Abstract

The distillation process in the Ammoniacal Carbonate Leaching technology was studied at bench-scale and on industrial scale. The dissolved sulfur effect in the Product-liquor that feeds to the columns, on the Basic Nickel Carbonate (BNC) properties and the operation expenses was determined. When increasing the sulfur in the liquor, we augment the selectivity towards the sulfate formation in the BNC molecule; therefore the energy consumption to the BNC thermal decomposition in the calcination process increases. Also, the nickel dissolved in the columns effluent increases due to complex reaction with [SO₄²⁻] and [S₂O₃²⁻] ions, thus the expenses for consumption precipitation reagent increase too. Feeding carbonated liquor in the range 1.60 ≤ NH₃/CO₂ < 1.80 and CO₂-rich solution increases the CO₂ in the BNC with decreasing in sulfate; then, the mean diameter particle increases, the filtration resistance and the cake moisture diminish, which augments the productivity and reduces the energy consumption in the process of filtration and calcination. Keeping a pH between 8.4 and 8.7 in the columns outlet the greatest economic benefit is obtained of 0.125 ($ · h⁻¹) per (m³ · h⁻¹) of Product-liquor.

Keywords: Basic Nickel Carbonate; steam-stripped columns; sulfur, leaching

1. Introduction

The ammoniacal carbonate leaching technology for the selective extraction of nickel and cobalt from lateritic ores began operations in the mid 1940’s in Cuba, in the Nicaro nickel plant. The process was originally described by M. H. Caron in 1924 and combines both hydro- and pyrometallurgy processes, it consists of the following main stages (see Fig. 1):

The lateritic ore is crushed and dried to reduce moisture from approximately 35% to 5% with combustion gases in a rotary dryer. The dried laterites are ground to size of 83% or more of the −0.074 mm class, before being reduction-roasting, into Herreshoff multiple-hearth furnaces. The additive fuel oil is fed in the mineral weighing system to enable high temperature inside the furnace through its partial combustion and provide the reducing agent for the reduction process, Eqs. (1), (2).

\[
2(Ni,Co)O(s) + (CO + H₂)(g) → 2NiO(s) + 2CO(g) + H₂O(g) \quad (1)
\]

\[
2Fe₂O₃(s) + 3(CO + H₂)(g) → 4Fe(s) + 3CO₂(g) + 3H₂O(g) \quad (2)
\]

The reduced ore cooled under neutral atmosphere below 250 °C is subsequently mixed with ammonia carbonate solution, and the resulting slurry is leached in aerated tanks, flow model perfect mixed. In this process, the nickel is selectively leached from the roast product, as described the following simplified reaction, Eq. (3):¹

¹ Vargas et al.: Ammoniacal Carbonate Leaching: Effect ...
Iron, cobalt and sulfur also are dissolved in leaching process. The Fe metal complex is unstable and precipitates as iron hydroxide. The sulfur remainder in the roast product, coming from the fuel oil, is oxidized to thiosulfate \([\text{S}_2\text{O}_3^{2-}]\), polythionates \([\text{S}_n\text{O}_{3m}^{2-}, \: 2 < n < 6]\), sulfate \([\text{SO}_4^{2-}]\) and sulphamate \([\text{SO}_3\text{NH}_2^{-}]\), Eq. (4).

\[
\begin{align*}
\text{Ni(OH)}_2 &\rightarrow \frac{1}{2} \text{O}_2 + 4\text{NH}_3 + (\text{NH}_4)_2\text{CO}_3 \rightarrow \\
&\rightarrow \text{Ni} (\text{NH})_3^{\text{2+}} + \text{CO}_3^{\text{2-}} + \text{H}_2\text{O}
\end{align*}
\]

(3)

The pregnant liquor is then separated from the undissolved solid in settler tank and later Cobalt is removed from the liquor by chemistry precipitation in a tubular reactor. Then, the Product-liquor is fed in the steam-stripped columns, descends by gravity and it is brought into direct contact and counter flow with the superheated steam in multiple bubble cap trays. The volatiles compounds \(\text{NH}_3, \text{CO}_2\) and \(\text{SO}_2\) evaporate, ascend and are separated by the top of the column; in turn, the Basic Nickel Carbonate (BNC) precipitates and it is obtained by the bottom in a suspension of concentration between 2.5% and 4.0% by weight, temperature of 80 °C to 90 °C and dissolved chemical species in the proportions \(1.5 < \text{NH}_3/\text{CO}_2 < 2.0; \: 1.8 < \text{Ni}/\text{S} < 3.2; \: 10.4 < \text{CO}_2/\text{S} < 13.8\) and pH of 7.4 to 9.0, Eqs. (5), (6).

\[
\begin{align*}
5\text{Ni} (\text{NH})_3^{\text{2+}} + 5\text{CO}_3^{\text{2-}} + 7\text{H}_2\text{O} &\rightarrow \\
&\rightarrow 2\text{NiCO}_3, 3\text{Ni(OH)}_2, 4\text{H}_2\text{O(OH)}_2 + 3\text{CO}_2(g) + 30\text{NH}_3(g) \\
6\text{Ni} (\text{NH})_3^{\text{2+}} + 5\text{CO}_3^{\text{2-}} + 3\text{SO}_4^{\text{2-}} + 3\text{H}_2\text{O} &\rightarrow \\
&\rightarrow 2\text{NiCO}_3, 3\text{Ni(OH)}_2, \text{NiSO}_4(g) + 3\text{CO}_2(g) + 36\text{NH}_3(g)
\end{align*}
\]

(5)

(6)

The BNC is separated from the liquid in a settler tank and afterward, by filtering process. Nickel dissolved remainder in the liquid is precipitated in a tubular reactor by chemistry reaction with \(\text{H}_2\text{S}\), but \(\text{NH}_3\) constitutes a loss affecting the operating expenses.

The BNC is subsequently processed in a rotary kiln operated under slightly reducing atmosphere conditions, and it is calcined at maximum temperatures between 1000 and 1200 °C, Eq. (7).

\[
\begin{align*}
2\text{Ni(OH)}_2 + 3\text{NiCO}_3 + \text{NiSO}_4 &\rightarrow \\
&\rightarrow 6\text{NiO} + 3\text{CO}_2(g) + \text{SO}_2(g) + 2\text{H}_2\text{O(g)} + \frac{1}{2} \text{O}_2(g)
\end{align*}
\]

(7)

Calcination process consists in four stages of BNC decomposition to \(\text{NiO}\). The first stage is the removal of physically entrained water, which represents between the 45% and 55% of heat supplied to the kiln.\(^\text{3,4}\) on the other hand, the last stage belong to sulfate decomposition and require activation energy higher than the rest of the stages, of 324.4 (+/- 23.8) kJ · mol\(^{-1}\). \(^\text{5}\) researchers suggested that high reduction temperature of 900 °C substantially diminishes the sulfur content,\(^\text{6}\) so the BNC must have the minimum humidity before being fed to the process and the lower sulfur concentration to reduce the energy consumption. Besides, during BNC decomposition, the surface segregation of sulfur, among other phenomena that occur simultaneously such as recrystallization and agglomeration, contribute to the change the chemical-physical properties of the particles, affecting the \(\text{NiO}\) final microstructure.\(^\text{7}\)

Finally, the mixture of \(\text{NiO}\) and anthracite coal is fed to the sintering process and a product with 93% Ni, 0.060% S and size 40% (+2 mm) is obtained.

This work focuses on the process of Product-liquor distillation and obtaining the Basic Nickel Carbonate. Several studies have been carried out with the purpose of reducing the concentration of nickel and ammonia in the liquid effluents of the distillation columns, also to improve the chemical-physical properties of BNC, as well as to diminish the operating expenses.

A complementary operating norm was proposed to control the thermal profile of the columns, which consists of measuring the pH of the BNC suspension at the bottom outlet of the columns and adopting the necessary corrective actions. The study was carried out on a bench-scale and industrial-scale, at the nickel producing plants in Nicaro and Punta-Gorda, Cuba. The recommended pH range

\end{align*}
\]

(4)
was between 8.3 and 8.7, it was obtained by optimizing the convenience function at a minimum expense due to ammonia losses and consumption of dissolved nickel precipitation reagent. If pH > 8.7, the Product-liquor distillation is characterized by low thermal profile, the concentration of dissolved NH₃ and Ni is high, therefore the operation expenses increase in relation to the recommended range (sub-distillation conditions). If pH < 8.3, so the thermal profile is high, the nickel is leached from BNC increasing the Ni cation in solution, thus the operation expenses increases although the NH₃ concentration continuous lowering (over-distillation conditions). The convenience function was based on the second-order polynomial function between Ni vs. pH, and the potential function between NH₃ vs. pH.²⁻⁸⁻⁹

Based on the principles of simultaneous equilibrium and mass balance, a series of thermodynamic equations of Ni(II)-NH₃-CO₃-H₂O systems at 25 °C were deduced and thermodynamic diagrams of log[Ni²⁺] versus pH at different solution compositions were drawn, to explain the mechanism of precipitation particles with different microscopic shapes. When the pH is above 7.0, the precipitation proceeds slowly and leads to the formation of dense spherical particles. Between pH 6 to 8, the nickel concentration in the solution goes down with pH to a minimum point, then goes up to a maximum point following a parabolic function, when concentration of [CO₃²⁻] increases, more nickel ions precipitate as the solid particle which leads to decrease of nickel in the solution. [Ni²⁺] cation gradually increase with increasing [NH₃] by the formation of nickel ammine-complexes, Ni(NH₃)ₙ²⁺, (n = 1–6). The higher the concentration of ammonia is, the higher [Ni²⁺] in the solution are.¹⁰ For the system Ni(II)-NH₃-CO₂-SO₂-H₂O these diagrams were drawn simulating the concentration of the ionic species at the bottom outlet of the columns, [Ni²⁺] cation increase with increasing [SO₄²⁻] and [S₂O₃²⁻] ions concentration because of complex reactions. As the sulfur concentration increases, the minimum point of nickel concentration shift towards a more alkaline pH.² Ni’s dependency on pH in both studies was similar to the results obtained experimentally in the distillation columns for 6.0 ≤ pH ≤ 8.0.

From experimental measurements in the distillation process at the nickel producing plants in Nicaro and Puntagorda, a statistical model was obtained by Multiple Linear Regression, for the Ni concentration dissolved estimate, in function of the concentration of [S], [NH₃] and [CO₃] in the Product-liquor that feeds the distillation columns and the pH in the BNC suspension. The evaluation of the model indicated that when operating with a high Ni/S ratio (Ni/S ≥ 1.8) and a correct carbonation (1.60 ≤ NH₃/CO₂ ≤ 1.75), in the suspension of BNC at the column outlet, a lower concentration of dissolved nickel is obtained and therefore the consumption of reagents for the chemical precipitation diminish resulting in lower expenses.² This was explained because it increases the selectivity towards the carbonate formation in the BNC molecule, while decreases the sulfate formation; however, no experimental results have been presented that show these changes in the chemical composition of BNC.

The effect of carbon dioxide dissolved in the Product-liquor over the BNC characteristic was represented in pseudo-equilibrium diagram, log[NH₃] versus log[CO₃²⁻], for the Ni-NH₃-CO₃²⁻-H₂O system at 100 °C, Eh 0.5V, Ni 0.001M, pH 6.75. This diagram indicated that the CO₂ concentration should be controlled in the liquor, to avoid the nickel hydroxide precipitation. The formation of hydroxylated products is undesirable, since their drying and dissolution properties are lower than that of Basic Nickel Carbonate.¹¹ For the Ni(II)-NH₃₂SO₄-H₂O systems, the speciation of nickel in ammonia solution has been examined by distribution-pH diagrams, 1M (NH₄)₂SO₄ solution, 0.01M Ni²⁺. In the region between pH 1.5 and pH 8 the predominant nickel species is a soluble, negatively charged sulfate complex [Ni(SO₄)₂²⁻], in the region from pH 8 to pH 12, there is a series of nickel ammine-complexes with successively increasing number of incorporated ammonia ligands, Ni(NH₃)ₙ²⁺, (n = 1–6). In 0.05M Ni²⁺ solution, nickel hydroxyl-sulfate precipitates in the region around pH 8,¹² which suggests that at pH<8.3 (according to the operating norm by pH), the nickel leaching from BNC may be particularly associated with the presence of sulfate in the BNC molecule, what is accentuated to conditions of low carbonation of the Product-liquor. It should be highlighted that in more diluted aqueous solution of nickel(I) sulfate, 10⁻⁴M, the ions [Ni₂(SO₄)₃(H₂O)ₙ]²⁻ and [Ni₅(SO₄)₆(H₂O)₇]²⁻ (m=6, n=12) have been identified, also, at 5 · 10⁻⁴M, triple ion [Ni(SO₄)₂]²⁻, nickel cluster [Ni₂(SO₄)₃]³⁻, [Ni₃(SO₄)₄]²⁻ and higher-mass ions [Ni₃(SO₄)₅(H₂O)ₙ]³⁻ (0 ≤ n ≤ 2).¹³

Few investigations on Basic Nickel Carbonate have considered the presence of sulfur in the molecule. Structures such as: 2NiCO₃·3Ni(OH)₂ · 4H₂O, NiCO₃ · 2Ni(OH)₂ · 4H₂O and NiCO₃ · Ni(OH)₂ · 2H₂O are reported, the particles are spherical and ellipsoidal in shape, ranging from 0.2 to 23 μm in diameter. The BNC dried at 105 °C contained approximately 52% wt Ni, 12.9% wt CO₂ and 0.001% wt S.² On the other hand, considering sulfur, the general structure (NiCO₃)ₓ · (Ni(OH)₂)ᵧ · (NiSO₄)ᵦ · nH₂O is presented.³ The BNC dried at 60 °C contained 45.6–50.0% wt Ni, 1.9–4.9% wt CO₂, 1.8–3.1% wt S, real density 2.8–3.2 mg · L⁻¹ and 12–22 μm in mean diameter of microparticles.³⁻¹⁴

Colloidal processing supplies great possibilities to obtain smart materials by means of manipulation of molecular structures and control of inter-particle forces.¹⁵ A colloid is a chemical system, in which one substance is microscopically dispersed evenly throughout another medium substance of a continuous phase. The behavior of colloidal particles in aqueous medium is a consequence of interaction between particles surface and liquid medium. Colloidal particle size distribution, between 10⁻³ μm and 1
Influence of ionic strength and pH on rheological properties; filtration, drying, sintering process; and in the final microstructure.\textsuperscript{7,14} The particle behaviour in suspension and its stability can be understood using electric double layer model (EDL) or DLVO theory (Derjaguin, Landau, Verwey and Overbeek), as well as the concepts surface potential, isoelectric point and zeta potential.\textsuperscript{15,16} Stability refers to the condition in which the colloidal particles do not aggregate at a significant rate. Aqueous suspension stabilization can be controlled by the mechanisms electrostatic, steric, electrosteric and nanoparticle haloing stabilization, by the following methods: adjusting either ionic strength or pH of the electrolyte solution; adding a component like a surfactant or polymer that adsorbs on the colloidal particles and changes their surface properties; a polyelectrolyte that impart electrostatic and steric stabilization to a given colloidal dispersion; or highly charged nanoparticles by forming a nonadsorbing nanoparticle layer around neutral colloidal particle, which presents as an effective surface charge and produces an electrostatic repulsion that mitigates the inherent van der Waals attraction between them.\textsuperscript{17,18} A method for purifying Basic Nickel Carbonate of Na\textsuperscript{+}, Cl\textsuperscript{−} ions and other impurities on its surface was clarified by the electric double layer model and it was proposed a washing-drying-rewashing-drying process,\textsuperscript{19} but other studies have not been performed about colloidal processing or sulfur removal of Ni(II)-NH\textsubscript{3}CO\textsubscript{2}SO\textsubscript{2}H\textsubscript{2}O system.

The purpose of this work was to determine the dissolved-sulfur concentration effect in the Product-liquor, on the BNC properties, the expenses in the distillation process and determine the pH range for the greatest economic benefit.

2. Materials and Methods

The evaluation was carried out on a bench-scale and industrial-scale.

A steam-stripped mini-column was used with 200 mm diameter, 1320 mm height, 2 separating trays at the top, 8 bubble cap trays, 1 cup/trays of 106 mm diameter and 1 sampler/ trays, which allowed performing the concentration profile of dissolved chemical species in six inner positions along the column, (Fig. 1).

On the other hand, the industrial-scale steam-stripped columns, at the Nicaro nickel plant, have 3.4 m in diameter, 18.0 m height, 18 bubble cap trays, 24 cups/trays, operating pressure at the bottom of 127.5 MPa and samplers in the fifth tray.\textsuperscript{20}

The samples were taken in the Product-liquor, in the BNC suspension at the columns outlet, and in the corresponding samplers along the columns. Also, a CO\textsubscript{2}-rich solution was used, which is produced in the gases absorption systems of the industrial process, with NH\textsubscript{3} 130–140 g · L\textsuperscript{−1} and CO\textsubscript{2} 90–100 g · L\textsuperscript{−1}.

The BNC suspension samples were processed as follows: the aliquot needed to determine the suspension pH and the dissolved compounds concentration (g · L\textsuperscript{−1}) of \[\text{NH}_3\], \[\text{CO}_2\], \[\text{Ni}\], \[\text{S}\], \[\text{SO}_4^{2−}\], \[\text{S}_2\text{O}_3^{2−}\] was taken; the rest was filtered in a Büchner funnel connected to a side-arm flask and a vacuum pump, the BNC was dried at 60 °C and it was characterized according the concentration (%) of \[\text{Ni}\], \[\text{Co}\], \[\text{MgO}\], \[\text{CO}_3^2\], \[\text{S}\]. The real and apparent BNC density was determined.

The chemical analyzes were performed applying volumetric, gravimetric, potentiometric and Atomic Absorption Spectrophotometry (AAS) methods. All the pH measurements were made at 25 °C, using a pH meter PHILIPS PW-9420115-230 V, 50–60 Hz, precision 0,001pH/ °C; and for determining the size distribution, the Laser-Particle-Sizer Analysette 22.

Experimental runs were performed in three stages:

Stage 01. Bench-scale. A full-factorial design, two-level, \(2^k\) experimental runs, \(k\)-factors with one center point, was carried out at the mini-column, with the aim of determining the effect of the independent variables and their domain, on the concentration of dissolved nickel and the BNC properties, also, the interaction Ni(II) and NH\textsubscript{3} versus pH. The independent variables (factors) were: temperature at the top: 80, 85 and 90 °C, and liquor flow: 12, 16 and 20 L · h\textsuperscript{−1}, 15 experiments in total, each lasting 10 hours. Once the operation stabilized, the samples were taken in 100 mL plastic bottles. The Liquor Product chemical composition remained fixed, it had a Ni/S ratio 2.66; Ni/[SO\textsubscript{4}^{2−}] 5.08, Ni/[S\textsubscript{2}O\textsubscript{3}^{2−}] 3.11 and NH\textsubscript{3}/CO\textsubscript{2} 1.73.

Stage 02. Bench-scale. In the mini-column, 6 experiments in total were carried out with and without feeding CO\textsubscript{2}-rich solution by a side trays of the column, at a flow of 2 L · h\textsuperscript{−1}, with the purpose of conducting an exploratory...
study and determining the effect on the concentration of nickel dissolved and the BNC properties. The temperature at the top was 90 °C and the Product-liquor flow of 20 L · h⁻¹, at the minimum nickel concentration in solution obtained in step 01. The Product-liquor chemical composition had a Ni/S ratio 3.32, Ni/[SO₄²⁻] 6.82, Ni/[S₂O₃²⁻] 4.25 and NH₃/CO₂ 1.78. The specific cake resistance and the medium resistance of filtration was determined, to a temperature of 80 °C, 16% in weight of solids and constant pressure drop of 37581.75 N/m², applying the Kraft paper as membrane.¹⁴

Stage 03. Industrial-scale. The experimental runs were carried out at Nicaro nickel plant, in order to validate the results previously obtained in the mini-column, at different ionic composition of the Product-liquor. The variables Liquor flow (Qa) 56.4 m³ · h⁻¹ (±4.5), temperature at the column top (Tp) 83.0 °C (± 1.4), and quotient between Liquor flow and steam flow (Qa/Wv) 5.7 m³ · kg⁻¹ (± 1.2) were fixed. The sampling was carried out in several periods or campaigns to guarantee the representativeness in the ionic composition of the Liquors processed in the columns, every 4 hours in 100 mL plastic bottles. The Product-liquor chemical composition was: 1.0 ≤ Ni/S ≤ 2.8, 1.8 ≤ Ni/[SO₄²⁻] ≤ 4.0, 1.2 ≤ Ni/[S₂O₃²⁻] ≤ 3.0, 1.60 ≤ NH₃/CO₂ ≤ 1.94.

The operating variables: flow, temperature and pressure were monitored in real-time using Supervisory Control and Data Acquisition EROS (SCADA EROS) and the values were taken from the data historian.

The chemical analysis database was organized into dataset (j = 1 to 10) according to the Ni/S and NH₃/CO₂ ratio in the Product-liquor, maintaining a standard deviation approximately equal to 0.5 g · L⁻¹. Only in this way was it possible to obtain the interactions of [Ni] and [NH₃] concentration (g · L⁻¹) as a function of the pH1 and pH2 concentration (g · L⁻¹) as a pH function and the consumption of reagent (P₂) 0.740 $ · kg⁻¹ was considered, as well as the reagent consumption dose (d) 1.33 kg · kg⁻¹ of precipitated nickel, Eq. (11).

To determine the economic benefit, certain pH range was set, and the average expense (G_f) was calculated. The interval width of pH was 0.4 (classes: 7.7 ≤ pH ≤ 8.0; 7.8 ≤ pH ≤ 8.1; …; 8.6 ≤ pH ≤ 8.9) and the number of class intervals equal to 13. Then, the economic benefit (A) for any range of pH was determined as the difference between the operating expenses in a dataset (G_j) with the average expenses (G_i) of the fixed pH range, considering relative frequency distribution (f_j) to make the summation. From this calculation, the pH range to operate at the greatest economic benefit was determined, Eq. (13).

### 3. Results and Discussion

#### 3.1. pH Interaction with Dissolved Nickel and Ammonia

The nickel and ammonia profile (g · L⁻¹) as a pH function at 25 °C in the in the steam-stripped mini-column are shown in Figure 3.
The relationship between nickel and ammonia with pH, in the trays along the mini-column, for the different levels of the factors temperature at the top and liquor flow was obtained. The alkalinity of the suspension decreased in the range of $9.7 \leq \text{pH} \leq 10.7$ with the fall of ammonia concentration from 80 g · L$^{-1}$ up to 3 g · L$^{-1}$, following a potential function, Eq. (14).

$$\left[NH_3\right] = 2.1941 \cdot 10^{-36} \cdot \text{pH}^{36.55} \quad R^2 = 0.9643$$

(14)

With regard to nickel cation, a slight descent of the concentration was appreciated due to the BNC precipitation, until reaching pH 10.3 and $[NH_3] = 20$ g · L$^{-1}$; starting from this point, Ni(II) cation precipitated according to a potential function, Eq. (15).

$$[Ni] = 3.32 \cdot 10^{-42} \cdot \text{pH}^{41.73} \quad R^2 = 0.9696$$

(15)

In this Figure 3, a view of the interaction between nickel and ammonia versus pH to pH$<9.7$ is included, corresponding to low concentrations in the inferior trays of the mini-column. Nickel in solution decreased with pH to a minimum point, and then increased to a maximum point in the BNC suspension, following parabolic function (over-distillation), Eq. (16).

$$[Ni] = 0.5384 \cdot \text{pH}^2 - 9.3621 \cdot \text{pH} + 40.93 \quad R^2 = 0.9696$$

(16)

On the other hand, form pH 9.7 to pH 7.8, the ammonia concentration diminished reaching concentrations as low as 1.0 g · L$^{-1}$ following a potential function; but this could result in a leaching of nickel from the BNC molecule and an increase in the Ni cation in solution, Eq. (17).

$$[NH_3] = 2.05 \cdot 10^{-4} \cdot \text{pH}^{4.1062} \quad R^2 = 0.9610$$

(17)

The interactions (Ni vs. pH, NH$_3$ vs. pH) were valid although CO$_2$-rich solution was fed to the mini-column, as it is shown in the Figure 4. At pH equal to 10.33, the precipitation of the BNC began, with a linear decrease of nickel concentration and slope $m_1 = 2.8$ (with CO$_2$-rich solution) and $m_2 = 2.3$ (without dissolution) until reaching pH 10.1 and $[NH_3] = 15.8$ g · L$^{-1}$. From that pH, [Ni$^{2+}$] cation precipitated intensely according to a potential function and exponents $k_1 = 39.3$ and $k_2 = 36.7$ with fit quality, $R^2$, 95% and 97% respectively.

$$\text{Figure 3.}$$ Profile of nickel and ammonia dissolved versus pH at 25 °C in the mini-column (Stage 01). Ni/S = 2.66, Ni/[SO}_4^{2–}] = 5.08, Ni/[S$_2$O$_3^{2–}] = 3.11, NH$_3$/CO$_2$ = 1.73

$$\text{Figure 4.}$$ Profile of nickel and ammonia dissolved versus pH at 25 °C in the mini-column (Stage 02). Product-liquor distillation with (1–) and without (2–) CO$_2$-reach solution. Ni/S 3.32, Ni/[SO$_4^{2–}] = 6.82, Ni/[S$_2$O$_3^{2–}] = 4.25, NH$_3$/CO$_2$ 1.78

From figure 4, at pH<9.6, corresponding to the lower trays, the concentration of both compounds decreased. For the same pH value, the dissolved nickel had a tendency to be slightly lower with the feeding of CO$_2$-rich solution, than when this solution was not supplied ($k_1>k_2$); and the ammonia concentration was similar in both experiments, keeping 90 °C in the top of the mini-column.

On the other hand, on an industrial-scale, according to the Ni/S and NH$_3$/CO$_2$ ratio in the Product-liquor, ten dataset were conformed, and similar interactions were obtained like these previously exposed. From Figure 5, for a liquor characterized by Ni/S 1.2, Ni/[SO$_4^{2–}] = 2.5, Ni/[S$_2$O$_3^{2–}] = 1.7$ and NH$_3$/CO$_2$ 1.63, at pH<9.08 while the $[NH_3]$ concentration decreased following a potential function ($R^2 = 96.8\%$), the $[Ni^{2+}]$ dissolved had a second-order polynomial tendency ($R^2 = 94.08\%$) and at pH< 8.5, the nickel concentration in the BNC suspension began to increase, due to the $[Ni^{2+}]$ leaching of the BNC molecule (over-distillation).

These experimental results showed the possibility of controlling the distillation operation, setting a pH range in
the BNC suspension, in the outflow of the columns, at the minimum expenses due to ammonia losses and reagent consumption for the chemical precipitation of the dissolved nickel. Other similar experimental results have already been reported.\textsuperscript{2,8,9}

3.2. Effect of Sulfur on the BNC Chemical Composition

The chemical-physical characterization of Basic Nickel Carbonate was performed, with regard to the nickel (Ni), cobalt (Co), magnesium expressed as magnesium oxide (MgO), carbon dioxide (CO\textsubscript{2}), sulfur (S) concentration and the real and apparent density; the average values are shown in table 1. The mean diameter ranged from 19 to 32 mm.

In the mini-column, when the [CO\textsubscript{2}] in the BNC increased, a tendency to decrease the [S] was obtained, with a second-order polynomial function and coefficient of determination, \( R^2 \), 92.1\%, (Fig. 6). From the experimental design, the biggest concentration of CO\textsubscript{2} in the BNC molecule was obtained at lowest thermal profile in the mini-column (low temperature and high flow), but the nickel dissolved at the mini-column effluent was high because of pH value 9.75 (+/–0.07), at sub-distillation conditions (see Fig. 3).

When CO\textsubscript{2}-rich solution was fed in the steam-stripped mini-column, the CO\textsubscript{2} in the BNC molecule increased (table 1, Stage 02) as well as the mean diameter of particle from 24 to 32 mm. The specific resistance presented by the filter cake diminished from 20 to 5 \( \times \) 10\textsuperscript{6} m\( \cdot \)kg\textsuperscript{−1} and the membrane resistance was constant equal to 1.5 \( \times \) 10\textsuperscript{9} kg\textsuperscript{−1}; the moisture content in filter cakes decreased from 70\% to 63\%, which benefits the subsequent process of filtration and calcination as for the productivity and energy consumption.

On the other hand, for the industrial process, the ionic composition of the Product-liquor was variable. In the period characterized by a carbonation in the range 1.60 \( \leq \) NH\textsubscript{3}/CO\textsubscript{2} < 1.80, when the [CO\textsubscript{2}] in the BNC increased, the sulfur (S), although first it had a tendency to increase between 0.2\% and 0.5\%, later it decreased as a second-order polynomial function, a similar result to those obtained in the mini-column, Fig. 7.

From Figure 7, it can be seen the strong dependence of the sulfur (% in the BNC with regard to the sulfur dissolved (g \( \cdot \) L\textsuperscript{−1}) in the Product-liquor: to lower [S] dissolved and higher Ni/S ratio, the sulfur concentration in the BNC was lower. However, for an [NH\textsubscript{3}/CO\textsubscript{2}] ratio greater than 1.80 in the Liquor, the [S] increased with a directly proportional relationship with the [CO\textsubscript{2}] in the BNC. Then, a correct carbonation of the Liquor, as well as feeding CO\textsubscript{2}-rich

| Experimental stage | Ni  | Co   | MgO  | CO\textsubscript{2} | S     | Density (kg/m\textsuperscript{3}) |
|-------------------|-----|------|------|---------------------|-------|-------------------------------|
| 01                | 47.1| 0.38 | 0.20 | 7.38                | 3.04  | 2.98                          |
| 02\textsuperscript{1} | 47.8| 0.43 | 0.09 | 9.68                | 2.39  | 2.85                          |
| 02\textsuperscript{2} | 47.4| 0.40 | 0.07 | 7.45                | 4.12  | 2.86                          |
| 03                | 48.5| 0.35 | 0.28 | 3.34                | 5.96  | 2.89                          |

\textsuperscript{1} Distillation of Product-liquor with CO\textsubscript{2}-rich solution \textsuperscript{2} Distillation without this dissolution

Vargas et al.: Ammoniacal Carbonate Leaching: Effect ...
solution by a side tray of the steam-stripped column, increases the selectivity towards the carbonate formation in the BNC molecule with sulfate decreasing, which is favorable for the calcination process reducing the energy consumption.

Regarding the effect of the pH of the BNC suspension, the sulfur concentration decreased in the BNC molecule with the increase in the alkalinity of the suspension (7.7 ≤ pH ≤ 9.1), which suggests that the thermodynamic equilibrium of the system tend to increase the relative stability (predominance) of NiCO₃ while deceases for NiSO₄, although both species coexist in the solid phase (Fig. 8 and Fig. 9). Figures 5 to 9 also suggest that under over-distillation conditions, nickel leached appreciably with a strong dependence on sulfur concentration.

3. Sulfur Effect on the Operating Expenses

Operating expenses, (G), were calculated for 10 data-set, and these were plotted as a pH function in the BNC suspension at the bottom outlet of the columns. The average values of sulfur concentration (g : L⁻¹), ratio Ni/S, Ni/[S₂O₃²⁻] and Ni/[SO₄²⁻] in the Product-liquor, were included in the graph, for the dataset that overlapped in the expense curve, in the interval 8.2 ≤ pH ≤ 8.7, (Fig. 10).

As shown in Figure 10, for the periods of operation characterized by carbonation according to 1.60 ≤ NH₃/CO₂ < 1.80 in the Product-liquor, between pH 8.3 and pH 8.7, there were a directly proportional relationship between the expenses and dissolved-sulfur concentration, and inversely proportional to the Ni/[S₂O₃²⁻] ratio; there-

Figure 7. Interaction between sulfur and carbon dioxide in the Basic Nickel Carbonate, industrial process (Stage 03). The [S] concentration (g·L⁻¹) and the [Ni/S] ratio in the Product-liquor can be appreciated. 1.60 ≤ NH₃/CO₂ < 1.80.

Figure 8. Interaction between sulfur contained in the BNC and pH suspension, mini-column (Stage 01).

Figure 9. Interaction between sulfur contained in the BNC and pH suspension, industrial process (Stage 03). 1.60≤NH₃/CO₂<1.80.

Figure 10. Operating expenses in pH function (1.60≤NH₃/CO₂<1.80). The [S] average concentration (g·L⁻¹), [Ni/S], [Ni/[S₂O₃²⁻]], [Ni/[SO₄²⁻]] ratio in the Product-liquor can be appreciated (Stage 03).
fore, at a low sulfur concentration and a high Ni/[S\text{O}_2\text{O}_3^{2−} \text{]} \text{ ratio, the expenses for ammonia losses and the consumption of nickel precipitation reagent decrease. This tendency was similar for carbonation corresponding to } 1.80 \leq \text{NH}_3/\text{CO}_2 \leq 2.0. \text{ The nickel cation concentration tends to increase, coordinated with } [\text{S}_x\text{O}_y\text{O}_z^{2−}] \text{ ligand, thus the operating expenses augments.}

The economic benefit (A) was calculated for several pH ranges. The greatest economic benefit of 0.125 ($ \cdot h^{-1}$) per (m$^3 \cdot h^{-1}$) of Product-liquor was obtained in the range $8.4 \leq \text{pH} \leq 8.7$ (Fig. 11, curve A). The losses are represented to $A \leq 0$, consequently, the operation for pH doesn’t produce an economic benefit due to the high operation expenses, so, should be avoided operating in pH ranges less than 8.0 in the BNC suspension. The curve B was estimated by increasing the price of ammonia and the precipitation reagent by 70%; and the curve C, modifying only the ammonia price by that same percent.

**Figure 11.** Interaction of suspension pH with the economic benefit (A, $\text{S} \cdot \text{h}^{-1}$ per m$^3 \cdot \text{h}^{-1}$), regarding ammonia losses and nickel precipitation consumption.

### 3.4. Nickel Leaching of BNC Molecule by Effect of Dissolved Sulfur

The nickel leaching of the Basic Nickel Carbonate in the distillation process, occur due to the interactions between the variables ionic species concentration in the liquid medium (system Ni(II)-NH$_3$-CO$_2$-SO$_2$-H$_2$O) and the chemistry composition of the BNC molecule, which, in turn, depends on the chemical composition of the Product-liquor that is fed to the process, the thermal profile in the columns and pH in the BNC suspension.

The sulfur ions [S$_x$O$_y$O$_z^{2−}$] will be present in the solution; these are formed by oxidation of the sulfur that is incorporated to the process with the petroleum. On the other hand, the equilibrium NH$_4^+$/NH$_3$ and HCO$_3^−$/CO$_3^{2−}$ depend on the suspension pH. The following reactions are proposed: Eqs. (18)–(22):\textsuperscript{2,21}

\[
\begin{align*}
\text{NiSO}_4 + n\text{NH}_3 + n\text{OH}^- &\rightarrow \text{Ni(NH}_3)_n\text{SO}_4 + H_2O \quad (1 \leq n \leq 5) \\
\text{NiCO}_3 \cdot (\text{NH}_4 \text{)}_2 \cdot (\text{NH}_3 \cdot \text{H}_2\text{O}) \rightarrow \text{Ni(NH}_3)_n\text{SO}_4 + CO_2 + H_2\text{O} \quad (0 \leq n \leq 2) \\
\text{Ni(OH)}_2 \cdot (\text{NH}_4 \text{)}_2 \cdot (\text{NH}_3 \cdot \text{H}_2\text{O}) &\rightarrow \text{Ni(NH}_3)_n\text{SO}_4 \cdot 4H_2\text{O} \quad (1 \leq n \leq 4) \\
\text{Ni(OH)}_2 \cdot (\text{NH}_4 \text{)}_2 \cdot (\text{NH}_3 \cdot \text{H}_2\text{O}) &\rightarrow \text{Ni(NH}_3)_n\text{SO}_4 \cdot 3H_2\text{O} \quad (1 \leq n \leq 4) \\
\text{Ni}^{2+} + n\text{NH}_3 \text{OH} + (n-1)\text{NH}_3 + CO_2 \cdot (n-1)H_2\text{O} &\rightarrow \text{Ni(NH}_3)_n\text{CO}_3 + nH_2\text{O} \quad (2 \leq n \leq 6)
\end{align*}
\]

When the sulfur concentration increases in the Product-liquor, the selectivity towards sulfate formation in the BNC molecule increases while the carbonate formation decreases (Fig. 6 and Fig. 7); this favors the nickel leaching of the BNC molecule (Fig. 8 and Fig. 9), increases the Ni cation in solution and the operational costs (Fig. 10).

The complex compounds concentration, simulating the species ionic in the steam-stripped columns discharge, were determined at [NH$_3$] 0.01M, [CO$_3^{2−}$] 0.1M, [SO$_4^{2−}$] 0.02M and [S$_2$O$_3^{2−}$] 0.01M. The measure that diminishes the pH in the BNC suspension in the columns effluents, the nickel cation concentration tend to decreasing coordinated with [NH$_3$] ligand with high coordination number, but tend to increasing with [S$_x$O$_y$O$_z$] ligands, propitiating the nickel leaching of the BNC molecule, (Fig. 12).

**Figure 12.** Log concentration of nickel complex compounds, [NH$_3$] 0.01M, [CO$_3^{2−}$] 0.1M, [SO$_4^{2−}$] 0.02M, [S$_2$O$_3^{2−}$] 0.01M

The predominance area diagram, (Fig. 13), represent thermodynamic stability area of solid and aqueous species, in function of pH and [CO$_3^{2−}$] anion concentration, under...
approximately the same conditions when the deep precipitation of BNC begin: pH < 10.33, Ni(II) 0.14M, [NH₃] 1.2M, [SO₄²⁻] 0.03M and –0.7 ≤ log[CO₃²⁻] ≤ –0.16. Based on this diagram, at higher carbonation of the Product-liquor, the thermodynamic stability area of NiCO₃ increases, while it decreases for the Ni(OH)₂; furthermore, it is important to control the pH, in order to reduce the tendency to NiSO₄ conversion, (Fig. 8 and Fig. 9). The experimental results have shown that when a Product-liquor is fed with low sulfur concentration, the highest Ni/S and Ni/[S₅O₇²⁻] ratio, NH₃/CO₂ < 1.8, as well as CO₂-rich solution by a side trays of the columns, it is also favorable to reducing the dissolved nickel, improve the BNC composition and its chemical-physical properties, (Fig. 4).

Using the complementary norm for the operation control by pH (8.4 ≤ pH ≤ 8.7), it is possible to adjust the thermal profile in the steam-stripped columns to reduce the nickel leaching from the BNC molecule and the [Ni²⁺] cation in solution, which allow to reduce expenses due to ammonia losses and in the nickel chemical precipitation process; in addition, the chemical-physical properties of BNC are improved, favoring the subsequent filtration and calcination processes. It is proposed to measure the pH at 25 °C in the BNC suspension at the columns outlet. If pH ≤ 8.4 (over-distillation), the temperature at the top of the column should be lowered by reducing the steam flow until reaching a pH in the recommended range; but if pH ≥ 8.7 (sub-distillation), the temperature should be raised by increasing the steam flow.

4. Conclusions
The distillation process in the Ammoniacal Carbonate Leaching technology was studied at bench-scale and industrial, in order to determine the dissolved sulfur effect in the Product-liquor that feeds to the steam-stripped columns, over the Basic Nickel Carbonate (BNC) properties and the operation expenses.

The BNC general structure is (NiCO₃)ₓ · (Ni(OH)₂)ᵧ · (NiSO₄)z · nH₂O. When increasing the sulfur concentration in the liquor, augment the selectivity towards the [SO₄²⁻] formation with diminishing of [CO₃²⁻] in the molecule; also, when decreases the alkalinity of the BNC suspension (7.8 ≤ pH ≤ 10.0) the thermodynamic stability area of NiSO₄ tend to increasing, which affects the operation expenses due to the sulfur requires high energy consumption for the thermal decomposition in the calcination process.

The concentration of species ionic in the system Ni(II)-NH₃-CO₂-SO₂-H₂O is dependent of pH, when decreases the alkalinity of the suspension the nickel is leached from the BNC, increases Ni(II) cation in solution because of complex reaction with [SO₄²⁻] and [S₂O₃²⁻] ions; therefore, it goes up consumption precipitation reagent and the operation expenses.

Feeding carbonated Product-liquor in the range 1.60 ≤ NH₃/CO₂ < 1.80 and CO₂-rich solution increase the CO₂ in the BNC with decreasing of sulfate; thus, the mean diameter particle increase, the filtration specific resistance and the cake moisture diminishes, which increase the productivity and decrease the energy consumption in the process of filtration and calcination; furthermore, keeping a pH between 8.4 and 8.7 in the columns outlet the greatest economic benefit is obtained of 0.125 ($ · h⁻¹) per (m³ · h⁻¹) of Product-liquor.

V laboratorijskem in industrijskem merilu smo preučevali proces destilacije v tehnologiji amoniakalnega karbonatnega izpiranja. Ugotovili smo, da žvepla v raztopini, ki jo dovajamo na kolone, vpliva na lastnosti bazičnega nikljevega karbonata in obratovalne stroške. S povečanjem vsebnosti žvepla v raztopini smo izboljšali selektivnost pri tvorbi sulfata v molekuli BNC; povečala se je poraba energije pri termičnem razkroju BNC v procesu kalcinacije. Prav tako se je povečala količina niklja raztopljenega v raztopini na kolonah zaradi tvorbe kompleksov z ioni [SO\(_4\)\(^{2-}\)] in [S\(_2\)O\(_3\)\(^{2-}\)], kar je znašalo stroške povezane z obarjalnim reagentom. Če na kolone dovajamo raztopino z dodatkom CO\(_2\) v območju 1.60 ≤ NH\(_3\)/CO\(_2\) < 1.80 povečamo vsebnost CO\(_2\) v BNC ob sočasnem zmanjšanju vsebnosti sulfata, povečamo povprečni premer delcev, zmanjšamo upor pri filtraciji in tako izboljšamo produktivnost in zmanjšamo porabo energije pri filtraciji in kalcinaciji. Z vzdrževanjem pH med 8.4 in 8.7 v iztoku iz kolon dobimo največjo ekonomičnost procesa 0,125 ($ \cdot h^{-1}$) na (m\(^3\) · h\(^{-1}\)) produkta.
