I. INTRODUCTION

Thin liquid films have considerable scientific and technological importance, and have numerous applications. In engineering, for instance, they serve to protect surfaces, and applications arise in paints, adhesives and membranes [1]. Thin films display a variety of interesting dynamics phenomena and have therefore been the focus of many experimental and theoretical studies [2]. In particular, thin polymer films have recently attracted a lot of interest since understanding their properties such as viscosity [3], chain mobility [4] and stability [5] is essential for optimization.

A long time ago, Taylor [6] and Culick [7] analyzed the growth of a circular hole in a thin liquid sheet [8]. By balancing surface tension forces against inertia [9], they found that the rim of liquid at the edge of the films retracts at a constant velocity, a prediction first checked experimentally by Mc Entee and Mysels [10, 11]. Debrégeas and collaborators [12] have recently studied the bursting of thin suspended films of very viscous liquids. These experiments revealed unexpected features: (a) First, the retraction velocity grows exponentially with time (with experiments revealed unexpected features: (a) First, the retraction velocity grows exponentially with time (with exp), and on the initial film thickness, and on the power-law index involved in the constitutive equation. In the thin-films regime, the dry radius and the rim height obey power-law time dependences. We then compare our predictions with the experimental results obtained by Debrégeas et al. [13] and Reiter [14].

II. THE MODEL

In this paper we aim at precising our methods of resolution, and characterizing the dewetting process for a Cross-type constitutive equation (interpolation between a viscous behavior at low strain-rates and a power-law dependence for the viscosity versus the shear strain rate), following recent experimental results by Dalnoki-Veress et al. for PS films [15]. We study the profile of the dewetting film, and characterize the time evolution of the dry radius, and of the rim height (as summarized in appendix A). Finally, we discuss the adequation between our theoretical predictions and experimental results by Debrégeas and Reiter.

Figure 1 shows the film geometry. for PS films [16]. We study the profile of the dewetting film, and characterize the time evolution of the dry radius, and of the rim height (as summarized in appendix A). Finally, we discuss the adequation between our theoretical predictions and experimental results by Debrégeas and Reiter.

trathin (i.e. thinner than the coil size), almost glassy polystyrene (PS) films deposited onto silicon wafers coated with a polydimethylsiloxane (PDMS) monolayer. He found that a highly asymmetric rim, with an extremely steep side towards the interior of the hole and a much slower decay on the rear side, builds up progressively [17], with the maximum height increasing linearly with the diameter of the hole. We recently [18] proposed a theoretical model to explain such deviations from the behavior of pure liquids, based on the shear-thinning properties of the polymer film. Assuming that the stresses inside the film saturate logarithmically with the strain rates, we showed that different regimes of growth are expected, depending on the initial film thickness and the experimental time range. Other theoretical approaches for polymer film dewetting have recently been proposed by Herminghaus et al. [19] and Shenoy et al [20].

In this paper we present a theoretical model for the dewetting of ultra-thin polymer films. Assuming that the shear-thinning properties of these films can be described by a Cross-type constitutive equation, we analyze the front morphology of the dewetting film, and characterize the time evolution of the dry region radius, and of the rim height. Different regimes of growth are expected, depending on the initial film thickness, and on the power-law index involved in the constitutive equation. In the thin-films regime, the dry radius and the rim height obey power-law time dependences. We then compare our predictions with the experimental results obtained by Debrégeas et al. [13] and Reiter [14].

length (cf. [23]). The range of thicknesses studied by Reiter allows this simplifying assumption.

A. Constitutive law of the material

In order to characterize the rheologic properties of the film, we introduce the stress tensor \( \sigma_{ij} = -p \delta_{ij} + \sigma^m_{ij} \), where \( p \) is the pressure and \( \sigma^m_{ij} \) represents the effects of internal friction. We relate \( \sigma^m_{ij} \) to the strain rate tensor \( \dot{\gamma}_{ij} \) by a constitutive law of the form:

\[
\sigma^m(\dot{\gamma}) = \sigma_0 \Phi(\dot{\gamma} \tau),
\]

where \( \sigma_0 \) and \( \tau \) are material constants, and \( \Phi \) is a generic function.

For a purely viscous liquid, the function \( \Phi \) is linear:

\[
\Phi(\dot{\gamma} \tau) = \dot{\gamma} \tau
\]

In this case, the fluid viscosity \( \eta = \sigma^m / \dot{\gamma} \) is constant and equals the zero-shear viscosity \( \eta_0 = \sigma_0 \tau \).

For polymers, just above \( T_g \), it is expected within the framework of the free-volume model that \( \sigma^m \) is expected to vary logarithmically with \( \dot{\gamma} \) as [24]:

\[
\Phi(\dot{\gamma} \tau) = \ln(1 + \dot{\gamma} \tau)
\]

The features of the dewetting regimes obtained with this rheological law were presented elsewhere [24], and will only be briefly mentioned in the present paper in Appendix B. As mentioned in [19], this logarithmic law does not permit a simple analytical description of all the regimes of time and thicknesses.

An alternative way of describing the polymer rheology is to use the well-known Cross model [24]:

\[
\Phi(\dot{\gamma} \tau) = \frac{\dot{\gamma} \tau}{1 + k(\dot{\gamma} \tau)^n},
\]

\( k \) and \( n \) being dimensionless constant parameters. A shear-thinning behavior is taken into account by taking the power-law index \( n \) strictly between 0 and 1. At low strain-rates \( (\dot{\gamma} \tau < k^{-1/n}) \), this law displays a viscous-type behavior \( (\sigma^m \approx \eta_0 \dot{\gamma}) \), with a zero-shear viscosity \( \eta_0 = \sigma_0 \tau \), while for large values of \( \dot{\gamma} \tau \), \( \sigma^m \) obeys the well-known power-law model. This popular expression, which will be used all along with this article, is applicable to a number of polymer materials and complex fluids [24].

B. Equations

Assuming the fluid to be incompressible, mass conservation leads to:

\[
\frac{1}{h(r,t)} \left( \frac{\partial h(r,t)}{\partial t} + \frac{r \beta(r,t)}{\tau} \frac{\partial h(r,t)}{\partial r} \right) = \alpha(r,t) - \beta(r,t) \tau
\]

Equation (5) involves two unknown functions \( \alpha(r,t) \) and \( \beta(r,t) \), that are positive, dimensionless forms of the strain-rate components \( \dot{\gamma}_{rr} \) and \( \dot{\gamma}_{\phi\phi} \):

\[
\left\{ \begin{array}{l}
\alpha = -\tau \dot{\gamma}_{rr} = -\tau \frac{\partial \sigma_{rr}}{\partial r} \\
\beta = \tau \dot{\gamma}_{\phi\phi} = \tau \frac{\partial \sigma_{\phi\phi}}{\partial r}
\end{array} \right.
\]

We thus need two additional equations to determine \( h(r,t) \). First, note that the following partial differential equation can be directly derived from Eq. (6):

\[
\frac{\partial \beta}{\partial r} = -\frac{\beta + \alpha}{r}
\]

Neglecting the inertial term, conservation of momentum (projected on the radial direction [27]) leads to:

\[
\frac{\partial \sigma_{rr}}{\partial r} + \frac{\sigma_{rr} - \sigma_{\phi\phi}}{r} = 0
\]

It can be shown that Eqs. (6) and (8), along with the free-surface boundary condition (i.e. \( \sigma_{zz} = 0 \)) at the contact with ambient atmosphere [23], allow one to express the strain rate \( \alpha \) as a function of \( \beta \) only: \( \alpha = F(\beta) \). Substitution of the shear-thinning constitutive law [24] in Eq. (8) then leads to the following differential equation for \( F \):

\[
\frac{d[F(\beta)]}{d\beta} = \frac{F(\beta) - F(\beta - \beta)}{F(\beta) + \beta},
\]

which has to be solved along with the condition \( F(0) = 0 \) (far away from the perturbed central region, the strain rates must decrease to zero). In Fig. 3, we present the form of functions \( \alpha = F(\beta) \) for the Cross model, taking for each curve \( k = 10 \) and different values of power-law index \( n \) between 0 and 1. This function can be approached by simpler expressions in the two opposite regimes \( \beta \ll 1 \) and \( \beta \gg 1 \), as explained below (cf. Appendix B).
In order to solve Eq.\ref{eq:cross}, we should supply it with initial and boundary conditions. Our initial profile is assumed to be uniform, with a thickness $h_i$, except in a bored region ranging from $r = 0$ to $r = R_0$ (as shown in fig.\ref{fig:experimental}). $R_0$ is our characteristic radial length used thereafter to make $r$ dimensionless:

$$h(r, t = 0) = \begin{cases} h_i & \text{if } r \geq R_0 = 1 \\ 0 & \text{otherwise} \end{cases}$$  \tag{10}$$

We do not consider here the origin of the initial dewetting process: experimentally, it is found that a thick PS film on a silicon substrate is metastable and dewets via nucleation and growth of dry patches \cite{12}. While thinner films ($h_i < 100 \text{ nm}$) are unstable and dewet by spinodal decomposition \cite{12} \cite{13}. In his latest experiments on ultra-thin films \cite{14}, Reiter characterized the early stage of the dewetting process by the formation and coalescence of little holes, with the displaced material uniformly distributed between the holes, without visible rims. Our initial time $t = 0$ might correspond to the end of this preliminary process.

Equation \ref{eq:cross} applies outside the dewetted region ($R_d(t) \leq r < \infty$). At the edge of the rim ($r = R_d(t)$), the rim height, $h_m(t)$, can be determined by taking into account capillary forces. The applied force on the rim, pushing the film away the dry area, must be balanced by the internal radial stress: $|S| = |\sigma_{rr}| h_m(t)$. Assuming the lateral extension of the film to be large enough, the film thickness must reach $h_i$ far from the dry region: $\lim_{r \to \infty} h(r, t) = h_i$ (\forall $t$). The complete resolution of our set of equations \ref{eq:cross} \ref{eq:cross} \ref{eq:cross} can be achieved using a method of characteristics (cf. appendix \ref{appendix}).

Thereafter, all thicknesses will be made dimensionless by normalizing with a characteristic length $h^* \equiv |S|/\sigma_0$. For Reiter's experimental conditions, at $T \approx 105^\circ C$, we estimate $h^*$ to be of the order of $500 \text{ Å}$. This parameter $h^*$ is of crucial importance in our model, because it discriminates two regimes of growth whose features are quite different. The films whose initial thickness $h_i$ is larger than $h^*$ will be considered as "thick" films, while the others ($h_i < h^*$) will be the "thin" ones.

### III. RESULTS

Note first that for a purely viscous liquid ($\Phi(\dot{\gamma}\tau) = \dot{\gamma}\tau$), our model leads to a constant and uniform thickness for the film, with an exponential growth of the dry radius:

$$\begin{aligned}
R_d(t) &= R_0 e^{\frac{|S|_t}{\tau_i}} = R_0 e^{\dot{\gamma} t} \\
h_m(t) &\approx h_i
\end{aligned}$$  \tag{11}$$

This is in complete agreement with the experimental results of Debrégeas et al. for the dewetting of suspended polymer films \cite{12} and supported films \cite{32}.

How are affected the growth laws of the dry radius $R_d(t)$ and the rim height $h_m(t)$ by the shear-thinning properties of the material?

In order to discuss the time dependence of the rim height and the dry radius, we need to compare $h_i$ with the characteristic thickness $h^*$. 

\begin{figure}
\centering
\includegraphics[width=\textwidth]{fig2}
\caption{The radial strain-rate, $\alpha$, and the orthoradial strain-rate, $\beta$, are related by $\alpha = F(\beta)$ (see Eq.\ref{eq:cross}). In the purely Newtonian case ($\Phi(\dot{\gamma}\tau) = \dot{\gamma}\tau$), the function $F$ is linear: $\alpha = \beta$. The other curves represent $F$ for the Cross model (Eq.\ref{eq:cross}), taking different values of $n$ for a given value of $k = 10$: $n = 1/4; 1/3; 1/2; 2/3$ (an important case, as precised in part IV \ref{appendix}); and $n = 3/4$. The two limit regimes $\beta \ll 1$ and $\beta \gg 1$, and the corresponding approached expressions for $F$ are also represented.}
\end{figure}

\begin{figure}

\end{figure}
FIG. 4: Short-time evolution of the rim height $h_m$: plot of $h_m$ versus $t/\tau$, for $h_i = 0.1$, 0.5, 1 and 2 $h^*$. Note that the curves corresponding to $h_i = 0.1$ and 0.5$h^*$ cannot be distinguished within the graph scale.

A. Thin films regime ($h_i \ll h^*$)

1. Initial stages of growth

The range $h_i \ll h^*$ allows different regimes of growth for the initial stage of hole formation, depending on the specific characteristics of the constitutive law.

Simple analytical laws can be obtained with the Cross law ($\Phi(\tau) = (\tau)/(1+k(\tau))$). It can be shown that the solution $\alpha[\beta]$ of Eq. $16$ is characterized by $\alpha \ll \beta$ for low strain-rates, and $\alpha \sim \psi(n)\beta$ for $\beta \gg 1$. It is worth noting that the coefficient $\psi(n)$ does not depend on $k$, but depends on $n$ as a solution of:

\begin{equation}
(\psi^{1-n} + (\psi - 1)^{1-n}(\psi + 1)(1-n) = \psi^{1-n} + 1
\end{equation}

As shown in Fig. 3, this coefficient ranges from $\psi = 1$ (for $n \to 0$) to $\psi \to +\infty$ (for $n \to 1$), and is involved in the laws of growth relative to the rim height and dry radius, as shown below.

The strain-rates $\alpha_m(t)$ and $\beta_m(t)$ at the rim edge (i.e. for $r = R_d(t)$) are simply related to the rim height by balancing the radial stress acting on the rim and the capillary forces. This gives the following equation:

\begin{equation}
\frac{h^*}{h_m} = \frac{\alpha_m}{1 + k\alpha_m^n} + \frac{\alpha_m - \beta_m}{1 + k(\alpha_m - \beta_m)^n},
\end{equation}

admitting the approached forms $\beta_m \sim h^*/h_m$ for large values of $h_m/h^*$, and $\beta_m \sim \mu(n,k)(h^*/h_m)^{1/1-n}$ for the thin films regime. $\mu(n,k)$ is a positive dimensionless parameter depending on $n$ and $k$ as:

\begin{equation}
\mu(n,k) = \frac{k}{\psi(n)^{1-n} + (\psi(n) - 1)^{1-n}}
\end{equation}

These expressions of strain-rates at the edge of the rim versus the rim height enable us to find analytical expressions of the growth laws during the initial stages of dewetting for thin films.

The rim height obeys the equation:

\begin{equation}
\frac{1}{h_m} \frac{Dh_m}{Dt} = \frac{\alpha_m - \beta_m}{\tau},
\end{equation}

where $D = \frac{2}{D_m} + v \frac{\partial}{\partial x}$ stands for the particular derivative. In Fig. 4 we present our results about the short-time evolution of rim height for different initial thicknesses, with $t$ ranging from 0 to $\tau$. The solution of Eq. 15 along with the initial condition $h_m(t=0) = h_i$ is:

\begin{equation}
h_m(t) = h_i \left(1 + \lambda(n,k,h_i) \frac{t}{\tau}\right)^{1-n},
\end{equation}

with $\lambda(n,k,h_i) = k \frac{\psi^{2-1} + (\psi)^{1/1-n}}{\psi^{1-n}}$. The adequation between our numerical results and this theoretical prediction is excellent.

The dry radius is given by:

\begin{equation}
\frac{R_d}{R_d} = \frac{\beta_m(l)}{\tau},
\end{equation}

and we thus obtain:

\begin{equation}
R_d(t) = R_0 \left(1 + \lambda(n,k,h_i) \frac{t}{\tau}\right)^{1-n},
\end{equation}

It is physically understandable that $R_d$, at a given time $t$, is larger for thinner films: for a given applied force $|S|$ per unit length, the thicker the film, the more the material to be displaced and the lower the dewetting velocity.

Equations 16 and 17 allow one to define a crossover time $t_c = \tau / \lambda(n,k,h_i)$. At short times (i.e. $t \ll t_c$), $h_m$ and $R_d$ vary linearly with time: $h_m \approx h_i(1 + \alpha_c(1-n)t)/t$ and $R_d \approx R_0(1 + (1-n)\lambda t)/t_c$. At longer times ($t \gg t_c$), the time dependence of $h_m$ and $R_d$ is a power-law: $h_m \sim t^{1-n}$ and $R_d \sim t^{1/(n-1)}$. Note that the thinner the film, the smaller the crossover time $t_c$.

A simple expression of $R_d$ versus $h_m$ can be directly derived from Eqs. 16 and 17:

\begin{equation}
R_d(t) = R_0 \left(\frac{h_m(t)}{h_i}\right)^{\frac{1-n}{1-n}}
\end{equation}

This relationship between the dry radius and the rim height is shown in Fig. 5 for different values of power-law index $n$. Note that, for $n = 2/3$, the expression 19 turns out to be linear: this important property will be discussed in the light of Reiter’s experiments in part IV B.

2. Long-time regime of growth

After the initial stages of hole growth, the driving force of the phenomenon, $|S|$, is distributed over a rim height larger than the characteristic thickness $h^*$. The resulting radial constraint becomes weak, and gives rise to very small values of strain-rates $\alpha$ and $\beta$. Then, to solve Eq. 15...
in this regime, we have to find the smallest-order correction to the linear behavior of function \( F \):

\[
\alpha = F(\beta) \approx \beta + \epsilon(\beta)
\]

Including this development in Eq.\[5\], and neglecting terms involving second-order (or higher) \( \epsilon \), we obtain a non-linear first-order differential equation for \( \epsilon \). Solving it along with the condition \( \epsilon(\beta = 0) = 0 \) leads to an explicit expression for \( \epsilon(\beta) \). Keeping the smallest order in development of \( \epsilon \) for small \( \beta \), we find [33]:

\[
\alpha \approx \beta + \left( \frac{n}{n+1} k \right) \beta^{n+1}
\]

From Eq.\[5\], it is then easy to obtain the following expression for \( h_m \):

\[
h_m(t) = h_i \left( 1 + \nu(n,k,h_i) \frac{t}{\tau} \right)^{1/n},
\]

with \( \nu(n,k,h_i) \equiv nk(\frac{h_i}{h^*})^{1+n} \). We have checked numerically (cf. Fig.\[8\]) that this power-law behavior is obeyed in the long-time regime of growth.

The corresponding law for dry radius in this regime is:

\[
R_d(t) = R_0 \exp \left[ \frac{1+n}{nk^2} \left( \frac{h_i}{h^*} \right)^n \left( 1 + \nu(n,k,h_i) \frac{t}{\tau} \right)^{1/n} - 1 \right]
\]

For \( t \gg \tau(h_i/h^*)^{1+n}/(nk) \), this law turns out to be a stretched exponential:

\[
R_d(t) \approx R_0 e^{\frac{t}{\tau(\frac{h_i}{h^*})^{1/n} \left( 1 + \nu(n,k,h_i) \frac{t}{\tau} \right)^{1/n}}}
\]

From Eq.\[4\], it is easy to define a crossover time \( t_c \) between the initial stages (part \( II A 1 \)) and the long-time regime of growth (part \( II A 2 \)):

\[
t_c = \mu \left( \frac{h^*}{h_i} \right)^{\frac{1}{1+n}} t_c
\]

3. Film profile

An example of profile obtained for \( h_i = 0.1h^* \) is shown in Fig.\[5\]. This profile is characterized by a highly asymmetric shape for the rim. There is a striking similarity between such a profile and those observed by Reiter for ultra-thin films [17]. On fig.\[8\] we present the time evolution of this profile (for \( t \) ranging from \( t = 0 \) to \( t = 5.10^{-2} \tau \), with a time step of \( 10^{-2} \tau \).

For the sake of conciseness, we focus here on the case corresponding to the range of thicknesses and times covered by Reiter’s experiments, i.e. the initial times of growth for thin films (cf. [17] and [18]). For clarity reasons, let us write \( \Omega(t) \equiv 1 + \chi(n,k,h_i) \frac{t}{\tau} \). In the regime \( h_i \ll h^* \), the partial derivative equation 3 for \( h(r,t) \) reduces to:

\[
\frac{\partial h(r,t)}{\partial t} + \frac{\kappa}{r^\psi} \Omega(t)^{\frac{2-n-p+q}{p}} \frac{\partial h}{\partial r} = (\psi - 1) \frac{\kappa}{r^{1+\psi}} \Omega(t)^{\frac{2-n-p+q}{p}} h
\]

The resolution of Eq.\[20\] can be achieved using a method of characteristics, as explained in appendix 4.
FIG. 7: Film profile for \( h_i = 0.1h^* \) and \( t = 2.10^{-2}\tau \). The constitutive equation of the material is the Cross law (Eq.4), with a power-law index \( n = 2/3 \). For clarity reasons, a sectional view is displayed on a quarter of circle, and cartesian coordinates \((x, y, z)\), naturally associated with cylindrical ones \((r, \Phi, z)\), are used.

![Film profile](image)

FIG. 8: Evolution of a film (Cross model, \( n = 2/3 \)) profile \( h(r, t) \), for \( h_i = 0.1h^* \) and \( t \) ranging from \( t = 0 \) (initial configuration, in dashed lines) to \( t = 5.10^{-2}\tau \) with a time step of \( 10^{-2}\tau \).

The solution is:

\[
h(r, t) = h_i \frac{r^{\psi-1}}{(1 + r^{\psi+1} - R_d(t)^{\psi+1})^{\frac{\psi+1}{\psi-1}}} \tag{27}
\]

We checked (cf. appendix) that this expression has a wide range of validity: during all the initial growth, the strain-rates remain high \((\alpha \text{ and } \beta \gg 1)\) far away the hole periphery, and thus Eq.27 is an acceptable description of the whole film profile.

For thick films, as shown in Fig.6 (for instance in the case \( h_i = 100h^* \)) two different time regimes can be distinguished: at the beginning of hole formation, \( h_m \) is nearly constant and equals its initial value \( h_i \) during a long period of time, before growing faster. Here again, a distinction between different time regimes is necessary.

1. Initial stages of growth

During the early stage, the strain rates at the rim are constant and small, as a consequence of the constant large thickness. In this case, the rheological law of the film is viscous-type and the dry radius increases exponentially, as for the case previously discussed (see Eq.4):

\[
\begin{aligned}
R_d(t) &= R_0 e^{\frac{t}{\tau_i}} = R_0 e^{\frac{t}{\tau}} \quad (28)
\end{aligned}
\]

This viscous-type behavior remains valid up to a crossover time \( t_0 \approx \tau (\frac{h}{h^*})^{1+n} \).

2. Long-time regime of growth

We have checked numerically (cf. Fig.8) that the anticipated analytical behavior

\[
h_m(t) = h_i \left( 1 + \nu(n, k, h_i) \frac{t}{\tau} \right)^{\frac{1}{1+n}} \tag{29}
\]

is obeyed after the crossover time \( t_0 \).

Similarly, the preceding exponential law for the dry radius connects with the stretched exponential, whose power depends on power-law index \( n \) (cf. Eq.24):

\[
R_d(t) \approx R_0 e^{\frac{t}{\tau} \left( \frac{n}{nk} \right)^{-1/1+n} \left( \frac{t}{\tau} \right)^{1/n}}
\]

Fig.9 which present the time evolution of \( R_d \) for different initial thicknesses \( h_i \) with the Cross model, shows that this anticipated behavior is obeyed for \( t \gg t_0 \).

We emphasize the fact that the crossover from a simple exponential to the stretched exponential regime is a consequence of the non-linearity of rheological law.

IV. DISCUSSION

A. Debregeas’ experiments

G. Debrégeas et al. [12] carried out experiments on viscous bursting of freely suspended films of long-chain polymers. The high molecular weights of polydimethylsiloxane used in these experiments lead to high viscosities
with a power-law index \( d = 0.65 \pm 0.03 \). For the following, let us suppose that the rheology of ultra-thin PS films used by Reiter can be described by the Cross model (Eq.1) with such a power-law index: \( n = 2/3 \). It is of course an hypothesis that would need an experimental validation. In particular, the rheology of PS films at temperatures very close to the glass transition may be quite different. Keeping this point in mind, the following remarks are tentative explanations of some regimes of dewetting experimentally observed by Reiter.

If \( n = 2/3 \), Eq.12 leads to the exact value \( \psi = 2 \). Then Eq.19 turns out to be simply linear:

\[
\frac{R_d(t)}{R_0} = \frac{h_m(t)}{h_i}.
\]

This property was indeed observed by Reiter: the maximum height of the rim grows at the same speed as the radius of the hole \( h_i \). The special role played by this value \( n = 2/3 \) was also pointed out by Shenoy and Sharma in their study of the dewetting of power hardening viscoplastic solid [21].

We can also focus on the individual dependences of \( h_m \) and \( R_d \) versus time. As precised in part III.A.1 for viscous polymer films.

B. Reiter’s experiments

G. Reiter [17] studied the dewetting of ultra-thin, almost glassy polystyrene films deposited onto silicon wafers coated with a polydimethylsiloxane monolayer. The thicknesses of the PS films used range from \( h_i = 10 \) to \( h_i = 60 \) nm. Compared with the characteristic scale \( h^* \approx 50 \) nm, the ratio \( h_i/h^* \) ranges from about 0.2 to unity. The characteristic time \( \tau \) for PS under the experimental conditions is very long, up to more than a year for the lowest temperatures conditions (\( T \) ranges from 103°C to 130°C, to be compared with the bulk glass transition temperature; \( T_g = 97.5°C \)). We can thus expect that the relevant regime for comparing our results with Reiter’s experimental findings is the limit \( h_i \ll h^* \), and \( t/\tau \) small (cf. III.A.1).

Three years ago, Dahnoki-Veress et al. made an experimental study of hole formation and growth in freely standing PS films [22]. In agreement with Debrégeas’ experiments, they observed exponential growth of the hole radius and uniform thickening, but with a deviation from this regime for long-time regimes of growth, a feature they analyzed in terms of shear-thinning properties. They indeed characterized the polymer rheology at the temperature of their experiments (\( T = 115°C \)) and found that the best fit for the viscosity \( \eta \) versus the shear strain rate \( \dot{\gamma} \) is a power-law dependence:

\[
\eta \sim |\dot{\gamma}|^{-d}, \tag{30}
\]

(\( \eta_0 \geq 600000 \) cP) bursting processes where viscous dissipation dominates inertia.

The range of thicknesses experimentally studied by Debrégeas et al. (5 to 250 \( \mu \)m) covers the domain \( h_i \gg h^* \). As the corresponding crossover time is very large (\( t_0 \gg \tau \)), these experiments mainly covered the first regime \( t \ll t_0 \) (the criterion \( h_i \gg h^* \) is in fact a basic hypothesis of their “soft balloon” model [34]). In our model, the velocity field \( v(r,t) \) is found to be almost proportional to 1/r at any time for thick profiles (cf. Fig.10), similar to the experimentally observed long range radial plug flow [22].

Thus, our model accounts well for the exponential growth and the absence of rim characteristics of the dewetting regime observed by Debrégeas et al. for vis-

![FIG. 9: Logarithmic plot of the dry zone radius \( R_d \) versus \( t/\tau \), for \( h_i = 0.1; 1; 10 \) and 100 \( h^* \), in the case of Cross law with \( n = 2/3 \) and \( k = 5 \). Note the linear behavior of \( \log_{10}(R_d(t)/R_0) \) with \( (t/\tau)^{(n+1)/(n+3)} \) after a transient time: the anticipated stretched exponential (Eq.2) is indeed obeyed.](image)

![FIG. 10: Velocity field \( v(r,t) \) for different initial thicknesses \( h_i = 0.1; 1; 10h^* \), at a given time \( t \). All radial distances are normalized by the dry radius at time \( t \), for each thickness. A curve \( 1/x \) is represented for comparison. It is clear that the velocity field is almost proportional to 1/r for a thick profile \( h_i \approx 10h^* \), similar to the long range radial plug flow observed by Debrégeas.](image)
As for the crossover time larger than about 1, Reiter [39] discovered the formation of straight lines, several microns long, starting to appear at hole diameters larger than about 1 μm. These lines are PS microfibrils, whose width can be as low as about 2 nm (to be compared with the radius of gyration of the polymer in the bulk, of order 50 nm). This observation suggests that the radial strain-rates are much larger than the orthoradial ones at the hole periphery and involve this elongational deformation of the molecules. This property could be related to the fact that, in our model, the radial strain-rate (α) is large compared with the orthoradial one (β) during the initial stages of growth for thin films (cf. Fig. 3).

Very recently, Reiter [2] characterized the time dependences of Rd and hm, for very thin films. He obtained several dewetting regimes, and work is in progress to analyze these results. It seems that several experimental factors must be taken into account for this analysis. Among them, the influence of film preparation appears to be decisive: the spin-cast PS film is a highly metastable form of matter [1]. The sample preparation (including the time of healing) can lead to thin films where residual constraints on the chains persist, and may have an influence on the dewetting process.

Quite interestingly, despite all these remarks, for a 20 nm PS film deposited on a 10 nm PDMS layer around T = 120°C, the results of Reiter’s experiments seem to indicate that the maximum height of rim and the hole radius obey power-laws:

\[
\begin{align*}
    h_m &\sim (t/\tau)^{1/3} \\
    R_d &\sim (t/\tau)^{1/3}
\end{align*}
\]

The time range on which Reiter calculated these power-law indexes is up to about 100 minutes. As for a 20 nm film, the ratio \( h_i/h^* \) is smaller than unity, the crossover time \( t_c \) is very short, and we can expect that the power-law regime (Eq. 32) is established. Thus we can compare Eqs. (2) and (3) and remark that the two experimental coefficients are indeed very close to the predicted one: 1/3. This adequation between our model and Reiter’s experimental results appears to be satisfying. But many questions remain open, as the role played by the initial stages of growth for thin films (cf. Fig. 2, \( t/\tau \gg 1 \)) is large compared with the orthoradial one (\( \psi \)), which can lead to viscous dissipation and to a marked decrease in the dewetting velocity [35].

Let us conclude by a tentative idea: observing by Tapping Mode atomic force microscopy (TM-AFM) the dry zone on the PDMS substrate after the removal of PS film, Reiter [3] discovered the formation of straight lines, several microns long, starting to appear at hole diameters larger than about 1 μm. These lines are PS microfibrils, whose width can be as low as about 2 nm (to be compared with the radius of gyration of the polymer in the bulk, of order 50 nm). This observation suggests that the radial strain-rates are much larger than the orthoradial ones at the hole periphery and involve this elongational deformation of the molecules. This property could be related to the fact that, in our model, the radial strain-rate (α) is large compared with the orthoradial one (β) during the initial stages of growth for thin films (cf. Fig. 3).

\[
\begin{align*}
    h_m &\sim (t/\tau)^a \\
    R_d &\sim (t/\tau)^b
\end{align*}
\]

\( a \approx 0.38 \pm 0.02 \) and \( b \approx 0.34 \pm 0.04 \) (33)

\[
\begin{align*}
    a \approx 0.38 \pm 0.02 \\
    b \approx 0.34 \pm 0.04
\end{align*}
\]

Acknowledgments

We are grateful to G. Reiter for very useful discussions and for providing us with his experimental results on the dewetting of ultra-thin polystyrene films prior to publication.

We also wish to acknowledge fruitful discussions with A. Aradian, G. Debrégeas, and M. Sferrazza.

APPENDIX A: A FEW REMARKS ABOUT THE VELOCITY FIELD INSIDE THE FILM

Our choice of model (see [1]) for the dewetting film deserves a few comments. As defined above, \( \nu(r,t) \) is
the radial part of flow field. The incompressibility of the material implies the additional existence of a small, but non-zero vertical component of the velocity field: let us note \( w \) this vertical part.

We already argued that the characteristic thickness of films studied by Reiter and Drégeaus allows a plug-flow assumption for the film: it implies that the radial part \( v(r, t) \) is independent of variable \( z \). This hypothesis does not imply the same property for \( w \): we must keep for it the most general dependence \( w(r, z, t) \).

In cylindrical coordinates, for a velocity field of the form \((v_r, v_\phi, v_z)\), the liquid incompressibility leads to:

\[
\frac{\partial v_r}{\partial r} + \frac{v_r}{r} + \frac{1}{r} \frac{\partial v_\phi}{\partial \phi} + \frac{\partial v_z}{\partial z} = 0 \quad (A1)
\]

Here, as \( v_\phi = 0 \) for symmetry reasons, one has:

\[
\frac{\partial v_r}{\partial r} + \frac{v_r}{r} = -\frac{\partial w}{\partial z} \quad (A2)
\]

Independence of \( v \) versus \( z \) allows a simple integration of Eq.(A2) at a given \( r \):

\[
\int_{z=0}^{h(r,t)} \left( \frac{\partial v_r}{\partial r} + \frac{v_r}{r} \right) dz = - \int_{z=0}^{h(r,t)} \frac{\partial w}{\partial z} dz,
\]

which gives:

\[
h(r,t) \left( \frac{\partial v_r}{\partial r} + \frac{v_r}{r} \right) = -w(r, z = h(r,t), t) \quad (A4)
\]

The vertical velocity at the top of the film, \( w(r, z = h(r,t), t) \), can be easily related to the particular derivative of \( h(r,t) \), provided that the film thickness remains small compared with the characteristic lengths of variation of the radial speed component and film thickness \[10\] :

\[
w(r, z = h(r,t), t) \approx \left( \frac{\partial h}{\partial t} + v_r \frac{\partial h}{\partial r} \right)
\]

Thus, in a more rigorous way, we recover the incompressibility condition (see Eq.[A1]):

\[
\frac{1}{h(r,t)} \left( \frac{\partial h(r,t)}{\partial t} + \frac{r \beta(r,t) \partial h(r,t)}{\tau} \frac{\partial v_r}{\partial r} \right) = \frac{\alpha(r,t) - \beta(r,t)}{\tau}
\]

The plug-flow assumption has a direct consequence: the left-hand side of Eq.(A2) is independent of \( z \); so does the right-hand side, i.e. \( \partial w/\partial z \), which implies that \( w \) has a simple linear dependence versus \( z \):

\[
w(r, z, t) = w(r, z = h(r,t), t) \frac{z}{h(r,t)} \quad (A6)
\]

To finish with this point, note that taking into account this small but non-zero vertical component of the velocity field induces the presence of a supplementary term in the conservation of momentum (equation [3]):

\[
\frac{\partial \sigma_{rr}}{\partial r} + \frac{\partial \sigma_{rz}}{\partial z} + \frac{\sigma_{rr} - \sigma_{\phi\phi}}{r} = 0 \quad (A7)
\]

The possible consequences of this supplementary friction force on our predictions for dewetting regimes will be studied in a forthcoming publication.

**APPENDIX B: RESULTS FOR LOGARITHMIC FORM OF \( \Phi \)**

For polymers, just above \( T_g \), it is expected within the framework of the free-volume model that \( \sigma^m \) varies logarithmically with \( \dot{\gamma} \) as \[24\]:

\[
\Phi(\dot{\gamma} \tau) = \ln(1 + \dot{\gamma} \tau) \quad (B1)
\]

At low strain-rates (\( \dot{\gamma} \tau < 1 \), this law displays a viscous-type behavior (\( \sigma^m \approx \eta_0 \dot{\gamma} \), with a zero-shear viscosity \( \eta_0 = \sigma_0 \tau \)), while for large values of \( \dot{\gamma} \tau \), \( \sigma^m \) reaches an almost constant value (shear-thinning behavior).

In order to deal with a minimum number of parameters, we assume that \( \sigma^m(\dot{\gamma}) \) is an odd function \( \sigma^m(\dot{\gamma}) = -\sigma_0 \ln(1 + |\dot{\gamma}| \tau) \) if \( \dot{\gamma} < 0 \).

This appendix briefly presents the main results for thin and thick films.

For thick films, at short times, the dry radius and rim height evolve as for a purely viscous fluid (cf. Eq.[11]):

\[
\begin{align*}
R_d(t) &= R_0 e^{-\frac{\mu}{\eta_0 \tau}} = R_0 e^{-\frac{t}{\tau}} \\
\eta m(t) &\approx \eta_i
\end{align*}
\]

For thick films, at long times \( (t > t_0 \sim \tau(h_i/h^*)^2) \), the rim height grows proportionally to \( \sqrt{t/\tau} \):

\[
h_m(t) \sim \frac{h^*}{2} \sqrt{t/\tau}, \quad (B2)
\]

while the dry radius expands like \( \exp(4\sqrt{t/\tau}) \):

\[
R_d(t) \sim R_0 e^{4\sqrt{t/\tau}}. \quad (B3)
\]

This law is also a stretched exponential, as for the Cross law. This property is due to the fact that the function \( \alpha = F(\beta) \) is analytical (in the mathematical sense), i.e. admits a series expansion near 0 whose first non-linear term is \( \beta^2 \). It indeed corresponds the limit behavior obtained by taking the Cross law with \( n \to 1 \).

For thin films, at short times, a sharp rim grows very quickly (with an initial speed \( h_m \approx h_i \exp h^*/2h_i \)). In
this regime, $h_m(t)$ is well described by the integral equation:

$$\int_{0}^{\frac{\kappa}{r_m}} \frac{e^{-x}}{x} dx \approx \frac{t}{r \cdot \tau} \quad \text{(B4)}$$

For thin films, at long times, as for the Cross law, the hole growth connects with the long-time regime of thick films (Eqs [3][3]).

APPENDIX C: SUMMARY OF THE DEWETTING REGIMES FOR A CROSS CONSTITUTIVE EQUATION

Figures 11 and 12 propose a summary of the different dewetting time regimes for a Cross constitutive law, depending on the initial thickness (to be compared with $h^*$), and relative to different time ranges (to be compared with crossover times $t_c$, $t_e$ and $t_0$).

APPENDIX D: ANALYSIS OF THE FILM PROFILE

Method of characteristics

To know the profile $h(r, t)$, the equation [22] has to be solved:

$$\frac{\partial h(r, t)}{\partial t} + \frac{\kappa}{r^\psi} \frac{\partial h}{\partial r} = (\psi - 1) \frac{\kappa}{r^{1+\psi}} \frac{\partial h}{\partial t}$$

along with the precedingly precised initial condition (Eq.[10]) and the boundary values $h(r \rightarrow \infty, t) = h_i$ (at $t$) and $h(t = R_d(t), t) = h_m(t)$. As a quasi-linear partial derivative equation, Eq.[22] can be solved using a method of characteristics, as precised in this appendix.

Writing $dh(r, t) = \frac{\partial h}{\partial t} dt + \frac{\partial h}{\partial r} dr$, we can replace the partial derivative with respect to $t$ thanks to Eq.[24]. Let define a characteristic by the function $r_\xi(t)$, indexed by the parameter $\xi$ with $r_\xi(t = 0) = \xi$, and obeying the following ordinary differential equation:

$$\frac{dr_\xi(t)}{dt} = \frac{\kappa}{r_\xi(t)^{\psi}} \Omega(t) \frac{2-n-\psi}{\psi-1}$$

Eq.[D1] is tractable, and gives each characteristic as a function of time:

$$r_\xi(t) = 1 - \mu(n, k) \frac{\psi(n-1)}{\psi-1} \frac{h_{i}^{\psi}}{h_{i}}$$

In Fig.[D3] is shown a representation of characteristics $r_\xi(t)$ versus time, for a thin film ($h_i = 0.1 h^*$). Note that these curves were extracted numerically from our model, and are not a graphic illustration of solutions of Eq.[D2].

Along a given characteristic, the rim height $h_\xi(t)$ obeys a simple equation:

$$\frac{dh_\xi(t)}{dt} = \frac{\kappa(\psi - 1)}{r_\xi(t)^{\psi+1}} \Omega(t) \frac{2-n-\psi}{\psi-1} h_\xi(t) \quad \text{(D3)}$$

whose solution is explicit and of the form:

$$h_\xi(t) = h_i \left( \frac{\Omega(t)^{\psi+1}}{\psi-1} + \xi^{1+\psi} - 1 \right)^{\frac{\psi}{\psi-1}} \quad \text{(D4)}$$

Inverting Eq.[D2] to express $\xi$ as a function of $r$ and $t$ enables us to extract the complete equation of the profile (Eq.[D7]):

$$h(r, t) = h_i \left( \frac{r_{\psi}^{1+\psi} - 1}{(1 + r_{\psi}^{1+1} - \mathcal{R}_d(t)^{\psi+1})^{\frac{\psi}{\psi-1}}} \right)$$

Range of validity

In the film zone near the hole ($r \gtrsim R_d(t)$), the strain-rates $\alpha$ and $\beta$ are high. Thus Eq.[D5] gives:

$$\beta(r, t) = \beta_m(t) \left( \frac{R_d(t)}{r} \right)^{1+\psi} = \frac{\Omega(t)^{2-n-n_\psi}}{r^{1+\psi}} \quad \text{(D5)}$$

Our description of film profile remains valid as long as $\beta(r, t) \geq 1$. Let us define the radial distance $r^*(t)$ up to which this condition is verified: $\beta(r^*(t), t) = 1$. The ratio $r^*(t)/R_d(t)$ is given by:

$$\frac{r^*(t)}{R_d(t)} = \kappa \Omega(t)^{1-n_\psi} \quad \text{(D6)}$$

We regard the equation of profile as valid if $r^*(t) \gg R_d(t)$, and arbitrarily choose a criterion $r^*(t) \geq \mathcal{Y} R_d(t)$ with a factor $\mathcal{Y} \sim 10$ for instance. It is then found that $r^*(t) \geq \mathcal{Y} R_d(t)$ as long as time $t$ is smaller than a critical value $t^*$ given by:

$$t^* = \frac{1 - \mu(n, k) \frac{\psi(n-1)}{\psi-1} \left( \frac{h_{i}^{\psi}}{h_{i}} \right)}{\mathcal{Y}^{\frac{\psi}{\psi-1}}} \quad \text{(D7)}$$

For $h_i = 0.1 h^*$, $n = 2/3$, $k = 5$, and $\mathcal{Y} = 10$, Eq.[D7] shows that the high-strain-rates hypothesis remains valid on a whole region as long as $t \lesssim 1000 \tau$. Thus, the Eq.[D3] is a good description of the film profile during all the initial regime of growth.

APPENDIX E: INFLUENCE OF THE INITIAL SHAPE OF FILM PROFILE

The results presented above are obtained taking a discontinuous shape for the initial profile of the film:

$$h(r, t = 0) = \begin{cases} h_i & \text{if } r \geq R_0 = 1 \\ 0 & \text{otherwise} \end{cases} \quad \text{(E1)}$$
FIG. 11: Summary of the different time regimes for the dewetting of thin films ($h_i \ll h^*$). Depending on each time range, the exact solutions and corresponding approximated time-dependences are precised. We also point out the laws for the special value $n = 2/3$ (discussed in part IV B).

FIG. 12: Summary of the different time regimes for the dewetting of thick films ($h_i \gg h^*$). Depending on each time range, the exact solutions and corresponding approximated time-dependences are precised.

Does this discontinuity at $r = R_0$ play a role in the hole growth? In other words, is it the source of the marked asymmetry observed for the profiles obtained with our model?

To probe this hypothesis, we made the same resolution of our system of equations, starting with a continuous profile:

$$h(r, t = 0) = \begin{cases} h_i e^{(r/R_0)^{\chi}} & \text{if } r > R_0 = 1 \\ 0 & \text{if } r \leq R_0 \end{cases}$$  \hspace{1cm} (E2)

This profile is infinitely derivable at $r = R_0$, the parameter $\chi$ giving an order of the characteristic length of transition between the regions $h = 0$ and $h = h_i$. The profiles obtained with this initial condition are shown in figure [4] with $\chi = 0.1$ (the shape of the initial profile, represented in dashed lines in Fig.[4] is very smooth). The rim growth seems to be very fast for a thin film (the time range of curves in Fig.14 is $0$ to $2.10^{-2}$). Similarly, the increasingly asymmetric shape of the profile shows that, even when starting with a smooth profile, the resulting morphology of the rim is the same as in Reiter’s experiments. These considerations prove that the discontinuity of the initial profile is not a necessary condition for the appearance, growth and stiffening of an asymmetric rim as those observed by Reiter.

[31] A theoretical approach to the spinodal dewetting is proposed in: S. A. Safran and J. Klein, J. Phys. II France
This exponential behaviour is observed during the initial stage of process, as long as the viscous friction on the liquid/substrate interface remains negligible compared with the dissipation in the plug flow of removing fluid.

The development of $F(\beta)$ at small $\beta$ shows that $F$ does not admit a Taylor expansion near 0. This is directly due to the fact that the Cross rheological equation itself is not analytical, since the second term of its development near 0 is of order $n + 1$.

It is clear that this exponential law cannot be valid for too thin films. Writing $\eta = E\tau_{rep}$ (where $E$ is an elastic modulus, and $\tau_{rep}$ is the reptation time of polymers, the relaxation time of the material), one obtains $\tau_\tau = \tau_{rep}\frac{h}{h_0}$ with $h_0 \equiv |S|/E$, which leads to a characteristic time $\tau$ smaller than $\tau_{rep}$ if $h_i < h_0$: the relaxation would be too fast.
