot}} = 2\Delta \alpha C_l^{\text{TE}}, \quad C_l^{\text{EB,rot}} = 2\Delta \alpha C_l^{\text{EE}}.$$  \hspace{1cm} (8)

The error $\sigma_{\Delta \alpha}$ to which $\Delta \alpha$ can be measured is given by

$$\sigma_{\Delta \alpha}^2 = \sum_l \sum_{A,A'} \frac{\partial C_l^{A}}{\partial \Delta \alpha} \frac{\partial C_l^{A'}}{\partial \Delta \alpha} [\Xi_l^{-1}]_{AA'}.$$  \hspace{1cm} (9)

Using the same instrumental parameters as in § II B and for $r = 0.22$, we obtain the following 1σ errors for the CB rotation angle: from WMAP-5, 3.2°; from SPIDER,
from Planck, 15.9'; from CMBPol, 9.4''; and from a CV-limited experiment, 1.9 μarcsec, in good agreement with previous forecasts [4, 23–25].

In Fig. 4, we plot, separately, the contributions from only TB and only EB correlation to the sum in Eq. (9), as a function of multipole moment \( l \), for the cases of SPIDER, Planck, and CMBPol, for \( r = 0.22 \). The off-diagonal terms that contain the covariance between TB and EB are small. The dominant contribution to the constraint on \( \Delta \alpha \) comes from the TB correlation for WMAP-5, and from EB for the higher-precision instruments. Different multipoles give the leading summands in \( \sigma_{\Delta \alpha}^{-2} \) for different instruments, but unlike the case of GW chirality, small angular scales \( (l \gtrsim 100) \) always dominate the sum.

**FIG. 4:** Diagonal (TB,TB and EB,EB) summands of Eq. (9), for \( r = 0.22 \), are plotted against the multipole \( l \) to show that the constraints to \( \Delta \alpha \) from future CMB experiments will come primarily from \( l \)'s of \( \sim 100, 500, \) or 700 (depending on the instrument).

### IV. SEPARATING GRAVITATIONAL CHIRALITY FROM COSMOLOGICAL BIREFRINGENCE

In this Section, we ask how well the effects of chiral gravity and CB can be distinguished, assuming that a TB/EB correlation has been detected.

#### A. First-Order Effects on the EB and TB Correlations

To first order in \( \Delta \alpha \) and \( \Delta \chi \), the TB/EB power spectra are a sum of a part \( C_{i}^{A,\chi} \) due to chiral GWs and a part \( C_{i}^{A,\text{rot}} \) due to CB. The combined EB and TB power spectra can be written,

\[
C_{i}^{TB,\text{obs}} = \Delta \chi C_{i}^{TB,t}(\Delta \chi = 1) + 2\Delta \alpha C_{i}^{TE},
\]

\[
C_{i}^{EB,\text{obs}} = \Delta \chi C_{i}^{EB,t}(\Delta \chi = 1) + 2\Delta \alpha C_{i}^{EE},
\]

where the superscript \( t \) indicates the tensor-induced part of the power spectrum, while the absence of it denotes the full power spectrum, including the scalar part.

**FIG. 5:** We show TB and EB power spectra from chiral GWs for \( \Delta \chi = 0.2 \) and \( r = 0.22 \) (dashed red curves) and from cosmological birefringence for \( \Delta \alpha = 5' \) (solid blue curves).

Fig. 5, which shows \( C_{i}^{A,\chi} \) and \( C_{i}^{A,\text{rot}} \), demonstrates that the contributions from these two mechanisms are qualitatively different. Our goal now is to quantify how well they can be distinguished, given the finite precision of the temperature/polarization maps.

The Fisher matrix for \( \Delta \alpha \) and \( \Delta \chi \) has the following...
which show that the $\Delta\chi$ significance, we will be able to distinguish CB from gravitational chirality and to cosmological birefringence, separately. We therefore not significantly different from the null-hypothesis ellipse. From Fig. 6, we see that once we take into account the covariance between $\Delta\alpha$ and $\Delta\chi$, the results differ very slightly from the two cases where we had only one of the $\Delta\chi$ parameter space. We conclude that if non-vanishing TB/EB correlations are detectable at the 3$\sigma$ level with a cosmic-variance–limited experiment, if $\sigma_{\Delta\chi}$ is just below 0.22, corresponds to about 65% of the GW background being of one handedness, and 35% of another. In an analogous analysis, we show that Planck has a 1$\sigma$ sensitivity to a CB rotation angle of about 16$\arcsec$, while a CV-limited experiment could reach about 2$\mu$arcsec.

FIG. 6: Constraints on the allowed $\Delta\alpha$-$\Delta\chi$ parameter space are shown for the case of null detection with different instruments. The solid-line ellipses on each plot are for the fiducial value of zero for both parameters, and for the following values of tensor-to-scalar ratios (going from the narrowest to the widest ellipse in the $\Delta\chi$ direction): 0.22, 0.1, and 0.06. The dot-dashed ellipse in each plot is for $r = 0.22$, for a model with $\Delta\chi = 0.2$ and $\Delta\alpha = 5^\circ$. In both models, the tilt of the ellipses is almost negligible, which means that the two $P$-violating mechanisms are separable to high accuracy, provided there is detection with high statistical significance. Thus, the constraints on both parameters are almost the same as those calculated in the previous Sections.

V. SUMMARY AND CONCLUSIONS

In this paper, we first revisit the sensitivity of current and future CMB experiments to gravitational chirality and to cosmological birefringence, separately. We show that the WMAP-5 polarization data are not precise enough to provide any information about gravitational chirality, even for the case where the tensor-to-scalar ratio is just below the current upper constraint of 0.22.

Planck and SPIDER may be able to make a marginal detection, but only if $r$ and $\Delta\chi$ are both close to their maximal allowed values. CMBPol may probe gravitational chirality over a larger range of the $r$-$\Delta\chi$ parameter space. As an illustration, the smallest amount of GW chirality detectable at the 3$\sigma$ level with a cosmic-variance–limited experiment, if $r$ is just below 0.22, corresponds to about 65% of the GW background being of one handedness, and 35% of another. In an analogous analysis, we show that Planck has a 1$\sigma$ sensitivity to a CB rotation angle of about 16$\arcsec$, while a CV-limited experiment could reach about 2$\mu$arcsec.

In the second part of this paper we show that there is no strong degeneracy between $\Delta\alpha$ and $\Delta\chi$ parameters. In other words, the effects of chiral gravity and CB can
be easily distinguished, provided that the TB/EB correlations are clearly detected. However, the same results can be interpreted as to infer that a marginal (e.g., $3\sigma$) detection of $\Delta \sigma$ could be due, alternatively, to gravitational chirality at some level. For example, if CMBPol were to measure $\Delta \sigma \simeq 15^\circ$ and find $r = 0.1$, that TB/EB detection could alternatively be attributed, with similar statistical significance, to gravitational chirality with $\Delta \chi = 0.6$. If, however, the earlier suggestion of a TB/EB signal corresponding to a rotation angle of $6^\circ$ had held up, it could not have been attributed to chiral GWs, as the implied value of $\Delta \chi$ would have been in the unphysical regime $\Delta \chi \gg 1$.

If a parity-violating signal is detected in the CMB and attributed to CB, it may be possible to test it further with observations of cosmological radio sources [20]. Off-diagonal correlations in the CMB may also provide additional information on CB, if the CB rotation angle is position dependent [23–25], as suggested in Refs. [27]. A parity-violating signal from chiral GWs might be distinguished from that due to CB through direct detection of the gravitational-wave background at shorter wavelengths [28]. Finally, it may be that any signals of chiral gravity in the CMB may be correlated, within the context of specific alternative-gravity theories, by a variety of other observations and measurements [23].

APPENDIX A: Power-Spectra Covariance Matrix

Suppose we have obtained multipole coefficients $d_{lm}^X$, for $X = \{T, E, B\}$ from a full-sky CMB map. Their variance is given by [7]

$$
\left(\langle d_{lm}^X \rangle^* d_{lm'}^{X'} \right) = \langle \langle |W_l^b|^2 C_{(l)}^{XX'} + w_{XX'}^{-1} \rangle \delta_{ll'} \delta_{mm'} \rangle,
$$

where $C_{(l)}^{XX'}$ is the power spectrum of the signal, $W_l^b \approx \exp(-l^2 \sigma_b^2/2)$ is the window function to take into account the effects of beam smearing, and $\sigma_b \equiv \theta_{\text{FWHM}}/\sqrt{8 \ln(2)}$ with $\theta_{\text{FWHM}}$ the beam width. The $w_{XX'}^{-1}$ are the contributions to the measured power spectra due to instrumental noise; they are given by

$$
w_{TT}^{-1} = \frac{4\pi \sigma_T^2}{N_{\text{pix}}}, \quad w_{EE}^{-1} = w_{BB}^{-1} = \frac{4\pi \sigma_P^2}{N_{\text{pix}}}.
$$

Here, $\sigma_T$ and $\sigma_P$ are the pixel noise in temperature and polarization, respectively, and $N_{\text{pix}} = 4\pi \theta_{\text{FWHM}}^2$ is the number of pixels. We assume that the signal is not correlated to the noise, and that the noise in the polarization is not correlated to the noise in the temperature; i.e. $w_{ET} = w_{BT} = w_{EB} = 0$.

The estimators for the power spectrum are then

$$
\hat{C}_l^{XX'} = |W_l^b|^{-2} \left( \sum_{m=-l}^l \frac{(d_{lm}^X)^* d_{lm}^{X'}}{(2l+1)} - w_{XX'}^{-1} \right),
$$

and the power-spectrum covariance matrix is then given by

$$
\Xi_l^{X_1X_2X_3X_4} = \left\langle \left( \hat{C}_l^{X_1X_2} - \hat{C}_l^{X_1} \hat{C}_l^{X_2} \right) \left( \hat{C}_l^{X_3X_4} - \hat{C}_l^{X_3} \hat{C}_l^{X_4} \right) \right\rangle
$$

$$
= \left\langle \hat{C}_l^{X_1X_2} \hat{C}_l^{X_3X_4} \right\rangle - \hat{C}_l^{X_1} \hat{C}_l^{X_2} \hat{C}_l^{X_3} \hat{C}_l^{X_4}
$$

$$
= |W_l^b|^{-4} \left( \sum_{m,m'} \left( \langle d_{lm}^X \rangle^* d_{lm}^{X'} \right) \left( \langle d_{lm}^Y \rangle^* d_{lm}^{Y'} \right) \right)
$$

$$
- \left( \langle d_{lm}^X \rangle^* \langle d_{lm}^{Y'} \rangle \right) \left( \langle d_{lm}^Y \rangle^* \langle d_{lm}^{Y'} \rangle \right).
$$

Using Eqs. [17] and [12] we get

$$
\Xi_l^{X_1X_2X_3X_4} = \frac{1}{(2l+1)} (\hat{C}_l^{X_1X_2} \hat{C}_l^{X_3X_4} + \hat{C}_l^{X_1X_4} \hat{C}_l^{X_2X_3}),
$$

where

$$
\hat{C}_l^{XX'} \equiv C_l^{XX'} + w_{XX'}^{-1} |W_l^b|^{-2}.
$$

To account for partial-sky coverage, we add a factor $f_{\text{sky}}^{-1}$ (the inverse of the fraction of the sky used in the analysis) to the right-hand side of Eq. [15]. We also multiply the factors $w_{XX'}^{-1}$ in Eq. [13] by a factor $(f_{\text{sky}})^{-1}$ (the inverse of the fraction of the sky surveyed).

APPENDIX B: Constraints on Tensor-to-Scalar Ratio

Here we examine a claim of Ref. [2] that if the GW background is chiral, it may be more easily detected through the TB signal than the BB signal, the reason being that it may be easier to detect a weak signal (B) by cross-correlation with a strong one (T) than against itself.

Under the null hypothesis (no GWs), the error with which the tensor-to-scalar ratio can be measured, from just one power spectrum A (where A is BB, TB, or EB) is

$$
\sigma_r^2 = \sum_l \left( \frac{\partial C_l^A}{\partial A} \right)^2 (\Xi_l, AA)^{-1}.
$$

Given that the power spectra are simply proportional to $r$, $(\partial C_l^A/\partial r) \propto C_l^A$. The relevant covariance-matrix
entries are

\[ \zeta_{l}^{BB} = \frac{2}{2l+1} \left( \tilde{C}_{l}^{BB} \right)^{2} = \frac{2}{2l+1} w^{-1}_{BB}(W_{l}^{w})^{-2}, \quad (19) \]

\[ \zeta_{l}^{TB} = \frac{1}{2l+1} \left[ \left( \tilde{C}_{l}^{TB} \right)^{2} + \tilde{C}_{l}^{TT} \tilde{C}_{l}^{BB} \right] = \frac{1}{2l+1} w^{-1}_{BB}(W_{l}^{w})^{-2} \left[ C_{l}^{TT,s} + w^{-1}_{TT}(W_{l}^{w})^{-2} \right], \quad (20) \]

(and similarly for EB, with T→E) where we have employed the null hypothesis in the second equality in each of these equations.

Given that \( w^{-1}_{TT} \ll C_{l}^{TT} \) already from current data for the low \( l \) at which the GW signal arises, we can set \( w^{-1}_{TT} = 0 \). Moreover, \( C_{l}^{TB} \sim \beta(C_{l}^{BB} C_{l}^{TB})^{1/2} \), with \( \beta \sim 0.1 \). As a result, while the summand for \( \sigma^{-2}_{T} \) from BB is \( \sim (C_{l}^{BB})^{2}/w^{2}_{BB} \), that from TB is \( \sim C_{l}^{BB}/w^{2}_{BB} \). Thus, in the limit of sufficiently high signal-to-noise, \( w^{-1}_{BB} \to 0 \), the BB signal provides a better probe (smaller \( \sigma_{T} \)). In other words, the value of the cross-correlation with \( T \) is ultimately limited by cosmic variance (as is also the cross-correlation with \( E \)), while the BB sensitivity improves without limit as the instrumental noise is reduced. (The importance of TB is also weakened slightly given that \( C_{l}^{TB} < [C_{l}^{TT} C_{l}^{BB}]^{1/2} \).) It is true that in the opposite limit, where \( w^{-1}_{BB} \) is large, TB is more sensitive to GWs (with \( \Delta \chi = 1 \)) than TT. However, this limit is only of academic interest, as it encompasses the regime of \( r \) that is already ruled out by temperature measurements.

To make these arguments more quantitatively precise, we have evaluated \( \sigma_{T} \) for BB, TB, and EB (for \( \Delta \chi = 1 \)) for WMAP-5, SPIDER, Planck, and CMBPol; the results are shown in Table III. We see that the sensitivity to GWs with future experiments will come primarily from BB, with only marginal improvement from TB. While the TB sensitivity of WMAP-5 is better than that from BB, the smallest \( r \) detectable with either is already larger than the upper limit from TT.

The bottom line: While TB may improve the sensitivity to a chiral-GW background, it does so only marginally, with most of the sensitivity due primarily to BB (see also Ref. [13]).

\[
\begin{array}{|c|c|c|c|}
\hline
\text{Instrument} & \text{from BB} & \text{from TB} & \text{from EB} \\
