Makanin-Razborov diagrams for limit groups

Emina Alibegović

March 29, 2022

Abstract

We give a description of $\text{Hom}(G, L)$, where $L$ is a limit group (fully residually free group). We construct a finite diagram of groups, Makanin-Razborov diagram, that gives a convinient representation of all such homomorphisms.

1 Introduction

The subject of this paper has the roots in the following problem: given a finitely presented group $G$, describe the set of all homomorphisms $G \to F$ to a fixed free group $F$.

When $G$ is the fundamental group of a closed surface, say of genus $g$, Stallings answered our question as follows. Denote by $q : G \to F_g$ an epimorphism to the free group of rank $g$ (defined by inclusion of the boundary to the handlebody). Then every $f : G \to F$ factors as $f = \phi \circ q \circ \alpha$, for some automorphism $\alpha : G \to G$, and some $\phi : F_g \to F$. Thus $\text{Hom}(G, F)$ is ‘parametrized’ by the product of the Teichmüller modular group of $G$ and the ‘affine space’ $F_g$. This theorem of Stallings was generalized to arbitrary finitely generated groups $G$ by Sela in [12] and Kharlampovich and Myasnikov in [10].

All homomorphisms $G \to F$ are encoded into a finite diagram of groups, called the Makanin-Razborov diagram. Each group in this diagram has a finite number of directed edges issuing from it. This number will be zero if the group in question is a free group. Each edge represents a quotient map, and all quotients are proper, see Figure 1

2000 Mathematics Subject Classification. 57M07, 20F28.
Key words and phrases. limit groups, homomorphisms.
Every homomorphism $h : G \to F$ can be written as:

$$h = h_0 \circ \varphi_k \circ \varphi_{k-1} \circ \ldots \circ \varphi_1 \circ \varphi_0,$$

where $\varphi_i \in \text{Mod}(L_i)$, $\varphi_i$ are the quotient maps and $h_0 : L_{t_i} \to F$, where $L_{t_i}$ is a free group. We say that $h$ factors through a branch of the M-R diagram. In addition, all groups in the M-R diagram naturally belong to the class of limit groups. Limit groups, also known as fully residually free groups, have been studied in \[12\], \[10\], \[9\], \[7\]. The structure of limit groups can be easily described. These groups can be built inductively: level 0 limit groups are finitely generated free groups, finitely generated free abelian groups and surface groups. A level $n$ limit group is obtained by taking a finite number of free products or amalgamated free products or HNN extensions of level $n-1$ limit groups along their maximal cyclic subgroups. We will talk more about this decomposition in Section 2.

We are interested in studying $\text{Hom}(G, L)$, when $G$ is a f.g. group, and $L$ is an arbitrary limit group, and constructing M-R diagrams for this case. The problem that occurs here lies in the fact that a homomorphism $h : G \to L$ might not factor through a complete branch of the M-R diagram. That is, the final homomorphism $h_0$ in the above representation of $h$ might be an embedding of some limit group into $L$. We need to ensure that there are only finitely many such embeddings, up to some equivalence relation. The following theorem is the objective of this work:

**Theorem 1.1.** [Main Theorem]

Let $G$ be a f.g. freely indecomposable group and $L$ a freely indecomposable limit group. There exist finitely many proper quotients $G_1, \ldots, G_r$ of $G$ so that for every homomorphism $f : G \to L$ with $d[f] \gg 0$ an element of the
equivalence class $\sim$ of $f$ factors through some $G_i$. Furthermore, there are only finitely many homomorphisms with uniformly bounded $d_f$ and nonabelian image, up to conjugacy.

We will define all the terms used in the statement of this theorem in the next section, and the proof will be given in Section 3.

2 Background

We list some of the properties of limit groups that are often used, without proofs, and we refer reader to [12], and [3].

Lemma 2.1. Let $L$ be a limit group.

(L0) $L$ is torsion free.
(L1) $L$ is finitely presented, in fact coherent.
(L2) Every f.g. subgroup of $L$ is a limit group.
(L3) Every abelian subgroup of $L$ is finitely generated and free, and there is a uniform bound on its rank.
(L4) Every abelian subgroup is contained in a unique maximal abelian sub-group.
(L5) Every maximal abelian subgroup of $L$ is malnormal.

In [11] we defined a class of groups that contains limit groups, and for this class we found $\delta$-hyperbolic spaces on which they act freely, by isometries. This class of groups was defined as follows:

Definition 2.2. A torsion-free, f.g. group $G$ is a depth 0 $C$-group if it is either an f.g. free group, or an f.g. free abelian group or the fundamental group of a closed hyperbolic surface. A torsion-free f.g. group $G$ is a $C$-group of depth $\leq n$ if it has a graph of groups decomposition with three types of vertices: abelian, surface or depth $\leq (n - 1)$, cyclic edge stabilizers and the following holds:

- Every edge is adjacent to at most one abelian vertex $v$. Further, $G_v$, the stabilizer of $v$, is a maximal abelian subgroup of $G$.
- Each surface vertex group is the fundamental group of a surface with boundary, and to each boundary component corresponds an edge of this decomposition. Each edge group is conjugate to a boundary component.
The stabilizer of a depth \( \leq (n-1) \) vertex \( v, G_v \), is \( C \)-group of depth \( \leq (n-1) \). The images in \( G_v \) of incident edge groups are distinct maximal abelian subgroups of \( G_v \) (i.e., cyclic subgroups generated by distinct, primitive, hyperbolic elements of \( G_v \)).

We say that the depth of a \( C \)-group \( G \) is the smallest \( n \) for which \( G \) is of depth \( \leq n \).

That limit groups belong to the class \( C \) follows from Theorem 3.2. and Theorem 4.1. in [12]. In fact, the decomposition of a limit group from this definition coincides with cyclic JSJ decomposition defined in [12].

Let \( L \) be a depth \( n \) limit group. Let \( \Delta_L \) be a graph of groups decomposition of \( L \) given in the above definition, call \( T_L \) the underlying graph, and let \( T \) be the tree so that \( T/L = T_L \). In [1] we showed that we can find a graph of spaces \( X/L \) corresponding to \( \Delta_L \) so that its universal cover \( X \) is \( \delta \)-hyperbolic. In order to establish necessary notation we give some properties of the space \( X \). \( X/L \) is quasiisometric to the wedge of \( k \) rays \([0, \infty)\) joined at \( 0 \). We lift \( k \) rays that correspond to \( \partial X/L \) to rays \( r_i : [0, \infty) \to X, \ i = 1, \ldots, k \), and we let \( h_i \) be the horofunction corresponding to \( r_i \). The stabilizer, \( L_i < L \), of the limit point \( r_i(\infty) \) of \( r_i \) preserves \( h_i \). Denote by \( B_i(\rho) \) the horoballs \( h_i^{-1}(-\infty, \rho) \subset X \). For sufficiently small \( \rho \) the intersection \( \gamma B_i(\rho) \cap B_j(\rho) \) is empty unless \( i = j \) and \( \gamma \in L_i \). Let

\[
LB(\rho) = \bigcup_{i, \gamma} \gamma B_i(\rho),
\]

\( i = 1, \ldots, k, \gamma \in L \). Let \( X(\rho) = X\setminus LB(\rho) \). \( X(\rho)/L \) is compact for all \( \rho \in (-\infty, \infty) \).

These properties in fact constitute the definition of relatively hyperbolic groups given by Gromov in [8]. Hence limit groups are hyperbolic relative the collection of the representatives of conjugacy classes of their maximal noncyclic abelian subgroups (see [11]). We will call the subgroups \( L_i \) parabolic subgroups.

The modular group \( Mod(L) \) associated to the decomposition \( \Delta_L \) of \( L \) is the subgroup of \( Aut(L) \) generated by

- inner automorphisms of \( L \),
- Dehn twists in the centralizers of edge groups,
- automorphisms induced by automorphisms of abelian vertex groups that are identity on peripheral subgroups and all other vertex groups, and
- automorphisms induced by homeomorphisms of surfaces underlying surface vertex groups that fix all boundary components.
Let $G$ be an f.g. group with a finite generating set $S$. We consider a sequence of homomorphisms $f_i : G \to L$. Each of the given homomorphisms induces an action of $G$ on the space $X$, and for each we define
\[
d_i = \inf \{ \sup \{ d(x, f_i(g)x) : g \in S \} : x \in X \}.
\]
If this infimum is attained at a point $x_i$ then $x_i$ is called a centrally located point for the action.

In order to apply Compactness Theorem, i.e., to see if we can extract a subsequence of actions that converges, we need to see whether each of these actions has a centrally located point and how the sequence $d_i$ behaves.

The following lemma has been proved by Bestvina in [2] for hyperbolic spaces $\mathbb{H}^n$ and by Paulin in [11] for Gromov hyperbolic spaces.

**Lemma 2.3.** For every $f : G \to L$ whose image is not an abelian group and for which an induced action on $X$ is nonelementary (no point at infinity is fixed by the whole group), there exists a centrally located point.

**Proof.** Suppose $d_f = 0$. Since the group $L$ contains no elliptic elements, this implies that for every $g \in S$, $f(g)$ is a parabolic element. Furthermore, $f(G)$ is an abelian subgroup of $L$. Note that a partial converse holds: if $f(G)$ is an abelian group and all generators are mapped into parabolic elements then $d_f = 0$ and centrally located point does not exist. So we need to show that if $d_f > 0$ then a centrally located point exists.

We would like to show that a map $F : X \to \mathbb{R}_+$ defined by
\[
F(x) = \sup_{g \in S} d(x, f(g)x)
\]
is a proper map away from the horoballs and consequently attains its infimum. Suppose it is not, that is there is a sequence $\{x_n\}$ in $X$ not contained in a compact set, such that $\{F(x_n)\}$ is bounded. Recall from the definition of $X$ that there is $\rho$ such that $B_i(\rho) \cap \gamma B_j(\rho) = \emptyset$, unless $i = j$ and $\gamma \in L_i$ and $X(\rho)/L$ is compact, where $X(\rho) = X \setminus \bigcup_{i, \gamma} B_i(\rho)$. We first note that our sequence has to stay within bounded distance from $X(\rho)$, for otherwise $F(x_n) \to \infty$ since $d_f > 0$. Namely, suppose $d(x_n, X(\rho)) \to \infty$ as $n \to \infty$. We also may assume that $x_n \in B_i(\rho)$. Since $d_f > 0$ not every $f(g), g \in S$, is contained in $L_i$. Let us assume that $h \in S$ is such that $f(h) \notin L_i$. Then $f(h)B_i(\rho) \cap B_i(\rho) = \emptyset$ implies that $d(x_n, f(h)x_n) \geq 2d(x_n, X(\rho))$, hence $F(x_n) \to \infty$ as $n \to \infty$. Contradiction. After passing to a subsequence, $\{x_n\}$ will converge to a point $x \in \partial X$. Since $d(x_n, f(g)x_n)$ is bounded for every $g \in S$, we conclude that the sequence $\{f(g)x_n\}$ also converges to $x$. Hence, $x$ is fixed by $f(G)$, which is a contradiction. \qed
Proposition 2.4. There are only finitely many homomorphisms $f : G \to L$ with (uniformly) bounded $d_f$ and nonabelian image, up to conjugation.

Proof. Suppose this is not true, and there are infinitely many homomorphisms $f_i : G \to L$ with $d_i$ bounded by $D > 0$. We assume that no $d_i = 0$, since otherwise $f_i$ has an abelian image, by Lemma 2.3. By the same lemma we know that a centrally located point $x_i$ exists for the action given by $f_i$.

To simplify the notation we will assume that $X/L$ has only one cusp. Let $r : [0, \infty) \to X$ be a ray in $X$ corresponding to this cusp, and let $h$ be the horofunction corresponding to $r$. Also, let $A$ be an abelian subgroup of $L$ that stabilizes the horoball $h^{-1}(-\infty, 0)$. Choose $\rho$ small enough so that $B(\rho) \cap \gamma B(\rho) = \emptyset$, for all $\gamma \in L \setminus A$. We first note that $x_i$ can not be too deep inside the horoball. By 'deep' we mean that the distance from $x_i$ to the boundary of the horoball has to be smaller than $D$. If it is not, then the ball of radius $D$ around $x_i$ is not only completely contained within the horoball, but also contains $f_i(g)x_i$, for all $g \in S$, since $d_i \leq D$. This implies that $f_i(G)$ is abelian. Hence, the $D$-ball around $x_i$, call it $B_i$, has to intersect $X(\rho)$. We consider $X(\rho - D)$. The action of $L$ on $X(\rho - D)$ is cocompact, hence we can find a compact set $K$ whose translates cover $X(\rho - D)$, see Figure 2. We can find $l_i \in L$ for each $x_i$ so that $l_ix_i \in K$. Since $K$ is compact there exist $r > 0$ and $x \in K$ so that $B_r(x)$ contains the translates $l_iB_i$, for all $i$.
\[ d(x, l_i f_i(g) l_i^{-1} x) = d(l_i^{-1} x, f_i(g) l_i^{-1} x) \leq d(l_i^{-1} x, x_i) + d(x_i, f_i(g) x_i) + d(f_i(g) x_i, f_i(g) l_i^{-1} x) \leq 2r + D \]

and so \( l_i f_i(g) l_i^{-1} \) moves a point \( x \) within a ball of radius \( 2r + D \), for all \( i \), and for all \( g \in S \). Since there are only finitely many translates of \( x \) within that ball we conclude that there can be only finitely many nonconjugate \( l_i f_i l_i^{-1} \).

We therefore conclude that if homomorphisms \( f_i \) belong to distinct conjugacy classes and have nonabelian images, the sequence of actions they induce contains a subsequence which converges to an action of \( G \) on an \( \mathbb{R} \)-tree \( T_\infty \) without a global fixed point. Let us call this limiting action \( \rho \).

For every homomorphism \( f : G \to L \) we get a measured lamination \( \Lambda_f \) on the complex \( \tilde{K} \) whose fundamental group is \( G \). We define a resolution \( \Phi : \tilde{K} \to X \) by defining it \( f \)-equivariantly on the vertices of the triangulation of \( \tilde{K} \). We extend it to edges so that each edge of the triangulation is mapped into the geodesic between the images of its endpoints. Finally extend the map equivariantly to 2-cells. The image of each triangle has a unique measured lamination on it. We will pull back this lamination to get \( \tilde{\Lambda}_f \), see Figure 3. Say \( ABC \) is a triangle in \( \tilde{K} \) whose image under \( \Phi \) is a triangle \( A'B'C' \) in \( X \). Suppose \( b' \) and \( c' \) are the points on \( A'B' \) and \( A'C' \), respectively, the same distance from \( A' \).

![Figure 3: Defining the lamination \( \tilde{\Lambda}_f \) on \( \tilde{K} \)](image)

Let \( b \) and \( c \) be the points on \( AB \) and \( AC \), respectively, for which \( \Phi(b) = b' \) and \( \Phi(c) = c' \), and let \([bc]\) be the segment for which \( \Phi([bc]) = [b'c'] \). The segment \([bc]\) is contained in a leaf of our lamination \( \tilde{\Lambda}_f \). Notice that the length of the image of \([bc]\) is smaller than or equal to \( 6\delta \). \( \Lambda_f \) is then a projection of \( \tilde{\Lambda}_f \) to \( K \).
Definition 2.5. For a measured lamination \((\Lambda, \mu)\) on \(K\) we define the length of \(\Lambda\) to be
\[
L(\Lambda) = \sum_{e \in K^{(1)}} \mu(e).
\]
The length of a resolution \(\Phi : \tilde{K} \to X\), \(L(\Phi)\), is the length of the induced lamination.

For each homomorphism \(f : G \to L\) we choose an \((f)\)-resolution \(\Phi_f\) so that
\[
L(\Phi_f) = \inf \{ L(\Phi) : \Phi \text{ is an } (f) - \text{resolution} \}.
\]
We need to verify that such a resolution \(\Phi_f\) exists.

Lemma 2.6. Let \(\{\Phi_i\}\) be a sequence of resolutions with bounded lengths for a homomorphism \(f : G \to L\) with \(d_f > 0\). There exists a resolution \(\Phi : \tilde{K} \to X\) such that \(L(\Phi) = \lim L(\Phi_i)\).

Proof. Let \(K'\) be the fundamental domain for the action of \(G\) on \(\tilde{K}\). We first note that \(\lim L(\Phi_i)\) has to be positive. If it were not, we would have that \(d(X(\rho), \Phi_i(K')) \to \infty\) as \(i \to \infty\). On the other hand, since the image of \(f\) is not abelian, there has to exist \(g \in G\) so that \(\Phi_i(gK')\) belongs to a horoball disjoint from the one containing \(\Phi_i(K')\). Hence, there should also exist a translate of \(\Phi_i(K')\) that intersects \(X(\rho)\) nontrivially, since \(\Phi_i(\tilde{K})\) is connected, but that is impossible under these hypotheses. Therefore, \(L = \lim L(\Phi_i) > 0\). By definition
\[
L(\Phi_i) = \sum_{j=1}^{E} \mu_i(e_j),
\]
where \(E\) is the number of edges in \(K^{(1)}\), and \((\Lambda_i, \mu_i)\) is a measured lamination induced by \(\Phi_i\). After passing to a subsequence, we may assume that for every \(j = 1, \ldots, E\), the sequence \(\{\mu_i(e_j)\}\) converges, and we denote its limit by \(\ell_j\). Hence,
\[
L = \sum_{j=1}^{E} \ell_j.
\]
Since \(\{L_i\}\) is a bounded sequence and its limit is positive, we know that all of the vertices of \(K'\) are mapped into a bounded neighborhood of \(X(\rho)\) by each \(\Phi_i\). Pick one of these vertices, say \(v\). We can assume that \(v\) is contained in \(X(\rho)\) (if it is not, we can always enlarge \(X(\rho)\) so as to cover \(\Phi_i(v)\)). If we denote by \(X'\) the fundamental domain of the action of \(L\) on \(X(\rho)\), then there
exists \( l_i \in L \) such that \( l_i\Phi_i(v) \in X' \). Furthermore, \( l_i\Phi_i(K') \) is contained in a bounded neighborhood of \( X' \). Hence, for every vertex \( v \) of \( K' \) we can find a convergent subsequence of \( l_i\Phi_i(v) \). We define
\[
\Phi(v) = \lim_{i \to \infty} l_i\Phi_i(v), \quad v \text{ vertex of } K'.
\]
We extend \( \Phi \) \( f \)-equivariantly, and get a resolution. Clearly, \( \Phi \) has the desired length, since \( l_i \)'s are isometries and preserve the lengths of \( \Phi_i \)'s.

We are interested in the closure, \( \text{LIM}(K) \), of all \( \Lambda_f \)'s inside the space of projectivized measured laminations, \( \mathcal{PML}(K) \). The space \( \text{LIM}(K) \) is compact.

**Remark 2.7.** Let us back up to the sequence \( \{f_i\} \) which converges to an action \( \rho \) of \( G \) on a tree \( T_\infty \). For each of \( f_i \)'s we take a short resolution \( \Phi_f \) and a corresponding lamination \( \Lambda_{f_i} \). This sequence will converge in \( \mathcal{PML}(K) \) to some \( \Lambda \). There exists a resolution \( \Phi : \tilde{K} \to T_\infty \) so that the leaves of \( \Lambda \) are mapped to points.

**Definition 2.8.** Let \( f : G \to L \) be a homomorphism between two limit groups. We define a collection of moves that are allowed to be performed on \( f \):

(M1) precompose \( f \) by an element of \( \text{Mod}(G) \),
(M2) conjugate \( f \) by an element of \( L \),
(M3) if there is an abelian vertex group \( A \) in \( \Delta_G \) such that \( f(A) \) is contained in a parabolic subgroup of \( L \), then redefine \( f \) on \( A \) so that the new homomorphism coincides with \( f \) on the adjacent edge groups,
(M4) bending: suppose there is an edge group \( E \) in \( \Delta_G \) whose image is nontrivial and contained in a parabolic subgroup of \( L \). If the edge \( X_E \) corresponding to \( E \) separates \( \Delta_G \), we conjugate the image of one of the connected components of \( \Delta_G \setminus X_E \) by an element of \( L \) that commutes with \( f(E) \). If edge \( X_E \) is nonseparating, i.e., corresponds to an HNN extension, we multiply the image of the Bass-Serre generator by an element of \( L \) that commutes with \( f(E) \).

We say that homomorphisms \( f, g : G \to L \) are equivalent, \( f \sim g \), if there is a sequence \( f = f_0, f_1, \ldots, f_n = g : G \to L \) such that \( f_{i+1} \) is obtained from \( f_i \) by performing one of the moves (M1)-(M4).

**Remark 2.9.** If we take \( L \) to be a free group then the only equivalent homomorphisms are the ones that either differ by an element of \( \text{Mod}(G) \) or are conjugates of each other. Why did we need to add moves (M3) and (M4)? Let us look at the following example.
Example 2.10. Let $G = \langle a, b, s, t \mid w(a, b) = s, [s, t] = 1 \rangle = F_2 \ast \mathbb{Z} \mathbb{Z}^2$, where the word $w(a, b)$ is chosen so that $G$ is a limit group. Consider the sequence of homomorphisms $f_i : G \to G$ defined by $f_i(a) = a, f_i(b) = b, f_i(s) = s$, and $f_i(t) = t^i$. This sequence has the property that $d_i \to \infty$, but all of its members are embeddings. This is where we will need move (M4).

Definition 2.11. A homomorphism $f$ is short if $\Phi_f$ is shortest among all $\Phi_g$ when $g \sim f$. $LIM'(K)$ will denote the closure of the set of $\Lambda_f$'s, for short $f$'s, in $\mathcal{PML}(K)$.

That the shortest homomorphism exists can be proved in the exactly same way as Proposition 2.4.

3 Proof of Main Theorem

Let us first note that it is sufficient to consider only groups which are $\omega$-residually free groups. If $G$ is not $\omega$-residually free, then there are nontrivial elements $g_1, \ldots, g_k$ so that every $f : G \to F$ kills at least one. We claim that every homomorphism $G \to L$ kills at least one of the $g_i$'s. Suppose not, i.e., there is a homomorphism $\phi : G \to L$ such that $\phi(g_i) \neq 1$, for all $i = 1, \ldots, k$. Since $L$ is $\omega$-residually free group, we can find a homomorphism $\rho : L \to F$ such that $\rho(\phi(g_i)) \neq 1$. We have found a homomorphism $\rho \phi : G \to F$ which is injective on the set $\{g_1, \ldots, g_k\}$, a contradiction. Hence the quotients $G \to G/\langle g_i \rangle$ satisfy the requirements of Main Theorem.

From now on we fix a complex $K$ that reflects the decomposition of the limit group $G$ as in Definition 2.2. We will prove our theorem by considering the space $LIM'(K)$. Our first concern is to find suitable proper quotients of $G$. The series of lemmas that follow will show how to obtain these quotients depending on the type of the individual laminations in $LIM'(K)$. We first concentrate on a lamination $\Lambda$ which is a limit of laminations $\Lambda_{f_i} \in LIM'(K)$, where $f_i : G \to L$ are homomorphisms with nonabelian images and the property that $d_i \to \infty$.

Lemma 3.1. If $\Lambda$ is entirely simplicial we form the following quotients:

- Abelianize the subgroup carried by a generic leaf in each Cantor set bundle, if these subgroups are nonabelian.
- If all of these subgroups are abelian, for each of them we make the following quotients:
  - mod out by its normal closure,
  - abelianize each vertex group in the splitting of $G$ inherited from $\Lambda$.

At least one of these quotients is proper.
Proof. We will assume that there is only one family of parallel leaves and let $N$ be its regular neighborhood. $N$ is homeomorphic to $\ell \times [0, 1]$, where $\ell$ is a leaf of the lamination $\Lambda$. Denote by $\ell_1$ and $\ell_2$ the boundary components of $N$, see Figure 4. Let $H$ be a subgroup of $G$ carried by $\ell_1$. $H$ cannot be trivial since that would imply that $G$ is freely decomposable. Suppose $H = \langle h_1, \ldots, h_k \rangle$.

(i) If $H$ is nonabelian, so are its conjugates, hence abelianization of a subgroup carried by a generic leaf yields a proper quotient.

(ii) If $H$ is abelian and $f_i(H) = 1$, then our homomorphism factors through a proper quotient $G/\langle H \rangle$. Hence we may assume that there is at least one $j \in \{1, \ldots, k\}$ for which $f_i(h_j) \neq 1$. Since $H$ is an abelian group, $f_i(H)$ is contained either in a parabolic subgroup of $L$ of rank $n$ or in a cyclic subgroup of $L$ generated by a hyperbolic element.

![Figure 4: Shortening the simplicial component](image)

We would like to know what the general position of $\Phi_i(\tilde{N})$ is within $X$. Due to the equivariance, the first thing we conclude is that $\Phi_i(\tilde{N})$ is contained in a bounded neighborhood of a horoball $B$ that corresponds to the parabolic subgroup of $L$ which contains the image of $H$. Further, we can also conclude that, since $\mu_i(\ell_1)/d_i \to 0$, all the points of $\Phi_i(\tilde{\ell}_1)$ are approximately at the same distance from $P$ (same for $\Phi_i(\tilde{\ell}_2)$).

$\Phi_i(\tilde{\ell}_1)$ and $\Phi_i(\tilde{\ell}_2)$ are completely contained in $B$

Suppose that $\Phi_i(\tilde{\ell}_2)$ is at a distance proportional to $d_i$ from $P$. Assume that the fundamental group of the vertex space, call it $K_2$, which is adjacent to $\ell_2$, is not abelian. If $f_i(\pi_1(K_2))$ is abelian then $f_i$ factors through the
proper quotient of \( G \) obtained by abelianizing \( \pi_1(K_2) \) and our claim holds. Otherwise, we can find a closed path \( p \subset K_2 \) whose measure is close to 0 and for which \([f_i(p), f_i(\ell_2)] \neq 1\) (we use the same notation for the elements of the fundamental group and loops they represent). Consider the image under \( \Phi_i \) of a lift \( \tilde{p} \) of \( p \). One of the endpoints of \( \Phi_i(\tilde{p}) \) lies on \( \Phi_i(\tilde{\ell}_2) \), but \( \Phi_i(\tilde{p}) \not\subset B \), for if it were we could conclude that \( f_i(\ell_2) \) and \( f_i(p) \) commute. Therefore the length of \( \Phi_i(\tilde{p}) \) is proportional to \( 2d_i \). On the other hand, \( \mu_i(p) \) is virtually zero, contradiction. Hence, if \( f_i(\pi_1(K_2)) \) is not abelian, the distance from \( \Phi_i(\tilde{\ell}_2) \) to \( P \) is much smaller than \( d_i \). The same holds for \( \Phi_i(\tilde{\ell}_1) \). We now have two cases to consider:

1. \( f_i(\pi_1(K_j)), \ j = 1, 2, \) is not abelian, and
2. at least one of \( f_i(\pi_1(K_j)), \ j = 1, 2 \) is abelian.

Our strategy is as follows. We consider an edge \( a \) of the triangulation of \( K \) that intersects leaves of the lamination \( \Lambda \). We will actually show more than we claimed to be true: all the quotients that we make are proper and \( f_i \) factors through at least one of them. If not, we will be able to decrease the measure of the edge \( a \), hence obtaining a lamination shorter than \( \Lambda_{f_i} \).

(1) Let \( a \) be an edge in \( K^{(1)} \) that intersects \( N \) nontrivially, and let \( a \cap \ell_1 = \{a_0\} \) and \( a \cap \ell_2 = \{b_0\} \). We know now that \( \Phi_i(\tilde{\ell}_1) \) and \( \Phi_i(\tilde{\ell}_2) \) are contained in the \( n_i \)-neighborhood of \( P \), and \( n_i/d_i \to 0 \) as \( i \to \infty \). If we assume that the euclidean height of \( P \) is 1, which we may without loss of generality, then for \( x, y \in N_{n_i}(P) \) we will have \( |\ln x_{n+1} - \ln y_{n+1}| \leq n_i \).

Let \( \tau_i \) denote the maximal displacement of points on \( \Phi_i(\tilde{\ell}_1) \) under the action of \( f_i(H) \), where \( H \) denotes the centralizer of \( H \). We know that \( \tau_i \leq \mu_i(\ell_1) \) and that \( d(\Phi_i(\tilde{a}_0), \Phi_i(\tilde{b}_0)) \sim d_i \). If there were a point in the \( f_i(h_j) \) -orbit of \( \Phi_i(\tilde{b}_0) \) whose distance to \( \Phi_i(\tilde{a}_0) \) is smaller than that of \( \Phi_i(\tilde{b}_0) \), then we could precompose \( f_i \) by an appropriate Dehn twist determined by \( h_j \) and obtain a resolution shorter than \( \Phi_i \), a contradiction (see Figure 4). Hence,

\[
d(\Phi_i(\tilde{a}_0), \Phi_i(\tilde{b}_0)) \leq d(\Phi_i(\tilde{a}_0), f_i(h_j)^m \Phi_i(\tilde{b}_0)), \forall m \in \mathbb{Z}.
\]

The orthogonal projections of \( \Phi_i(\tilde{\ell}_1) \) and \( \Phi_i(\tilde{\ell}_2) \) to \( P \) will be contained in small Hausdorff neighborhoods of parallel real lines. There exists an element \( g \) of the parabolic subgroup of \( L \) corresponding to \( B \) which will translate these lines towards each other. For \( i \) large enough, the translation length of \( g \), call it \( \tau_P(g) \), while acting on \( P \) is going to be ‘much’ smaller than \( d_i \). We can find \( m, k \in \mathbb{Z} \) and a point \( y \) on \( \Phi_i(\tilde{\ell}_1) \) so that

\[
d(g^m \Phi_i(\tilde{b}_0), y') \leq \tau_P(g) \quad \text{and} \quad d(f_i(h_j)^k y, \Phi_i(\tilde{a}_0)) \leq \tau_i.
\]
where $y'$ is the orthogonal projection of $y$ onto the horizontal hyperplane in $B$ containing $\Phi_i(\tilde{b}_0)$, see Figure 5. We then have

$$
d(f_i(h_j)^k g^m \Phi_i(\tilde{b}_0), \Phi_i(\tilde{a}_0)) \leq d(g^m \Phi_i(\tilde{b}_0), y') + d(f_i(h_j)^k y', \Phi_i(\tilde{a}_0)) \leq \tau_P(g) + d(f_i(h_j)^k y, \Phi_i(\tilde{a}_0)) \leq \tau_P(g) + \left| \ln \left( \frac{\Phi_i(\tilde{a}_0)}{\Phi_i(\tilde{b}_0)} \right) \right|_{n+1} + \tau_i \ll d_i.
$$

Therefore, performing the bending (a power of it, to be more precise) determined by $g$ and precomposing the obtained homomorphism with a power of the Dehn twist determined by $h_j$ will, contrary to our assumption, give us a homomorphism in the same class with $f_i$ which has a shorter resolution.

(2) In the case that one of $f_i(\pi_1(K_j))$, $j = 1, 2$, is abelian we may in fact assume that $\pi_1(K_j)$ is abelian itself. If not, $f_i$ will factor through the quotient of $G$ obtained by abelianizing $\pi_1(K_j)$. Further, only one $K_j$ can have abelian fundamental group, and without loss of generality we may assume it is $K_1$. As noted before $\Phi_i(\tilde{\ell}_2)$ lies in the $n_i$-neighborhood of $P$. If we further have that $\Phi_i(\tilde{\ell}_1)$ also lies in the $n_i$ neighborhood of $P$, we apply (1). We therefore may assume that the distance from $\Phi_i(\tilde{a}_0)$ is proportional to $d_i$. $\Phi_i(\tilde{\ell}_1)$ being mapped so deep into the horoball is a consequence of $\mu_i(p)$, for every loop $p$ in $K_1$, being very short compared to both $\mu_i(\tilde{\ell}_2)$ and $d_i$. We consider a new $f_i$-resolution $\Phi'_i : \tilde{K} \to X$ which coincides with $\Phi_i$ on $\tilde{\ell}_2$, but lowers $\tilde{\ell}_1$. We explain the term ‘lowers’ formally: there are constants $c_1, \ldots, c_n \in \mathbb{R}$ so that for every point $x \in \tilde{\ell}_1$ there is a point $x' \in \tilde{\ell}_2$ such that $(\Phi_i(x))_j = \ldots \ldots$
Unfortunately we increased the measures of closed paths $p$ in any way, we only changed the resolution. By doing that we shortened the edge $a$ substantially. Unfortunately we increased the measures of closed paths $p \subset K_1$ and $\ell_1$. However, if we perform move (M3) on $f$, we obtain a homomorphisms with a shorter resolution. Namely, the measure of the path $a$ will be the same as under the new resolution for $f$, but the paths $p$ will now have measures 0. This contradicts our assumption.

This concludes our discussion when $\Phi_i(\tilde{\ell}_1)$ and $\Phi_i(\tilde{\ell}_2)$ are contained in $B$. Further, these arguments remain valid when the intersection of $\Phi_i(\tilde{N})$ with the boundary horosphere $P$ is a disjoint union of segments.

$\Phi_i(\tilde{\ell}_j)$, $j = 1, 2$, are contained in $X(\rho)$ If $\Phi_i(\tilde{\ell}_j)$, $j = 1, 2$, belong to different connected components of $X(\rho)$, or if $\Phi_i(\tilde{N}) \cap B \neq \emptyset$ we can shorten the resolution by shortening, as above, the distance between the connected components of $\Phi_i(\tilde{N}) \cap P$. Suppose then that $\Phi_i(\tilde{N})$ is contained in a single connected component of $X(\rho)$. $\Phi_i(\tilde{N})/L$ is an annulus $F$ in a compact part of $X/L$ with boundary components of length $\ll d_i$ and of length approximately $d_i$. Without loss of generality we may assume that $N$ had a drum triangulation, and $\Phi_i(\tilde{N})$ has the same. Further we may assume that the triangulation on $\tilde{N}$ is formed out of $k$ triangles. Each of these triangles has two sides that are extremely long, meaning their lengths are greater than or equal to $d_i - \mu_i(\ell_1)$, or $d_i - \mu_i(\ell_2)$, depending on which boundary component of $N$ the short side of the triangle lies. Let $s_0, \ldots, s_k$ denote the lifts of these long sides of the triangles belonging to the same lift of $F$ in $\Phi_i(\tilde{N'})$, where $s_k$ is a translate of $s_0$ under an element $g \in L$. Let $x$ be a point on $s_0$ at distance at least $\mu_i(\ell_1) + k\delta$ and $\mu_i(\ell_2) + k\delta$, along $s_0$, from $\Phi_i(\tilde{\ell}_1)$ and $\Phi_i(\tilde{\ell}_2)$, respectively. There is a point $x_1$ on $s_1$ at a distance less than or equal to $\delta$ from $x$ ($\delta$-hyperbolicity of $X$). We continue moving through all the triangles in $\Phi_i(\tilde{N'})$, and conclude that there is a point $x_k \in s_k$ at a distance less than or equal to $k\delta$ from $x$. If the distance along $s_0$ between $x$ and $g^{-1}x_k$ is greater than $k\delta$ then performing a Dehn twist will shorten the side $s_0$, and all the others, and hence we obtain a shorter resolution. Therefore, for the points $x, x_k$ as above $d_{s_0}(x, g^{-1}x_k) < k\delta$. For every $j = 0, \ldots, k$, let $s'_j$ denote the projection to $F$ of a segment obtained from $s_j$ by removing the ending subsegments of length $\mu_i(\ell_1) + k\delta$ and $\mu_i(\ell_2) + k\delta$ that are adjacent to $\Phi_i(\tilde{\ell}_1)$ and $\Phi_i(\tilde{\ell}_2)$, respectively. For each $x \in s'_0$ we then have a loop based at $x$ of length $\leq 2k\delta$. Hence, boundary loops of $F$ are homotopic to loops of length $\leq 2k\delta$, and there are only finitely many such. Moreover,
there is a constant $C$ so that for each two homotopic loops of length $\leq 2k\delta$
there is a homotopy between them of length $\leq C$. Let $\gamma_1$ and $\gamma_2$ be two of the
short loops we have found; the ones based at the initial and the end point of
$s_0^\prime$, respectively. Also, let $F'$ denote the part of $F$ between them. As we said
earlier there is an annulus $F_1$ between $\gamma_1$ and $\gamma_2$ of length $\leq C$, given by the
forementioned short homotopy. We now replace $F'$ by $F_1$, see Figure. We
obtain a shorter resolution that corresponds to a homomorphism obtained
from $f_i$ by bending (the torus $F_1 \cup F'$ gives us the element which determines
the bending).

If $\Lambda$ has more than one family of parallel leaves, we shorten the resolution
as above working on each family at the same time. Hence, we conclude that
if $\Lambda$ is completely simplicial, the subgroups carried by generic leaves are all
abelian, and $f_i$'s do not factor through the quotients we made in this case,
then the resolutions $\Phi_i$ were not shortest as assumed.

Remark 3.2. We have assumed that $\Lambda$ induces a splitting of $G$ with two
vertex groups. We realize that that assumption is not critical, as the case
of an HNN extension would be proved in the exactly same way. It is worth
noting that bending in the case of HNN extensions, which we perform in
order to shorten the resolutions, will yield a multiplication by elements of
parabolic subgroups. This is exactly what we needed in Example 2.10.

Lemma 3.3. If $\Lambda$ has a minimal component of either surface or thin type
we make quotients by trivializing all the loops in the prechosen leaf and by
abelianizing the fundamental group of the regular neighborhood of \( \Lambda \). These quotients are proper quotients of \( G \).

**Proof.** If \( \Lambda \) has a component of thin type, then the quotient as above has to be proper for otherwise \( G \) was freely decomposable.

Suppose now \( \Lambda \) has a surface component. If the annuli that we quotiented out were nontrivial in \( G \), we obviously get a proper quotient. Suppose that was not the case. We have a certain number of annuli attached to the surface in our complex \( K \), and to those annuli are maybe attached different components of \( K \), which we will call black boxes. Let us remind ourselves that the annulus \( S^1 \times I \) with a lamination \( S^1 \times \{ \text{Cantor set} \} \) is attached along an arc transverse to the lamination, Figure 7.

![Figure 7: Lamination on the surface with the attached annuli](image)

Since all the loops in the leaves of the lamination that are contained in the annulus, i.e., \( S^1 \times \{ \text{pt} \} \), are trivial we may collapse all of them, including the circles that are not contained in the leaves of the lamination. After this collapsing the black boxes are attached either directly to the surface, that is to the components complementary to the lamination, or to a boundary component of the surface. Since the lamination on the surface is the filling one, the components complementary to the lamination are either simply connected or homotopy equivalent to a boundary component. Hence if the fundamental group of one of the black boxes attached to the simply connected complementary component is nontrivial we get a free decomposition of \( G \), which is a contradiction. We conclude that all black boxes are either attached to the boundary components of the surface or have trivial fundamental groups (and hence can be collapsed). In both cases we get a pure surface component and a surface vertex group in a cyclic decomposition of \( G \). This surface vertex group must be conjugate to a QH vertex group in the JSJ of \( G \), see \[3\]. The fact that \( \Lambda \) was obtained as a limit of \( \Lambda_{f_i} \)'s and that it is filling on the surface implies that the loops that correspond to each generator of
our surface group have positive measures. Proposition 5.8. in [5] guarantees the existence of the set of short generators. That is: by applying Process II to the component of $K$ that carries $\Lambda$, we can obtain from $K$ a new band complex $K'$ which resolves the same tree, but so that the fundamental group of the component carrying the lamination is generated by loops short with respect to an interval $s$ of arbitrarily small measure. That the loop $p$ is short with respect to $s$ means that $p = p_1 \ast \lambda \ast p_2$, where $p_1$ and $p_2$ are contained in $s$ and $\lambda$ is contained in a leaf of $\Lambda$. This now tells us that these generators are shorter with respect to the measure $\mu_i$ than the original generators were. Since the combinatorial type of band complexes that correspond to these two sets of generators are the same we can find a modular automorphism that takes one of these sets into the other. Precomposing the $f_i$’s by this modular automorphism will give us homomorphisms shorter than $f_i$’s, which is a contradiction with our choice of $f_i$’s.

Finally, if $\Lambda$ has either surface or thin type component the the fundamental group of the regular neighborhood of that component is not abelian, hence its abelianization leads to a proper quotient of $G$.

**Lemma 3.4.** Suppose $\Lambda$ has a minimal component $\Lambda_0$ which resolves a line. Let $N$ be a standard neighborhood of $\Lambda_0$. We form the following quotients:

- Abelianize $\pi_1(N)$, where $N$ is a standard neighborhood of $\Lambda_0$, if it is nonabelian.
- If $\pi_1(N)$ is abelian, make the following quotients:
  - abelianize the subgroup of $G$ generated by $\pi_1(N)$ and all vertex groups adjacent to it,
  - mod out by the direct summand of $\pi_1(N)$ that intersects trivially the peripheral subgroup, if such exists.

At least one of these quotients is proper.

**Proof.** If $H = \pi_1(N)$ is nonabelian, then its abelianization leads to a proper quotient. Assume then that $H$ is an abelian group and $N$ is a genuine torus. If $\Lambda$ also has a simplicial, surface or thin component, we apply Lemmas 3.1, 3.3. Hence our only concern is when $\Lambda$ has only toral components, each of which has a torus as a standard neighborhood. Since $G$ is a limit group, these tori can not be glued directly to each other, i.e., an edge space cannot embed into both of them.

Let $H'$ denote the peripheral subgroup of $H$. Suppose first $H'$ is contained in a proper direct summand of $H$. We will call the smallest such $H'$ so that $H = H' \oplus H''$. For each $i$ we define a homomorphism $f_i' : G \rightarrow L$ that
coincides with $f_i$ on all vertex groups in the decomposition of $G$ except for $H$ where we define it to be:

$$f'_i(h) = \begin{cases} f_i(h), & h \in H' \\ 1, & h \in H'' \end{cases}$$

$f_i$ and $f'_i$ are equivalent under our moves, and $f'_i$'s factor through the quotient $G / \ll H'' \gg$. If, on the other hand, $H'$ is a finite index subgroup of $H$ there exists an edge $a$ of the triangulation of $K$ intersecting an edge space $E$ adjacent to $N$ nontrivially so that $\mu_i(a) \sim d_i$. Let $V$ be the vertex space at the other end of $E$. Since $f_i(H) < A$ is abelian, $\Phi_i(\tilde{N})$ is contained in a bounded neighborhood of the horosphere $P$ bounding the horoball $B$ whose stabilizer is $A$. We first assume that the minimum distance between points in $\Phi_i(\tilde{N})$ and points in $P$ is proportional to $d_i$. We can find a closed path $\tilde{p}$ of $p$ having a nonempty intersection with $\tilde{N}$. One of the endpoints of $\Phi_i(\tilde{p})$ will belong to $\Phi_i(\tilde{N})$, but $\Phi_i(\tilde{p})$ is not completely contained in $B$, since $f_i(p)$ does not commute with $f_i(H)$. Hence, $\ell(\Phi_i(\tilde{p})) \geq 2d_i$, contradicting the assumption that $\mu_i(p) \sim 0$.

We know now that $\Phi_i(\tilde{N}) \subset N_{n_i}(P)$ and $\lim_{i \to \infty} \frac{n_i}{d_i} = 0$.

All the hypotheses of Lemma 3.1(1) are satisfied by our resolutions. Therefore, we find the homomorphisms shorter than $f_i$ belonging to the same equivalence classes.

**Lemma 3.5.** Suppose $\Lambda \in LIM'(K)$ is a limit of $\Lambda_{f_i}$, where $f_i : G \to L$ is a sequence of short homomorphisms for which $d_{f_i} \to \infty$. There is a neighborhood $U \subset LIM'(K)$ of $\Lambda$ such that if $\Lambda_f \in U$ then $f$ factors through one of the quotients defined in Lemmas 3.1, 3.3, and 3.4.

**Proof.** It can be shown that if a subgroup of $G$ fixes an arc in the limiting tree $T_\infty$, then the image of that subgroup under almost all $f_i$ is abelian. The proof in [6] needs only small addition that deals with the existence of cups.

- $\Lambda$ is entirely simplicial:

  The subgroup $H$ carried by a generic leaf fixes an arc in $T_\infty$. If $H$ itself is abelian, we noted in Lemma 3.1 that $f_i$ would factor through the quotients we made in that case. If $H$ is not abelian, then $f_i(H)$ is, hence $f_i$ will factor through the abelianization of $H$. 

18
Λ has \textit{toral components}.

Any two bands will commute, and so every commutator fixes an arc in $T_\infty$, i.e., $[H, H]$ fixes this arc. By the same argument as in the simplicial case we get that, for a sufficiently large $i$, $f_i([H, H])$ is an abelian group. By the Tits alternative the subgroup $f_i(H)$ is either virtually abelian or contains a free group on two generators. If the latter is the case, then $[f_i(H), f_i(H)]$ could not be an abelian group, hence $f_i(H)$ is virtually abelian. Now we have $f_i(H)$ as a virtually abelian subgroup of a torsion-free limit group, which means it is abelian. We conclude that $f_i([a, b]) = 1$, $\forall a, b \in H$.

- Λ has a \textit{surface or thin component}

The following argument is due to M. Bestvina. We consider a standard neighborhood $N$. A loop in an annulus will fix an arc $I$ in $T_\infty$. Choose the segment $I$ so that every subsegment has the same stabilizer, and let $g \in G$ be the element corresponding to the loop that fixes $I$. We will argue that if $f_i(g) \neq 1$ for almost all $i$, then almost all $f_i$ map $\pi_1(N)$ into an abelian subgroup of $L$ and hence they all factor through an abelianization of $\pi_1(N)$. Suppose there is an element $h \in G$ such that $J = h(I) \cap I$ is a nonempty interval. Then both $g$ and $g' = hgh^{-1}$ fix $J$, and hence $I$ since the action on $T_\infty$ is stable. Our remark at the beginning says that $[f_n(g), f_n(g')] = 1$ for almost all $n$. Since $f_n(h)$ conjugates $f_n(g)$ into $f_n(g')$ and maximal abelian subgroups of $L$ are malnormal, we conclude that all three images must belong to the same abelian subgroup of $L$. Therefore, $[f_n(h), f_n(g)] = 1$, for almost all $n$. We get that $f_n(g)$ commutes with $f_n(h)$ whenever $h(I) \cap I \neq \emptyset$. Since $I$ belongs to the surface component such elements $h$ generate the whole surface (existence of “small” finite generating set of $\pi_1(N)$ (see [5] – this only uses minimality), and so $f_i(\pi_1(N))$ is abelian for almost all $i$.

\textit{Proof of Main Theorem.} Consider a sequence of homomorphisms for which the sequence $\{d_i\}$ is bounded. Proposition \ref{prop:boundedness} tells us that in such a sequence we can have only finitely many nonconjugate homomorphisms. We pick a representative of each conjugacy class, say $k_i : G \to L$, $i = 1, \ldots, k$ and form quotients $K_i = G/\ker(k_i)$. If this quotient is not proper, then $k_i$ was an embedding.

If on the other hand, $\Lambda \in LIM'(K)$ such that $\Lambda_{f_i} \to \Lambda$ and $d_{f_i} \to \infty$, then our previous four lemmas prove the claim: we have formed finitely many quotients of $G$ and we have found a neighborhood $U_\Lambda$ of $\Lambda$ so that whenever $\Lambda_f \in U_\Lambda$ and $d[f] \gg 0$ then a homomorphism equivalent to $f$ factors through one of these quotients. $U_\Lambda$’s together with neighborhoods of $\Lambda_{k_i}$’s cover $LIM'(K)$. Since this space is compact, it is covered by finitely many of these neighborhoods. Hence we have finitely many quotients through
which an element of the equivalence class \( \sim \) of any \( f : G \to L \) with \( d_f > 0 \) factors. If \( d_f = 0 \), then \( f \) factors through abelianization of \( G \).

This concludes the proof of our theorem. \( \square \)

It would be useful to know what happens if we iterate this construction, i.e., if we apply Theorem 1.1 to all the quotients we obtained. The following lemma is well known.

**Lemma 3.6.** A sequence of epimorphisms between \( \omega \)-residually free groups eventually stabilizes.

**Proof.** Let

\[
G_1 \to G_2 \to \cdots \to G_n \to \cdots
\]

be a sequence of epimorphisms between \( \omega \)-residually free groups. For a fixed free group \( F \) the sequence

\[
\text{Hom}(G_1, F) \leftarrow \text{Hom}(G_2, F) \leftarrow \cdots \text{Hom}(G_n, F) \leftarrow \cdots
\]

eventually stabilizes, i.e., consists of bijections, see [3]. Suppose

\[
\text{Hom}(G_k, F) \cong \text{Hom}(G_{k+1}, F),
\]

where the isomorphism is given by the obvious inclusion of \( \text{Hom}(G_{k+1}, F) \) into \( \text{Hom}(G_k, F) \). Let us also suppose that \( e : G_k \to G_{k+1} \) is a proper epimorphism. Let \( g \in \ker(e) \). Since \( G_k \) is \( \omega \)-residually free there is a homomorphisms \( f : G_k \to F \) such that \( f(g) \neq 1 \). On the other hand, there exists \( f' : G_{k+1} \to F \) such that \( f = f' \circ e \). We now have

\[
1 \neq f(g) = f'(e(g)) = 1.
\]

Hence, \( G_k \cong G_{k+1} \). \( \square \)

We now form the Makanin-Razborov diagram, Figure [4] except we add an edge issuing from each group in this diagram and ending in \( L \) representing the embeddings. All the groups in this diagram, except possibly \( G \), will be limit groups. Furthermore, each branch of this diagram is finite, as we have just shown.

**Remark 3.7.** At a first glance it may appear as if the proof of Main Theorem should hold for a broader class of groups, in particular for groups that are hyperbolic relative to a collection of their maximal noncyclic abelian subgroups. There are two problems that appear. The first one is that we do not know that a finitely generated subgroup of a relatively hyperbolic group
is finitely presented, and so the proof would need to be modified in order to deal with not necessarily finite complexes. The second problem is that the proof of Lemma 3.6 does not apply in this context. However, we believe that the proof of descending chain condition on (hyperbolic)-limit groups given in [13] will transfer to this setting easily. Nonetheless, until a more elegant solution is found to both of these problems, we leave the discussion at the level of this remark.
