**IMPORTANCE** Spontaneous coronary artery dissection (SCAD) has been associated with fibromuscular dysplasia (FMD) and other extracoronary arterial abnormalities. However, the prevalence, severity, and clinical relevance of these abnormalities remain unclear.

**OBJECTIVE** To assess the prevalence and spectrum of FMD and other extracoronary arterial abnormalities in patients with SCAD vs controls.

**DESIGN, SETTING, AND PARTICIPANTS** This case series included 173 patients with angiographically confirmed SCAD enrolled between January 1, 2015, and December 31, 2019. Imaging of extracoronary arterial beds was performed by magnetic resonance angiography (MRA). Forty-one healthy individuals were recruited to serve as controls for blinded interpretation of MRA findings. Patients were recruited from the UK national SCAD registry, which enrolls throughout the UK by referral from the primary care physician or patient self-referral through an online portal. Participants attended the national SCAD referral center for assessment and MRA.

**EXPOSURES** Both patients with SCAD and healthy controls underwent head-to-pelvis MRA (median time between SCAD event and MRA, 1 [IQR, 1-3] year).

**MAIN OUTCOME AND MEASURES** The diagnosis of FMD, arterial dissections, and aneurysms was established according to the International FMD Consensus. Arterial tortuosity was assessed both qualitatively (presence or absence of an S curve) and quantitatively (number of curves >45%; tortuosity index).

**RESULTS** Of the 173 patients with SCAD, 167 were women (96.5%); mean (SD) age at diagnosis was 44.5 (7.9) years. The prevalence of FMD was 31.8% (55 patients); 16 patients (29.1% of patients with FMD) had involvement of multiple vascular beds. Thirteen patients (7.5%) had extracoronary aneurysms and 3 patients (1.7%) had dissections. The prevalence and degree of arterial tortuosity were similar in patients and controls. In 43 patients imaged with both computed tomographic angiography and MRA, the identification of clinically significant remote arteriopathies was similar. Over a median 5-year follow-up, there were 2 noncardiovascular-associated deaths and 35 recurrent myocardial infarctions, but there were no primary extracoronary vascular events.

**CONCLUSIONS AND RELEVANCE** In this case series with blinded analysis of patients with SCAD, severe multivessel FMD, aneurysms, and dissections were infrequent. The findings of this study suggest that, although brain-to-pelvis imaging allows detection of remote arteriopathies that may require follow-up, extracoronary vascular events appear to be rare.
Spontaneous coronary artery dissection (SCAD) is a cause of acute coronary syndrome predominantly affecting young to middle-aged women, including a minority during or after pregnancy. SCAD is characterized by the development of a false lumen within the coronary artery wall that leads to coronary insufficiency due to external compression of the true lumen. This event has the potential to cause myocardial infarction.1,2 Although SCAD has historically been considered a very rare diagnosis, its prevalence has been recently reevaluated, and SCAD is now estimated to cause 10% to 25% of acute coronary syndrome presentations in women younger than 50 years.3,4

SCAD has been associated with various extracoronary arteriopathies.5 The most frequent of these is fibromuscular dysplasia (FMD), a nonatherosclerotic, noninflammatory disease of arterial walls that also occurs predominantly in middle-aged women and shares a common genetic risk variant with SCAD.6 The reported prevalence of FMD in SCAD ranges widely, from 11% to 86%.1,2 Lesions were reported to be almost exclusively the multifocal string-of-beads subtype and have been identified most commonly in renal, cerebrovascular, and iliac arteries.7,8 In addition to typical FMD lesions, other extracoronary vascular abnormalities, such as aneurysms, dissections, irregularities, undulations, and/or arterial tortuosity, have been reported.7 Based on these findings, both the SCAD1,2 and FMD9,10 consensus statements recommend brain-to-pelvis imaging by computed tomographic angiography (CTA) or magnetic resonance angiography (MRA) at least once.

To date, studies assessing the prevalence and type of extracoronary lesions in patients with SCAD have had important limitations. First, the diagnostic criteria for FMD, arterial tortuosity, and other vascular abnormalities have not always been clearly defined. Second, all previous studies lacked a control group or blinded analysis. Third, assessment of severity and quantification of extracoronary arterial lesions have not been provided. Therefore, some investigators may have reported only the typical string-of-beads lesions, while others may have also considered mild arterial irregularities as evidence of FMD.

The objectives of this blinded study were to assess the prevalence, type, and severity of FMD lesions and other extracoronary arterial abnormalities in patients with SCAD and quantify extracoronary arterial tortuosity in this population.

Methods

Study Participants
Patients from the UK SCAD Registry were invited to participate in the SCAD Deep Phenotyping Study. Patients with angiographically confirmed SCAD in the registry were recruited between January 1, 2015, and December 31, 2019 (median time between SCAD event and MRA, 1 [IQR, 1-3] year) throughout the UK by referral from the clinical team at the presenting hospital, primary care referral, or self-referral to an online web portal. The study protocol was approved by the UK National Research Ethics Service and the UK Health Research Authority and conducted in accordance with the Declaration of Helsinki.31 All participants gave fully informed and signed consent; there was no financial compensation. The study followed the reporting guideline for case series.

Of 315 eligible patients recruited to the UK SCAD registry, 192 consented to undergo phenotyping. Of these, 1 patient died before imaging was conducted, 3 patients had implantable cardioverter defibrillators, 1 patient had claustrophobia, 5 were excluded on angiographic grounds as not meeting the study criteria for definite SCAD, 8 individuals were excluded due to technical issues preventing complete or adequate quality scanning, and 1 patient subsequently declined to attend despite initially consenting (eFigure in the Supplement). Therefore, 173 patients (55%) from the Registry were included in this analysis. Participants attended the national SCAD referral center for assessment and MRA imaging. A subset of patients also underwent CTA screening assessment as part of routine clinical care of SCAD with scans undertaken at 2 UK SCAD national centers (Leicester and London [Royal Brompton/Chelsea and Westminster]).

Medical records and imaging results from the index SCAD event and subsequent potential major adverse cardiovascular and cerebrovascular events were obtained. Basic demographic information collected included self-reported race and ethnicity because it is not known whether the prevalence and spectrum of extracoronary arteriopathies in patients with SCAD differs between racial and ethnic groups. A detailed medical history and clinical examination, including determination of a Beighton score (a simple 9-point clinical score to assess hypermobility and joint laxity, with higher scores indicating greater hypermobility and joint laxity),32 was obtained at the time of the patient visit. Pregnancy-associated SCAD was defined as an event occurring during gestation or within 12 months of delivery.

Healthy individuals serving as controls were recruited by open advertisement and targeted to match the age and sex profile of the SCAD cohort. This control cohort was used for interpretation of MRA images by investigators blinded to participants’ status. These control participants were screened to exclude those with prior hypertension to reduce the likelihood of including individuals with potential renovascular disease.

All angiographic analysis was conducted with investigators blinded to the results of the MRA/CTA analysis. All patients had their SCAD diagnosis confirmed by 2 experienced SCAD clinicians (A.A.-H. and M.G.-G.) with adjudication of any
differences by a third experienced SCAD clinician (D.A.). Patients with atherosclerotic, traumatic, or iatrogenic dissection (except in the context of definite SCAD) were excluded.

Genetic Testing
Genotyping at the PHACTR1 locus rs9349379 was performed by assay as previously described (TaqMan; ThermoFisher Scientific) in 114 patients with SCAD and 49 healthy controls.

Imaging
Patients with SCAD and healthy controls underwent research MRA scanning using a common protocol on a 3-T platform (Siemens Avanto). Imaging of the head and neck vessels was performed using time-of-flight noncontrast MRA sequences. Whole aorta MRA with iliac/femoral arteries was performed using a 3-dimensional TI gradient echo sequence, with parallel imaging. Gadoterate meglumine, 0.1 mmol/kg, was administered in a single injection at 4 mL per second followed by a 20-mL saline flush at the same speed.

Computed tomographic angiography was performed using a standard protocol (Somatom Definition Flash; Siemens Healthineers). Scan range was from the circle of Willis to the femoral heads. A biphasic injection protocol was used with 100 mL of iodinated contrast and a 100-mL bolus of sodium chloride injected at 2 mL per second. To ensure adequate opacification of the entire arterial system, bolus tracking was used (with a region of interest placed in the aortic arch) with a 7-second delay. Raw data were reconstructed using 1-mm contiguous slices for subsequent analysis.

All anonymized MRA and CTA images were jointly analyzed by a vascular medicine specialist (M.L.-S.) and a vascular radiologist (I.R.) using a detailed preestablished case report form, with adjudication of any differences by a third FMD specialist (A.P.). All 3 specialists were unaware of the participant’s clinical status (healthy control vs SCAD), the number of controls, and any other demographic or disease-related characteristics. Magnetic resonance angiography and CTA from the same patient were unlinked and analyzed independently.

Extracoronary Arterial Abnormalities
Analysis was undertaken in a single center, using viewing software (Carestream Vue PACS; Carestream Health Inc). Analysis included cerebrovascular, renal, visceral, and iliofemoral vascular beds as well as the thoracoabdominal aorta. The following lesions were considered: multifocal stenosis (string of beads, ie, the presence of alternating areas of stenosis and dilatation), focal stenosis, arterial aneurysms, and dissections. Aneurysm was defined as the presence of greater than 50% enlargement in the diameter of an artery in the orthogonal plane or perpendicular to the long axis of the vessel compared with an adjacent normal arterial segment. The diagnosis of FMD was based on the identification of a string of beads in at least 1 arterial bed. Multivessel FMD was defined as the presence of a string of beads in at least 2 different arterial beds or a string-of-beads in 1 vascular bed and aneurysm or dissection in 1 or more vascular beds in accordance with the international consensus on FMD.9,10

Arterial tortuosity was assessed by the number of angulations greater than or equal to 45° in the carotid, vertebral, renal, and iliac arteries. In cases of 1 or more loops greater than or equal to 45°, tortuosity index ([direct length of the vessel/stretched vessel length −1] × 100)13 was also calculated.14 For the calculation of arterial length, the same anatomical references were used for each measurement (vertebral artery: from origin to second cervical vertebra42; internal carotid: from carotid bifurcation to horizontal segment; and renal, common, and external iliac arteries: from the ostium to first bifurcation).

Statistical Analysis
All analysis was performed using SPSS, version 21.0 (IBM Corp). Continuous variables are expressed as mean (SD) or median (IQR) according to their distribution; categorical variables are expressed as counts and percentage. Data were analyzed with the Kolmogorov-Smirnov test to determine their distribution. Continuous variables were analyzed using the unpaired t test if distribution was gaussian or the Mann-Whitney test in case of nongaussian distribution. Categorical variables were compared using the χ2 test. Statistical significance was set at 2-sided P value <.05 for all analysis.

Results

Characteristics of Patients With SCAD vs Controls
Clinical characteristics of patients with SCAD and healthy controls are reported in Table 1. Magnetic resonance angiography analysis was undertaken on 173 patients with SCAD and 41 controls with investigators blinded to the clinical diagnosis. The SCAD cohort comprised 167 women (96.5%) and 6 men (3.5%); mean (SD) age at diagnosis was 44.5 (7.9) years. Of 170
participants with race and ethnicity data known, the categories comprised Black African and/or Caribbean (2 [1.2%]), Indian (5 [2.9%]), and White (163 [94.2%]); 2 participants reported Other (2 [1.2%]) and 1 did not report data. Risk factors for vascular disease included smoking (49 [28.3%]), hypertension (31 [17.9%]), and dyslipidemia (14 [8.1%]). The control group was also predominantly female (40 [97.6%]) but slightly younger (41.6 [7.4] years) and more ethnically diverse than the SCAD cohort (Table 1).

Characteristics of Patients With SCAD
SCAD was predominantly diagnosed following a non–ST segment elevation myocardial infarction (105 [60.7%]); 59 patients (34.1%) underwent percutaneous coronary intervention and 5 patients (2.9%) underwent coronary artery bypass grafting. The most frequently affected vessel was the left anterior descending coronary artery (122 [70.5%]). Twenty-seven patients (15.6%) had multivessel SCAD, 16 (9.2%) had experienced recurrent SCAD, and 15 of the episodes (9.0%) were associated with pregnancy (Table 2). Eighty-three patients (48.0%) reported migraines. The Beighton score was greater than 4 in 53 patients (30.6%). The distribution of genotypes at the PHACTR1 locus (n = 163) was AA, 44.8% (n = 73); AG, 47.9% (n = 78); and GG, 7.4% (n = 12).

aSaw class categories: 1, multiple radiolucent lumens or arterial wall contrast staining; 2a, diffuse arterial narrowing bordered by normal segments; 2b, diffuse narrowing that extends to the distal tip of the artery; 3, focal or tubular stenosis; and 4, total occlusion, usually of a distal vessel.1

Prevalence and Type of Extracoronary FMD and Other Arterial Abnormalities in Patients With SCAD
The prevalence of FMD was 31.8% (55 of 173) in the SCAD cohort. Among the 55 patients with SCAD and FMD, 70.9% (n = 39) had involvement of 1 arterial bed; 25.5% (n = 14), 2 arterial beds; and 3.6% (n = 2), 3 arterial beds. The most commonly affected arterial beds of the total 173 patients with SCAD were renal (27 [15.6%]), cervical (23 [13.3%]), iliac (17 [9.8%]), and visceral (5 [2.9%]) (Table 3). The prevalence of hypertension was not significantly different in patients with 3 of 27 (11.1%) or without (28 of 146 [19.2%]) renal FMD (P = .32).

Focal stenosis in at least 1 arterial bed was reported in 15 patients (8.7%) with SCAD. Thirteen patients (7.5%) had aneurysms and 3 patients (1.7%) had dissections (Table 3). Subsets of patients...

* Tortuosity index was calculated in the subset with at least 1 curve greater than or equal to 45°.

Prevalence of FMD and Other Arterial Lesions Assessed by CTA vs MRA

We subsequently compared the MRA assessment of remote arteriopathy prevalence through comparison with CTA assessment in 43 of 173 patients with SCAD in whom CTA arteriopathy screening had been conducted as part of routine clinical care in addition to paired research MRA. No significant difference was found in the prevalence, severity, and/or localization of FMD or arterial abnormalities as detected by either imaging modality (Figure and eTable 3 in the Supplement). The median dose length product for the CTAs was 710 (IQR, 419-745) mGy•cm.

Clinical Follow-up

Extracoronary vascular events (stroke, dissection, limb claudication, and revascularization of extracoronary arterial beds) were assessed in 170 of 173 patients at a median follow-up of 5 (IQR, 4-7) years after the index SCAD event. The remaining 3 patients were lost to detailed follow-up but are known to be alive. A single stroke event was reported (secondary to embolism of a left ventricular thrombus following recurrent SCAD). There were no other extracoronary vascular events or revascularization procedures. Major adverse events were reported in 41 of 170 patients with 2 deaths (both from noncardiovascular causes), 35 cases of recurrent myocardial infarction, and 4 cases of coronary revascularization.

Discussion

To our knowledge, this study is the first blinded assessment of the prevalence and spectrum of FMD and other extracoronary arterial abnormalities in a large cohort of patients with SCAD. First, in this cohort assessed by MRA, we report a prevalence of FMD of 31.8%. Second, the prevalence of the most serious arterial abnormalities was 9.2% (aneurysms, 7.5%; dissections, 1.7%), which is substantially lower than that reported in noncontrolled, unblinded observational analyses of primary FMD.9,10,16-19 Third, the prevalence of multivessel involvement in patients with SCAD and FMD was 29.1% (2 arterial beds, 25.5%; 3 arterial beds, 3.6%), again much lower than that reported for patients with primary FMD.9,10,16-19 In addition, clinical sequelae from SCAD-related noncoronary arteriopathies were seldom observed.

According to a recent state-of-the art review by Hayes et al.,20 the prevalence of extracoronary FMD in unblinded, uncontrolled studies including over 100 patients with SCAD...
was between 45.2% and 77.6%. In our blinded analysis strictly based on International FMD Consensus criteria, including both SCAD cases and healthy controls (which may reduce the risk of overdiagnosis), we reported a lower prevalence of 31.8%. Notably, this estimate is in keeping with a recently reported large Canadian SCAD cohort (n = 750) explored using various imaging modalities (52.4% CTA; 43.5% catheter-based angiography; and 4.0% MRA) in which the proportion of extracoronary FMD lesions was similar (ie, 31.1%), albeit from an incompletely screened population.
In patients with SCAD and FMD, the prevalence of FMD in multiple vascular beds (multivessel FMD) was 29.1%, consistent with that documented by Prasad et al\textsuperscript{2} (29%), but lower than in previous SCAD studies by Saw et al\textsuperscript{8} (49%) and Liang et al\textsuperscript{22} (44%), as well as in patients with primary FMD included in large registries (57%-66%).\textsuperscript{9,10,16,17,19} Similarly, in this series of patients with SCAD, the prevalence of arterial aneurysms (7.5%) and dissections (1.7%) was much lower than that reported in registries of primary FMD (aneurysms: 21.6%-26.0%; dissections: 5.6%-28.1%).\textsuperscript{16-18} In addition, although arterial tortuosity is considered a manifestation of primary FMD,\textsuperscript{9,10} in our series of patients with SCAD, whether in the presence or absence of FMD, the prevalence of extracoronary arterial tortuosity was not higher than in healthy controls. In view of similar performance of MRA and CTA in 43 patients explored by both imaging modalities, these findings are unlikely to be explained by a lesser sensitivity of MRA vs CTA for detection of clinically relevant lesions.

Furthermore, the absence of an increased prevalence of hypertension in patients with SCAD and renal artery FMD supports the visual impression that most patients had mild renal FMD lesions, which are unlikely to have hemodynamic consequences. This finding is also in keeping with low rates of noncoronary vascular events reported in this and another study.\textsuperscript{23} Our findings lend further support to the concept that SCAD with FMD and primary FMD may correspond to distinct although overlapping entities. Along the same lines, dissections in patients with FMD are associated with the male sex\textsuperscript{21,24,25} and patients with SCAD are primarily female. Also, recent studies report only a partial overlap between genetic determinants of FMD and SCAD.\textsuperscript{26} In addition, a historical correlate for the radiological FMD in SCAD remains to be demonstrated.\textsuperscript{23} Further studies are needed to fully understand the interrelationship between SCAD and FMD.

Limitations

This study has limitations; the first is the retrospective and cross-sectional design leading to the potential for bias. This was an observational study and therefore we cannot conclude that the documented associations are causative. Of 315 eligible patients recruited to the UK SCAD registry, only 192 consented to undergo phenotyping. However, the demographic and SCAD-related characteristics in our series are in line with those reported in other large SCAD cohorts.\textsuperscript{7,21,28} Second, the comparison of the prevalence of multivessel FMD, aneurysms, and dissections with that reported in registries focused on patients with primary FMD\textsuperscript{16-18} needs to be considered with caution. Indeed, in the latter, with the exception of the Assessment of Renal and Cervical Artery Dysplasia study,\textsuperscript{16} whole body scanning was not performed in all patients. Furthermore, data were registered by multiple investigators, central image analysis was not exhaustive, and analysis was limited to patients with FMD and therefore unblinded. Third, the size of the subgroup explored by both CTA and MRA was limited (n = 43), which reduces the power of the statistical comparisons presented. Larger studies will be needed to confirm our findings and assess smaller differences.

Conclusions

In this blinded analysis of patients with SCAD, severe multivessel FMD, aneurysms, and dissections were infrequent. Although brain-to-pelvis imaging allows detection of remote arteriopathies which may require follow-up, supporting the current recommendation\textsuperscript{1,2} to perform a systematic arterial screening in all patients with SCAD, more research is required to assess whether this strategy leads to a reduction in clinical events. The findings of this study suggest that clinical complications from these extracoronary arterial lesions over the short to medium term appear to be very rare.
Conflict of Interest Disclosures: Dr McCann reported receiving grants from the British Heart Foundation, the National Institute for Health Research (NIHR), and the Medical Research Council outside the submitted work; and was a collaborator on research with Circlevi. Dr Adlam reported receiving grants from Abbott Vascular to support a clinical research fellow, honoraria from General Electric as a consultant to support general research funds, grants from AstaZeneca to support unrelated research, and nonfinancial support from AstaZeneca to support spontaneous coronary artery dissection (SCAD) genetics research outside the submitted work; in addition, Dr Adlam had patents issued for EP3277337A1 and PCT/GB2017/050877 unrelated to this work. No other disclosures were reported.

Funding/Support: This work was supported by BeatScAD, the British Heart Foundation PG/13/196/30608, NIHR rare disease translational collaboration, and the Leicester NIHR Biomedical Research Centre. Dr McCann is directly funded by the NIHR (CDF-2014-07-45 and RP-2011-08-ST-007).

Role of the Funder/Sponsor: The funding organizations had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Additional Contributions: We acknowledge the leadership of the European Society of Cardiology-Association for Acute Cardiovascular Care Study Group. We are grateful for the support of the study participants and thank our clinical colleagues throughout the UK who referred patients with SCAD to our study. We specifically acknowledge the support of research nurses or nursing assistants Ellie Tomlinson, BSc; Deirdre Adult Nursing, Jane Plume and Donna Alexander, MSc; SCAD study administrators Jenny Middleton, BA(Hons), and Rebecca Wrack; Sue Sterland, Richard Bramley, BSc(Hons), Diploma in Computing for Commerce and Industry, and Daniel Lawday for building and supporting the study eCRF; Emma Beeston, BSc, Diploma Adult Nursing, Tara Maltland, BA(Hons), and Andrea Marshall for study management and research governance support (all affiliated with the University Hospitals of Leicester, UK), and Bruno Morgan, BM, MA, PhD, for technical support and advice on secure image anonymization and transfer (affiliated with the University of Leicester, UK). We are grateful to them for all their support for SCAD research.
