Varicella pneumonia associated with spontaneous popliteal arterial thrombosis in an adult: a case study and review of the literature

Alex Smithson, Jessica Ruiz, Xavi Ramos, Esther Niño and Fernando Armestar

Introduction: Chickenpox is generally a childhood exanthematic benign self-limited disease. In contrast, most complications and fatal cases occur among adults, which is the group that suffers less commonly from this disease. The frequency of chickenpox in adults is increasing worldwide, together with the associated complications, mainly varicella pneumonia, which can lead to death. The incidence of other complications such as peripheral artery thrombosis is much lower but can cause important morbidity.

Case presentation: We report the case of a 63-year-old male smoker, who was otherwise previously healthy, who was admitted to the Emergency Department with chickenpox and varicella pneumonia with respiratory insufficiency requiring mechanical ventilation and intensive care unit admission. During hospitalization, the patient developed spontaneous popliteal artery thrombosis that finally led to transfemoral amputation.

Conclusions: Varicella pneumonia and peripheral artery thrombosis are two of the known complications of chickenpox. Both complications seem to be much more frequent in men with an active smoking habit. Clinicians should be aware of these complications in order to recognize them promptly and provide adequate treatment.

Keywords: arterial thrombosis; chickenpox; pneumonia; varicella-zoster virus.

Introduction

Varicella-zoster virus (VZV) is an enveloped dsDNA virus that belongs to the family *Herpesviridae*. VZV primary infection leads to chickenpox or varicella, an exanthematic disease typical of childhood (Gershon & Gershon, 2013). Despite chickenpox being an infrequent disease in adults, most complications and fatal cases are seen in adulthood (Tunbridge & Breuer, 2008). Here, we present the clinical case of an adult who developed extensive chickenpox complicated with varicella pneumonia and a peripheral ischaemia.

Case report

A 63-year-old male active smoker with a medical history of hypertension and diabetes mellitus was admitted because of varicella pneumonia. Treatment with acyclovir and non-invasive mechanical ventilation was started. After 48 h, he presented acute symptoms of arterial ischaemia of the right lower limb, and treatment with intravenous heparin and prostaglandins was initiated. Arteriography showed a non-occlusive thrombus in the right common iliac artery and occlusion of the popliteal artery, without evident atherosclerotic disease (Fig. 1). A transfemoral embolectomy was carried out with extraction of embolic material and evidence of distal thrombosis. Despite medical treatment, he required transfemoral amputation of the right lower limb 12 days after onset of the ischaemic symptoms.

Discussion

Our patient presented a spontaneous peripheral arterial thrombosis, which we believe was associated with the VZV infection. VZV is one of the few viruses that shows tropism for the endothelium and the only one with a demonstrated ability to replicate in endothelial cells, mainly in cerebral arteries. The relationship between VZV and cerebrovascular disease has been clearly established. It is the most
common cause of ischaemic stroke in children and occurs with less frequency in adults (Gilden et al., 2009). In a recent study, it was observed that children who experience chickenpox have a fourfold increased risk of stroke in the subsequent 6 months (Thomas et al., 2014). VZV can also cause aneurysms, cerebral or subarachnoid haemorrhage, vascular ectasias and carotid artery dissection (Gilden et al., 2009).

Despite the predominant preference of VZV for cerebral arteries, it can also affect, although with much less frequency, peripheral arteries with a clear predilection for the lower limbs. After reviewing the literature using PubMed, we found only four cases of peripheral thrombosis associated with chickenpox in healthy adults, and all of them involved the lower limbs (Limb & Binning, 2009; Massano et al., 2008; Peyton et al., 1998). The main characteristics of these cases and our own case are summarized in Table 1. All the cases were male, generally smokers, with chickenpox complicated with varicella pneumonia, without prior history of peripheral vascular disease, who developed lower limb ischaemic symptoms between 2 and 8 days from the onset of chickenpox cutaneous symptoms. Three of the four patients in which a complete coagulation study was carried out had abnormalities causing a hypercoagulable state. Our patient had in common with the previous published cases the fact that he was smoker without known peripheral vascular disease and that the peripheral arterial thrombosis appeared in association with varicella pneumonia.

The origin of this complication is unknown, although it has been suggested that it is mediated by autoantibodies induced by the VZV infection and directed against proteins involved in the coagulation pathway. It is well known that chickenpox is a risk factor for thrombophilic disorders in children, including purpura fulminans, deep-vein thrombosis and

M, male; DM, diabetes mellitus; Ht, Hypertension; R, rash; VP, varicella pneumonia.

Figure 1. Lower limb angiography showing occlusion of the right popliteal artery.
pulmonary embolism (Raffini et al., 2009). Low protein S and protein C levels, autoantibodies directed against phospholipids, and coagulation proteins and lupus anticoagulant have been detected in children with chickenpox, particularly in those who develop thrombophilic disorders (Ferrara et al., 2013; Josephson et al., 2001). In the case we have presented, the levels of protein S or lupus anticoagulant or other pro-coagulant factors were not measured as the ischaemic complication was not thought to be related to a thrombophilic state induced by the VZV infection.

In summary, chickenpox in adults, even in those who are previously healthy, is a life-threatening infectious disease with a significant number of potential and serious complications such as spontaneous arterial thrombosis. Clinicians should be well aware of these to provide early recognition and optimal therapeutic management.
