Transport across a normal-superconducting interface: a novel probe of electron-electron interactions in the normal metal.

In this letter, we examine the effect of Coulomb interactions in the normal region of a normal-superconducting (N/S) mesoscopic structure, here the change from an attractive to a repulsive coulombic interaction, at the N/S interface, causes a shift in the order parameter phase. We show that this shift has a pronounced effect on Andreev bound states and demonstrate that the effect on Andreev scattering of non-zero order-parameter tails, can be used to probe the sign of the interaction in the normal region.

Recent advances in material technology have enabled the fabrication of normal/superconducting (N/S) mesoscopic hybrid structures with well defined dimensions and interfaces. Due to the proximity of the normal region to the superconductor the pairing field \( f(x) = \langle \psi(x) \psi(x) \rangle \), in the normal region, decays to zero on the scale of a coherence length \( \xi \). During the past decade this proximity effect has been extensively investigated both experimentally and theoretically (see for example [1]).

In contrast to the pairing field \( f(x) \), the effective electron-electron interaction, \( V(x) \), changes abruptly at the S/N interface, from an attractive interaction in the superconductor to either zero, a much diminished attractive interaction or to a repulsive interaction, in the normal (N) material. Consequently the order parameter, \( \Delta = V(x) f(x) \), of a s-wave superconductor also changes abruptly at the S/N interface, as shown in figure 1. To date theoretical research into the transport properties of N/S interfaces have mainly considered the order parameter in the normal region to be zero (figure 1b) [1,4].

In this letter we consider the effect of an attractive or repulsive electron-electron interaction \( V(x) \neq 0 \), as shown in figure 1c. The difference between figures 1b and 1c is the \( \pi \) phase shift in \( \Delta(x) \), induced by the cross-over from an attractive to a repulsive interaction at the N/S interface. In what follows we examine how this phase shift affects the transport properties associated with Andreev bound states.

To investigate this regime we adopt a general scattering approach to dc transport, which was initially developed to describe phase-coherent transport in dirty mesoscopic superconductors [2]. For simplicity in this letter, we focus solely on the zero-voltage, zero-temperature conductance, for the structure shown in figure 1. In the linear-response limit, at zero temperature, the conductance of a phase-coherent structure may be calculated from the fundamental current voltage relationship [1,4].

\[
I_i = \sum_{j=1}^{2} a_{ij}(v_j - v),
\]

The above expression relates the current \( I_i \) from a normal reservoir \( i \) to the voltage differences \( (v_j - v) \), where \( v = \mu/e \) and the sum is over the 2 normal leads connected to the scattering region. The \( a_{ij} \)'s are linear combinations of the normal and Andreev scattering coefficients and in the absence of superconductivity satisfy \( \sum_{j} a_{ij} = \sum_{i} a_{ij} = 0 \) in which case the left hand side of equation 1 becomes independent of \( v \). In units of \( 2e^2/h \) [1,2], \( a_{ii} = N_i + R_i^A - R_i^O \) and \( a_{ij} \neq i = T_{ij}^A - T_{ij}^O \), where \( T_{ij}^A, T_{ij}^O \) are Andreev and normal transmission coefficients from probe \( j \) to probe \( i \), \( R_i^A, R_i^O \) are Andreev and normal reflection coefficients from probe \( i \) and \( N_i \) is the number of open scattering channels in lead \( i \).

Setting \( I_1 = -I_2 = I \) and solving equation 1 for the 2 probe conductance yields [3],

\[
G = \frac{I}{(V_1 - V_2)} = T_{21}^A + T_{12}^A + \frac{2(R_i^A R_i^A - T_{21}^A T_{12}^A)}{R_i^2 + R_i^4 + T_{21}^2 + T_{12}^2},
\]

where \( G \) is the conductance in units of \( 2e^2/h \). As noted in [2], the various transmission and reflection coefficients can be computed by solving the Bogoliubov - de Gennes equation on a tight-binding lattice of sites, where each site is labelled by an index \( i \) and possess a particle (hole) degree of freedom \( \psi(i) \) (\( \phi(i) \)). In the presence of local s-wave pairing described by a superconducting order parameter \( \Delta_i \), this takes the form,

\[
E\psi_i = \epsilon_i \psi_i - \sum_{\delta} \gamma (\psi_{i+\delta} + \psi_{i-\delta}) + \Delta_i \phi_i,
E\phi_i = -\epsilon_i \phi_i + \sum_{\delta} \gamma (\phi_{i+\delta} + \phi_{i-\delta}) + \Delta^*_i \psi_i,
\]

In what follows, the Hamiltonian of eq.[3] is used to describe the structure of figure 2, where for all \( i \), the on-site energy \( \epsilon_i = \epsilon_0 \). In the S-region, the order parameter \( \Delta_i \) is set to a constant, \( \Delta_i = \Delta_0 \), while in the normal region \( \Delta_j \) is approximated by,

\[
\Delta_j = \pm \frac{\Delta_0}{2} (\tanh(j - L_n) + 1).
\]

The nearest neighbour hopping element \( \gamma \) merely fixes the energy scale (ie the band-width), whereas \( \epsilon_0 \) determines the band-filling, and \( L_n \) is the length of the normal region. In what follows we choose \( \gamma = 1 \) and \( \Delta_0 = 0.1 \).
By numerically solving for the scattering matrix of equation 3, exact results for the dc conductance can be obtained and therefore the effects of a repulsive/attractive coulomb interaction in the normal region can be examined. For simplicity in this letter we consider the transport properties of the structure shown in figure 2. Consisting of two normal, semi-infinite, crystalline leads, 20 sites wide, joined by a scattering region. The normal scattering region is 40 sites long and the superconducting region is of length $L_S$. To form Andreev bound states we create quasiparticle confinement in the area in front of the superconductor by introducing a weak point-like contact between the left lead and the scattering region, and ensuring that there is no or very little quasiparticle transmission through the superconductor. For this reason the superconductor length was set to $L_S = 150$ sites. However care must be taken since the decay length of sub-gap states in the superconductor increases with quasiparticle energy. At energies close to the gap energy the decay length is long enough for transmission through the superconductor, see figure 3. The weak contact is created by placing a potential barrier, one site wide, between the left lead and the normal scattering region, via a mean potential $U$ added to the on site energy $\epsilon_0$. Figure 2 shows a plot of the transmission coefficient of the barrier as a function of $U$. From this plot we see that a for low quasiparticle transmission through the barrier a high potential is needed. For these reasons the barrier potential was set at $U = 20$.

These conditions produce discrete states within the normal regions. Allowing the formation of Andreev bound states, when these energy levels become populated resonances appear in the conductance of the system, analogous to Breit-Wigner resonances. By plotting $G$ as a function of quasiparticle energy (all energies are with respect to the Fermi energy) we are able to investigate transport resonances in the conductance due to the formation of Andreev bound states. Figure 2 shows the conductance as a function of quasiparticle energy for the three proximity tails corresponding to the vanishing, attractive and repulsive electron-electron interactions respectively. These represent the central result of this letter. We see that the introduction of a proximity tail has the effect of shifting the energy at which the Andreev bound states occur. A positive proximity tail causes a shift in the resonance energies to the right of the zero-tail spectrum shown in figure 3, whereas a negative proximity tail shifts the spectrum to the left. These results suggest a novel method for detecting the sign of the electron-electron interaction in the N-metal. Namely by suppressing the order parameter in the normal region, the resonances will either shift to higher energies indicating a repulsive interaction, or lower energies in the case of an attractive interaction. This suppression can be achieved by, for example applying a magnetic field or via a control current in the superconductor.
