The plasma emission model of RBS1774

N. Chkheidze

Center for theoretical Astrophysics, ITP, Ilia State University, 0162 Tbilisi, Georgia

Received 26 October 2010 / Accepted 15 December 2010

1. Introduction

RBS1774 (1RXS J214303.7+065419) has been the most recent XDIN (X-ray dim isolated neutron star) to be found (Zampieri et al. 1983). According to these works, in the electron-positron distribution of the surface temperature is more likely artificial and needs to be examined by convincing theory. The plasma emission model of RBS1774 is described by quasi-linear diffusion developed by means of the cyclotron instability on the basis of the Vlasov’s kinetic equation. This mechanism provides generation of measured optical and X-ray emission on the light cylinder lengthscales. A different approach of the synchrotron theory is considered, giving the spectral energy distribution that is in a good agreement with the XMM-Newton observational data. We also provide the possible explanation of the spectral feature at 0.7 keV, in the framework of the model.

Key words. X-rays – stars: pulsars: individual: RBS1774 – radiation mechanisms: non-thermal

2. Emission model

The distribution function of relativistic particles is one-dimensional at the pulsar surface, because any transverse momenta \( p_\perp \) of relativistic electrons are lost in a very short time \( \lesssim 10^{-20} \) s via synchrotron emission in very strong magnetic fields. For typical pulsars the plasma consists of the following components: the bulk of plasma with an average Lorentz-factor \( \gamma_p \approx 10^2 \), a tail on the distribution function with \( \gamma_t \approx 10^5 \), and the primary beam with \( \gamma_b \approx 10^7 \) (see Fig. 1). However, plasma with an anisotropic distribution function becomes unstable, which can lead to a wave excitation in the pulsar magnetosphere. The generation of waves is possible during the further motion of the relativistic particles along the dipolar magnetic field lines if the condition of cyclotron resonance is fulfilled (Kazbegi et al. 1991):

\[
\omega - k_\parallel V_\parallel - k_\perp u_\perp + \frac{\omega_B}{\gamma_t} = 0,
\]

where \( u_\perp = eV_\perp / \rho \omega_B \) is the drift velocity of the particles due to curvature of the field lines, \( \rho \) is the radius of curvature of the field lines and \( \omega_B = eB / mc \) is the cyclotron frequency. During the generation of waves by resonant particles, one also has a simultaneous feedback of these waves on the electrons (Vedenov et al. 1961). This mechanism is described by quasi-linear diffusion, leading to the diffusion of particles as along as across the magnetic field lines. Therefore, resonant electrons acquire...
transverse momenta (pitch angles) and, as a result, start to radiate through the synchrotron mechanism.

The kinetic equation for the distribution function of the resonant particles can be written as (Machabeli & Usov 1979; Machabeli et al. 2002):

\[
\frac{df^0}{dt} + \frac{\partial}{\partial p_\perp} \left( G_{\parallel} + F_{\parallel} + Q_\parallel f^0 \right) + \frac{1}{p_\perp} \frac{\partial}{\partial p_\perp} \left( p_\perp (G_{\perp} + F_{\perp}) f^0 \right) = \frac{1}{p_\perp} \frac{\partial}{\partial p_\perp} \left( p_\perp \left( D_{\perp\perp} \frac{\partial}{\partial p_\perp} + D_{\perp\parallel} \frac{\partial}{\partial p_\parallel} \right) f^0 \right) \]

\[+ \frac{\partial}{\partial p_\parallel} \left( D_{\parallel\parallel} \frac{\partial}{\partial p_\parallel} + D_{\parallel\perp} \frac{\partial}{\partial p_\perp} \right) f^0 \right), \quad (2)

where \( G \) is the force responsible for conserving the adiabatic invariant \( p_\perp^2 / B(r) = \text{const.} \), \( F \) is the radiation deceleration force produced by synchrotron emission, and \( Q_\parallel \) is the reaction force of the curvature radiation. They can be written in the form:

\[
G_{\parallel} = -\frac{mc^2}{\gamma} \gamma_{\parallel} \psi, \quad G_{\perp} = -\frac{mc^2}{\gamma} \gamma_{\perp} \psi^2, \quad (3)
\]

\[
F_{\parallel} = -\alpha_e \psi \left( 1 + \gamma_{\parallel} \psi^2 \right), \quad F_{\perp} = -\alpha_e \gamma_{\parallel} \psi^2, \quad (4)
\]

\[
Q_\parallel = -\alpha_e \gamma^4, \quad (5)
\]

where \( \alpha_e = 2e^2 \omega_b / 3 c^2 \), \( \gamma_c = 2e^2 / 3p^2 \) and \( \psi \approx p_\perp / p_\parallel \ll 1 \) is the pitch angle.

Now let us compare the transverse components of the forces \( G \) and \( F \). If we consider the case \( \gamma \psi \gg 1 \) we will have:

\[
G_{\perp} = \frac{3m^3 c^6}{8e^4 B_t^2 r} \left( \frac{r}{R_t} \right)^6 \frac{1}{\gamma^4 \psi^3}, \quad (6)
\]

where \( B_t \) is the magnetic field at the star surface, \( R_t \) is the star radius and \( r \) is the distance from the pulsar. For the typical parameter values of pulsars \( |G_{\perp}| \ll |F_{\perp}| \). Then taking into account \( \frac{\partial}{\partial \psi} \gg \frac{\partial}{\partial \gamma} \) the equation for the diffusion across the magnetic field can be written in the form (Chkheidze et al. 2010)

\[
\frac{df^0}{dt} + \frac{\partial}{\partial p_\perp} \left( p_\perp F_{\perp} f^0 \right) = \frac{1}{p_\perp} \frac{\partial}{\partial p_\perp} \left( p_\perp D_{\perp\perp} \frac{df^0}{dp_\perp} \right), \quad (7)
\]

where

\[
D_{\perp\perp} = \frac{e^2}{8e} \frac{|E_\parallel|^2}{2}, \quad (8)
\]

is the diffusion coefficient and \( |E_\parallel|^2 / \omega \) is the density of electric energy in the waves.

The transversal quasi-linear diffusion increases the pitch-angle, whereas force \( F \) resists this process, leading to the stationary state (\( \partial f / \partial t = 0 \)). Then the solution of Eq. (7) is

\[
f_{\perp} = Ce^{-\frac{\rho_{\parallel}}{\rho_{\perp}}}, \quad (9)
\]

To evaluate \( p_{\parallel\perp} \), we use the quantity

\[
|E_\parallel|^2 \approx \frac{m c^2 n_e \gamma_c}{2 \omega}, \quad (10)
\]

where \( \omega \) is the frequency of original waves, excited during the cyclotron resonance and can be estimated from Eq. (1) as follows \( \omega \approx \omega_b / \delta \gamma_{\parallel} \). Consequently, we will get

\[
p_{\parallel\perp} \approx \frac{\omega^{1/2}}{B_{\perp}^2} \left( \frac{3m^2 c^5 \gamma_{\parallel}^2}{32e^6 \rho^3} \right)^{1/4}, \quad (11)
\]

The mean value of the pitch-angle \( \gamma_{\parallel} \sim p_{\parallel\perp} / p_\parallel \approx 10^{-3} \) (i.e. the assumption \( \gamma_{\parallel} \gamma_{\parallel} \gg 1 \) done at the beginning of our computations proves to be true). As a result of the appearance of the pitch angles, the synchrotron emission is generated.

3. X-ray spectrum

Let us consider the synchrotron emission of the set of electrons. The number of emitting particles in the elementary dV volume is \( p_\parallel dp_\parallel dp_\perp d\Omega \), with momenta from the intervals \([p_\parallel + dp_\parallel, p_\parallel + dp_\parallel]\) and \([p_\perp, p_\perp + dp_\perp]\), and with the velocities that lie inside the solid angle \( d\Omega \) near the direction of \( \tau \). If we write the parallel distribution function of the emitting particles as \( \int p_\parallel dp_\parallel \equiv f_{\parallel}(p_\parallel) \), then the emission flux of the set of electrons will be (Ginzburg 1981)

\[
F_{\parallel} = \int L_{\parallel} f_{\parallel}(p_\parallel) dp_\parallel d\Omega, \quad (12)
\]

where \( L_{\parallel} \) is the Stokes parameter, which is additive in this case, as the observed synchrotron radiation wavelength \( \lambda \) is much less than the value of \( n^{-1/2} \) the average distance between particles, where \( n \) is the density of plasma component electrons. The integral (12) is easily reduced to (see Ginzburg 1981)

\[
F_{\parallel} \approx \int f_{\parallel}(p_\parallel) B_\parallel^2 \epsilon_{m} \left( \int_{\epsilon_{m}}^{\infty} K_5(\zeta) d\zeta \right) d\epsilon_{\parallel}, \quad (13)
\]

Here \( \epsilon_{m} \approx 5 \times 10^{-12} B_{\parallel} \psi^2 \gamma^2 \text{keV} \) is the photon energy of the maximum of synchrotron spectrum of a single electron and \( K_5(\zeta) \) is a Macdonald function. After substituting the mean value of the pitch-angle in the above expression for \( \epsilon_{m} \), we get

\[
\epsilon_{m} \approx 5 \times 10^{-12} \psi^2 \gamma^2 \left( \frac{3m^5 c^7 \gamma_{\parallel}^2}{32e^6 \rho^3} \right)^{1/4}, \quad (14)
\]

For the primary beam electrons with the Lorentz factor \( \gamma_b \approx 10^7 \) the emitted photon energy \( \epsilon_{m} \sim 0.1 \text{keV} \) comes in the energy domain of the observed X-ray emission of RBS1774. Thus we suppose that the measured X-ray spectrum is the result of the synchrotron emission of primary beam electrons (the resonance occurs on the right slope of the distribution function of beam electrons (see Fig. 1)), switched on as the result of acquisition of pitch angles by particles during the quasi-linear stage of the cyclotron instability.
To find the synchrotron flux in our case, we need to know the one-dimensional distribution function of the emitting particles \( f_\parallel \). Let us multiply both sides of Eq. (2) on \( p_\parallel \) and integrate it over \( p_\perp \). Using Eqs. (3)–(5) and the following expressions for the diffusion coefficients (Chkheidze et al. 2010)

\[
D_{\perp\parallel} = D_{\perp\perp} = -\frac{e^2}{8c}\psi|E_k|^2,
\]

\[
D_{\parallel\parallel} = \frac{e^2\psi^2}{8c}f_k^2.
\]

And also taking into account that the distribution function vanishes at the boundaries of integration, Eq. (2) reduces to

\[
\frac{\partial f_\parallel}{\partial t} = \frac{\partial}{\partial p_\parallel}\left[(\frac{\alpha_x}{m_e c^2 \pi^{1/2} p_\perp^0} + \alpha_c \gamma^4 - \frac{e^2}{4mc^2\gamma|E_k|^2}f_k)\right].
\]

Let us estimate the contribution of different terms on the right-hand side of Eq. (16). The estimations show that the first term is much bigger than two other terms. Consequently, for the primary-beam electrons instead of Eq. (16), one gets

\[
\frac{\partial f_\parallel}{\partial t} = \frac{\partial}{\partial p_\parallel}\left(\frac{\alpha_x}{m_e c^2 \pi^{1/2} p_\perp^0}f_k\right).
\]

Considering the quasi-stationary case we find

\[
f_k \propto \frac{1}{p_{\parallel}^4|E_k|^2}.
\]

For \( \gamma\psi \ll 10^{10} \), a magnetic field inhomogeneity does not affect the process of wave excitation. The equation that describes the cyclotron noise level, in this case, has the form (Lominadze et al. 1983)

\[
\frac{\partial|E_k|^2}{\partial t} = 2\Gamma_e|E_k|^2f_k,
\]

where

\[
\Gamma_e = \frac{\pi^2e^4}{k_e}(p_{\mathrm{res}}),
\]

is the growth rate of the instability. Here \( k_e \) can be found from the resonance condition (1)

\[
k_{\mathrm{res}} = \frac{\omega_B}{c\delta\gamma_{\mathrm{res}}}.
\]

Combining Eqs. (17) and (19) one finds

\[
\frac{\partial}{\partial t}\left(f_\parallel - \alpha \frac{\partial}{\partial p_\parallel}\left(\frac{|E_k|^2}{p_\parallel^2}\right)\right) = 0,
\]

\[
\alpha = \left(\frac{4e^2}{3\pi^2e^4} \frac{\delta_{\parallel}^3}{\omega_p^5}\right)^{1/4},
\]

which reduces to

\[
\left\{f_\parallel - \alpha \frac{\partial}{\partial p_\parallel}\left(\frac{|E_k|^2}{p_\parallel^2}\right)\right\} = \text{const.}
\]

Taking into account that for the initial moment the major contribution of the left-hand side of the Eq. (24) comes from \( f_{\parallel\parallel} \), the corresponding expression writes as

\[
f_\parallel - \alpha \frac{\partial}{\partial p_\parallel}\left(\frac{|E_k|^2}{p_\parallel^2}\right) = f_{\parallel\parallel}.
\]

The distribution function \( f \) is proportional to \( n \sim 1/r^3 \), then one should neglect \( f_k \) in comparison with \( f_{\parallel\parallel} \). Consequently, the above equation reduces to

\[
\alpha \frac{\partial}{\partial p_\parallel}\left(\frac{|E_k|^2}{p_\parallel^2}\right) + f_{\parallel\parallel} = 0.
\]

As we can see the function \( E_k(p_{\parallel}) \) drastically depends on the form of the initial distribution of the primary beam electrons. Here we assume that the initial energy distribution in the beam has a Gaussian shape

\[
f_{\parallel\parallel} = \frac{n_0}{\sqrt{\pi\gamma_{\parallel}}} \exp\left[\frac{(\gamma - \gamma_{\parallel})^2}{\gamma_{\parallel}^2}\right],
\]

where \( \gamma_{\parallel} \simeq 10^-1 \) is the half width of the distribution function and \( n_0 = B/P_{\mathrm{ce}} \) is the density of primary beam electrons, equal to the Goldreich-Julian density (Goldreich & Julian 1969). Since \( \gamma_{\parallel} \ll \gamma_{\parallel} \), this distribution is very close to \( \delta \)-function. Consequently, the electron distribution can be taken as monoenergetic.

In this case for the energy density of the waves we get

\[
|E_k|^2 \propto p_{\parallel}.
\]

The effective value of the pitch angle depends on \( |E_k|^2 \) as follows

\[
\psi_0 = \frac{1}{2\omega_B}\left(\frac{3m_e^2c^3\omega_B^2}{p_{\parallel}^2\gamma_p^2|E_k|^2}\right)^{1/4}.
\]

According to our emission model, the observed radiation comes from a region near the light cylinder radius, where the magnetic field lines are practically straight and parallel to each other (Osmanov et al. 2009), therefore, electrons with \( \psi \approx \psi_0 \) efficiently emit in the observer’s direction.

Using expression (18), (28) and (29), and replacing the integration variable \( p_\parallel \) by \( x = \epsilon/\epsilon_\mathrm{m} \), from Eq. (13) we will get

\[
F_\epsilon \propto \epsilon^{-0.3} \int \chi_0^{0.3}\left[\int_x^\infty K_{5/3}(z)dz\right]dx.
\]

The energy of the beam electrons vary in a small interval. In this case the integral (30) can be approximately expressed by the following function

\[
F_\epsilon \propto \epsilon^{-0.3} \exp(-\epsilon/\epsilon_\mathrm{m}).
\]

We performed a spectral analysis by fitting the model spectrum (Eq. (31)) absorbed by cold interstellar matter, with the combined data extracted of the three EPIC X-ray cameras of the XMM-Newton Telescope. The resulting \( \chi^2 = 1.63 \) and the amount of interstellar matter \( n_\mathrm{H} = (3.36 \pm 0.2) \times 10^{20} \text{ cm}^{-2} \), which appears to be close to the total Galactic absorption in the source direction (\( n_\mathrm{H} = 5 \times 10^{20} \text{ cm}^{-2} \) Dickey & Lockman 1990). The spectral feature at \( \sim 0.7 \text{ keV} \) that is mostly described as an absorption edge or line (Zane et al. 2005; Schwope et al. 2009) is also evident in our case from inspection of Fig. 1. We find that adding an absorption edge at \( 0.7 \text{ keV} \) improves the fit, leading to a reduced \( \chi^2 = 1.50 \). The best-fitting energy of the edge is \( E_{\mathrm{edge}} = 0.679 \text{ keV} \), and the optical depth is \( \tau_{\mathrm{edge}} = 0.20 \) (see Fig. 3). The fitting results are listed in Table 1. We suppose that existence of the absorption feature in spectra of RBS1774 is caused by wave damping at photon energies \( \sim 0.7 \text{ keV} \), which takes place near the light cylinder.

Notes. \(^a\) The fitting results with a pure blackbody model absorbed by cold interstellar matter are from Schwope et al. (2009).

Fig. 2. EPIC-pn and EPIC-MOS spectra of RBS1774, fitted with a model.

4. Possible nature of the spectral feature

During the farther motion in the pulsar magnetosphere, the X-ray emission of RBS1774 that is generated on the light cylinder lengthscales, might come in the cyclotron damping range (Khechinashvili & Melikidze 1997):

\[
\omega - k \nu_i - k_i \omega_i - \frac{\omega_B}{\gamma_r} = 0. \tag{32}
\]

The condition for the development of the cyclotron instability may be easily derived for the small angles of propagation with respect to the magnetic field. Representing the dispersion of the waves as

\[
\omega = kc, \tag{33}
\]

and neglecting the drift term, the resonance condition (32) may then be written as

\[
\frac{1}{2\gamma_r^2} \frac{\theta^2}{2} = \frac{\omega}{\gamma_r}, \tag{34}
\]

where \( \theta \approx \psi \) is the angle between the wave vector and the magnetic field. Taking into account that \( \theta_0^2 \gg 1/2\gamma_r^2 \) one finds from Eq. (34) the frequency of damped waves

\[
\omega_0 = \frac{2\omega_B}{\gamma_r \theta_0^2}. \tag{35}
\]

Page 4 of 5

If we assume that the resonant particles are the primary beam electrons, then the estimation shows that on the light cylinder lengthscales \( \epsilon_0 = (\hbar/2\pi)c\omega_0 \approx 0.7 \text{ keV} \).

5. Discussion

According to the generally accepted point of view, the X-ray spectrum of RBS1774 is purely thermal and is best represented by a Planckian shape. A fit with a pure blackbody component absorbed by cold interstellar matter gives \( \chi^2 = 1.81 \) (Schwope et al. 2009). Including a Gaussian absorption line at \( \sim 0.7 \text{ keV} \) (as the largest discrepancies between model and data are around 0.7 keV) improves the fit \( \chi^2 = 1.50 \) (parameters are listed in Table 1). However, the nature of this spectral feature is not fully clarified as yet. The most likely interpretation is that it is due to proton cyclotron resonance, which implies ultrastrong magnetic field of \( B_{\text{cyg}} \sim 10^{13} \text{ G} \) (Zane et al. 2005; Rea et al. 2007). Although, the required strong magnetic field is inconsistent with timing measurements giving \( B_{\text{dip}} = 3.2 \times 10^{19} \sqrt{PP} \approx 2 \times 10^{13} \text{ G} \) (Kaplan & van Kerkwijk 2009).

We are not about to reject the existing thermal emission models, but in present paper we propose an alternative explanation of the observed X-ray spectrum of RBS1774. It is supposed that the emission of this source is generated by the synchrotron mechanism. The distribution function of relativistic particles is one
dimensional at the pulsar surface, but plasma with an anisotropic distribution function is unstable which can lead to wave excitation. The main mechanism of wave generation in plasmas of the pulsar magnetosphere is the cyclotron instability, which develops on the light cylinder length scales. During the quasi-linear phase of the instability, a diffusion of particles arises along and across the magnetic field lines. Therefore, plasma particles acquire transverse momenta and, as a result, the synchrotron mechanism is switched on. If the resonant particles are the primary beam electrons with $\gamma_b \approx 10^7$ their synchrotron emission enters the same energy domain as the measured X-ray spectrum of RBS1774.

We construct a self-consistent theory interpreting the observations of RBS1774. Differently from the standard theory of the synchrotron emission (Ginzburg 1981), which only provides a power-law spectrum with the spectral index less than 1, our approach gives the possibility to obtain different spectral energy distributions. In the standard theory of the synchrotron emission, it is supposed that the observed radiation is collected from a large spacial region in various parts of which, the magnetic field is oriented randomly, thus, it is supposed that along the line of sight the magnetic field directions are chaotic and when finding emission flux, Eq. (13) is averaged over all directions of the magnetic field (which means integration over $\psi$ varying from 0 to $\pi$). In our case the emission comes from a region of the pulsar magnetosphere where the magnetic field lines are practically straight and parallel to each other. And differently from standard theory, we take into account the mechanism of creation of the pitch angles. Thus we obtain a certain distribution function of the emitting particles from their perpendicular momenta (see Eq. (10)), which restricts the possible values of the pitch angles.

In the framework of the model we obtain the following theoretical X-ray spectrum of RBS1774 $F_x \propto \varepsilon^3 \exp(-\varepsilon/\varepsilon_m)$ and perform a spectral analysis by fitting data from the three EPIC detectors simultaneously. The fit with a model spectrum absorbed by cold interstellar matter yields $\chi^2 = 1.63$ (see parameters in Table 1).

During the farther motion in the pulsar magnetosphere, the X-ray emission of RBS1774 comes in the cyclotron damping range (see Eq. (32)). If we assume that damping happens on the left slope of the distribution function of primary beam electrons (see Fig. 1), then the photon energy of damped waves will be $\varepsilon_0 = (h/2\pi)\omega_0 = (h/2\pi)2\omega_B/\gamma_b \varepsilon^2 \approx 0.7$ keV. Taking into account the shape of the distribution function of primary electrons, we interpret the large residuals around ~0.7 keV (see Fig. 2) as an absorption edge. Including an absorption edge improves the fit leading to a reduced $\chi^2 = 1.50$. The best-fitting energy of the edge is $E_{\text{edge}} = 0.67$ keV, and the optical depth is $\tau_{\text{edge}} = 0.20$ (see Table 1). However, adding an absorption edge to the model spectrum does not produce a statistically significant improvement of the fit. According to Schwore et al. (2009) if one uses the RGS X-ray spectra of RBS1774 in place of EPIC spectra, the resulting $\chi^2$ is changed just marginally when a Gaussian absorption line is included at ~0.7 keV. Thus, we conclude that the nature of the feature at 0.7 keV is uncertain and might be related to calibration uncertainties of the CCDs and the RGS at those very soft X-ray energies. The same can be told about a feature at ~0.3 keV (the large residuals around 0.3 keV are evident from inspection of Figs. 2 and 3). A feature of possible similar nature was detected in EPIC-pn spectra of the much brighter prototypical object RXJ1856.4-3754 and classified as remaining calibration problem by Haberi (2007). Consequently, more data are necessary to finally prove or disprove the existence of those features.

The frequency of the original waves, excited during the cyclotron resonance can be estimated from Eq. (1) as follows $\nu \approx 2 \pi \omega_c / \eta_b \gamma_b \sim 10^{14}$ Hz. As we can see the frequency of cyclotron modes comes in the same domain as the measured optical emission of RBS1774 (Zane et al. 2008; Schwope et al. 2009).

Acknowledgements. The authors are grateful to George Machabeli for valuable discussions and Axel Schwope for providing the X-ray data.
