The requirements for new technologies to serve as anticancer agents go far beyond their toxicity potential. Novel applications also need to be safe on a molecular and patient level. In a broader sense, this also relates to cancer metastasis and inflammation. In a previous study, the toxicity of an atmospheric pressure argon plasma jet in four human pancreatic cancer cell lines was confirmed and plasma treatment did not promote metastasis in vitro and in ovo. Here, these results are extended by additional types of analysis and new models to validate and define on a molecular level the changes related to metastatic processes in pancreatic cancer cells following plasma treatment in vitro and in ovo. In solid tumors that were grown on the chorion-allantois membrane of fertilized chicken eggs (TUM-CAM), plasma treatment induced modest to profound apoptosis in the tissues. This, however, was not associated with a change in the expression levels of adhesion molecules, as shown using immunofluorescence of ultrathin tissue sections. Culturing of the cells detached from these solid tumors for 6d revealed a similar or smaller total growth area and expression of ZEB1, a transcription factor associated with cancer metastasis, in the plasma-treated pancreatic tissues. Analysis of in vitro and in ovo supernatants of 13 different cytokines and chemokines revealed cell line-specific effects of the plasma treatment but a noticeable increase of, e.g., growth-promoting interleukin 10 was not observed. Moreover, markers of epithelial-to-mesenchymal transition (EMT), a metastasis-promoting cellular program, were investigated. Plasma-treated pancreatic cancer cells did not present an EMT-profile. Finally, a realistic 3D tumor spheroid co-culture model with pancreatic stellate cells was employed, and the invasive properties in a gel-like cellular matrix were investigated. Tumor outgrowth and spread was similar or decreased in the plasma conditions. Altogether, these results provide valuable insights into the effect of plasma treatment on metastasis-related properties of cancer cells and did not suggest EMT-promoting effects of this novel cancer therapy.

Keywords: epithelial-to-mesenchymal transition, kINPen, plasma medicine, plasma sources, reactive oxygen species, ROS
INTRODUCTION

Cancer is the second leading cause of death worldwide after cardiovascular diseases [1]. Cancer incidence is increasing, and the spectrum of regionally dominating tumors and their mutational burden is heterogeneous. Hence, efficient cancer treatment remains challenging and is one of the significant difficulties of today. However, new concepts of cancer therapies are under investigation. This includes immunotherapies [2], target-specific drugs [3, 4], or technological innovations such as photodynamic [5, 6] and cold physical plasma therapy [7]. Cold physical plasmas are partially ionized gases generating a plethora of reactive species (ROS) besides other components such as electric fields, temperature, light of different wavelengths, and charged particles [8, 9]. At sufficient concentrations, these species mediate oxidation-induced damage and death in tumor cells [7]. Plasma treatment was previously shown to control tumor growth in pre-clinical models effectively [10–12]. Moreover, first patients with tumors of the head and neck benefited from this new therapeutic approach and experienced a reduced tumor burden [10, 11].

Today, increased tumor toxicity is only one of the columns of promising new cancer therapies. The other aspects include tolerability (beneficial ratio between anticancer activity and side effects) and safety aspects, for instance. Such risk assessment includes the investigations of whether a new treatment is void of inducing cancer cell detachment and metastasis. Metastasis is one of the greatest challenges in cancer therapies. Disseminated tumor growth induces organ dysfunction and often hinders surgical resection [12–15]. Especially in pancreatic cancer, the disseminated spread into the peritoneal cavity (peritoneal carcinomatosis) hinders successful cancer therapies [16–23]. Therefore, this type of cancer is a challenging but ideal model to investigate the effect of a novel treatment on cellular detachment and metastatic phenotype.

Treatments with the kINPen argon plasma jet had been shown to be void of genotoxicity according to OECD-based protocols [24–27] and did not introduce cell detachment through physical irritations (argon gas flow), or biological modulations of adhesion markers [28]. Moreover, the absence of tumor formation after six repetitive treatments of skin was validated in a 1-year follow up study in mice [26]. Also, clinicians that treated patients with the kINPen argon plasma jet in similar settings as investigated here (no modulation of feed- or sheath gases), did not report any severe side-effects [29–32]. This study now extends on the previous investigations of four different pancreatic cancer cell lines (MiaPaCa2, PaTuS, PaTuT, and Panc01) and tissue from in ovo-grown tumors, to a more detailed analysis of factors that can mediate an altered cell detachment and outgrowth. This includes (i) adhesion molecules, that are responsible for cell-cell and cell-matrix contact being essential to maintain tissue integrity [33–35], (ii) markers of the epithelial-mesenchymal transition (EMT), that are associated with cancer cell polarization and transformation to a more metastatic phenotype [18, 36, 37], and (iii) molecules of inflammation known to drive or limit inflammation-mediated cellular escape from the bulk tumor mass. In a series of experiments, it was demonstrated that the plasma treatment regime using the kINPen argon plasma jet was safe with respect to the aspects mentioned above and the model systems employed in this study. There were no hints for the promotion of EMT changes or metastasis and therefore further research in this field is strongly encouraged.

MATERIALS AND METHODS

Cell Cultivation and Plasma Treatment

The experiments were carried out with four human pancreatic cancer cell lines: MiaPaCa2 (ATCC: CRL-1420), PaTuS (DSMZ: ACC-162), PaTuT (DSMZ: ACC-204), and Panc01 (ATCC: CRL-1469). The culturing was performed in Dulbecco’s modified Eagle’s medium (DMEM; Pan Biotech, Aidenbach, Germany), which was supplemented with 10% fetal bovine serum, 2% glutamine, and 1% penicillin and streptomycin (all Sigma, Steinheim, Germany) in a cell culture incubator (Binder, Tuttingen, Germany). For co-culture experiments, cells transduced with nuclear fluorescent proteins were used. The pancreatic stellate cell line RLT-PSC (developed at the Faculty of Medicine of the University of Mannheim [38], kindly provided by Prof. Ralf Jesenofsky) was transduced to express nuclear mKate2 (RLT-PSC Red) using a lentiviral vector (Essen BioScience, Essen, Germany). MiaPaCa2 (MiaPaCa2 Green) and Panc01 (Panc01 Green) were transduced to express nuclear green fluorescent protein (Essen BioScience, Essen, Germany). Cells were cultured in DMEM-F12 medium (Gibco, Dreieich, Germany). For experiments, absolute cell counting was performed using an Attune NxT flow cytometer (Thermo Scientific, Waltham, USA), and seeding was done in Roswell Park Memorial Institute medium 1640 (RPMI; Pan Biotech, Aidenbach, Germany) with similar supplements as for DMEM. For FACS experiments, 2 × 10⁴ cells per well were seeded in 96-well flat-bottom plates (Eppendorf, Hamburg, Germany). For three-dimensional tumor spheroids, 3 × 10⁵ cells per well in medium containing 0.24% Methocel (ratio 2:1, 2 × 10⁵ RLT-PSC, 1 × 10³ pancreatic cancer cells) were seeded in ultra-low attachment plates (Nunclon Sphera; Thermo Scientific, Waltham, USA). For seeding on the chorion allantois membrane of fertilized chicken eggs (TUM-CAM model), 2 × 10⁹ cells were supplemented with 15 µl Matrigel (Corning, New York, USA).

Before plasma treatment, the cells were cultured for an additional 24 h (FACS experiments), 72 h (spheroid experiments), and 96 h (TUM-CAM model). Plasma treatment was done using high-purity (99.9999%) argon gas (Air Liquide, Paris, France) at two standard liters per minute running the atmospheric pressure argon plasma jet kINPen (neoplas tools, Greifswald, Germany). The plasma treatment of co-cultured spheroids (in 150 µl PBS and medium exchange 90 min later) was done for 120 s and standardized using an xyz-table (CNC Step, Gelfern, Germany), which fixed the plasma jet and operated the computer-driven treatment protocol.

In ovo Experiments

Specific pathogen-free chicken eggs (Valo BioMedia, Osterholz-Scharmbeck, Germany) were incubated in an egg incubator (Thermo de Luxe 250, Hemel, Verl, Germany) at 37.5°C and...
65% humidity at constant turning (for the first 6 days). The preparation of the eggs' chorion-allantois membrane (CAM) as well as the treatment was performed as described before [28]. Briefly, the tumor cells were implanted at day 8 of the incubation, and the plasma treatments were performed at days 12 and 14. The cell floaters were detached from the tumors by gently pipetting 150 µl of growth medium (RPMI) up and down and collecting the supernatant after the second plasma treatment. A part of the supernatant was stored for cytokine quantification, and the detached cell floaters were further incubated in vitro for the following 6 days (144 h). For this, flat-bottom 96-well cell culture plates (Eppendorf, Hamburg, Germany) were utilized that supply a ring which was filled with water to prevent excessive evaporation of culture medium during that time. After incubation, cells were subjected to imaging and flow cytometry analysis.

Tumor Tissue and Live-Cell Imaging

Tissues from the in ovo grown tumors were explanted from the CAM and embedded in OCT medium (Tissue-Tek; Sakura Fintek, Alphen aan de Rijn, Netherlands) before freezing in liquid nitrogen and storage at −80°C. Ultrathin tissue sections were cut (5 µm) and mounted (Dako fluorescence mounting medium; Agilent Technologies, Santa Clara, USA) on microscopy slides. For the quantification of apoptotic cells, the In situ Cell Death Detection Kit (TUNEL red; Roche, Basel, Switzerland) was utilized according to the manufacturer’s instructions. For nuclear counterstaining, diamide-2-phenylindol (DAPI; BioLegend, San Diego, USA) was used. For the staining of cellular adhesion molecules, the tissue slides were fixed with 4% paraformaldehyde (PFA) and permeabilized with Triton-X (both Sigma Aldrich, St. Louis, USA). Blocking was performed with 5% bovine serum albumin (BSA; Sigma Aldrich, St. Louis, USA) before they were stained with the respective antibodies targeting CD49b conjugated with phycoerythrin (PE; clone: P1E6-C5; BioLegend, San Diego, USA), CD326 conjugated with AlexaFluor (AF) 488 (clone: 9C4; BioLegend, San Diego, USA), and CD324 conjugated with AF647 (clone: EP700Y; Abcam, Cambridge, UK). The images were acquired using a BZ-9000 fluorescence microscope (Keyence, Frankfurt, Germany). The ratio of TUNEL+ cells over the area of the tissue region was quantified utilizing the image analysis software ImageJ.

For the investigation of cultured ex ovo tumor cell floaters, and in vitro grown three-dimensional tumor and pancreatic stellate cell spheroids, high content imaging was performed utilizing the Operetta CLS imaging system (PerkinElmer, Waltham, USA). The ex ovo floaters were fixed and permeabilized as described above and were imaged with a 20 × air objective (NA = 0.4; Carl Zeiss, Jena, Germany) acquiring brightfield as well as fluorescence images at λ ex 365 nm and λ em 430–500 nm for the detection of DAPI, and λ ex 630 nm and λ em 655–760 nm for the detection of Zinc finger E-box-binding homeobox 1 (anti-ZEB1 AF700, clone: 639914, R&D Systems / biotechne, Minneapolis, USA). For the algorithm-driven (Harmony 4.9; PerkinElmer, Waltham, USA) image and cell quantification strategy, a pseudo-fluorescence channel was calculated by merging the fluorescence channels. The total cellular proliferation area resulting from the initial cell floaters added as well as the ZEB1 fluorescence intensity inside that growth area was calculated. The three-dimensional tumor and stellate cell spheroids were imaged 72 h after their treatment with plasma. This was done utilizing a 5 × objective (NA 0.16; Carl Zeiss, Jena, Germany) capturing the brightfield channel, as well as the fluorescence channels for the detection of GFP-expressing tumor cells at λ ex 475 nm and λ em 500–550 nm, and for mKate-expressing stellate cells at λ ex 560 nm and λ em 570–650 nm. The detection of the spheroid area was done by creating a pseudo fluorescence image out of the merged fluorescent channels and an inverted brightfield image, which had the highest intensities in the area of spheroid growth. The cell outgrowth was calculated by determining the number of cells outside the spheroid region. Their distance to the spheroid border region was calculated automatically based on algorithms implemented in the quantitative imaging software.

Flow Cytometry

To quantify the expression of adhesion molecules and markers of the epithelial-to-mesenchymal transition (EMT), the cells were treated in 96-well flat-bottom plates and were harvested 24 h later with accutase (Pan Biotech, Aidenbach, Germany). Subsequently, the cells were transferred to a u-bottom plate (Nunclon; Thermo Scientific, Waltham, USA) and were fixed and permeabilized. The cells were stained with DAPI and antibodies targeting αSMA conjugated with AF594 (clone: 1A4; Abcam, Cambridge, UK), anti-vimentin conjugated with PerCP/Cy5.5 (clone: H84; Santa Cruz Biotechnology Dallas, USA), and anti-ZEB1 conjugated with AF700 (clone: 639914; R&D Systems, Minneapolis, USA). After washing, cells were acquired with a Cytoflex S (Beckman-Coulter, Brea, USA) flow cytometer. The expression of the markers was quantified in viable (DAPI−) cells and normalized to that of untreated cells. Unstained controls were treated like their counterparts and were acquired using the same settings. Data analysis was done using Kaluza 2.1 (Beckman-Coulter, Brea, USA).

Quantitative Polymerase Chain Reaction (qPCR)

The cell lines were cultured in optimal growing conditions before they were harvested with the enzyme accutase, and cell pellets were generated via centrifugation and washing of the cells. Afterward, they were suspended in lysis buffer, and cellular RNA was isolated utilizing an isolation kit according to the manufacturers’ instructions (RNA Mini Kit; Bio&SELL, Feucht, Germany). The RNA was quantified using a NanoDrop 2000C (Thermo Scientific, Waltham, MA, USA). Quantitative polymerase chain reaction (qPCR) was then carried out with 1 µg RNA that was synthesized into cDNA using a thermocycler device (Thermo Scientific, Waltham, USA). For these experiments, 96-well v-bottom plates loaded with Sybr Green (BioRad, Munich, Germany) were used to label the mRNA-targets during 50 heat cycles (Light Cycler 480; Roche, Mannheim, Germany). Expression levels were calculated with formulas provided by the 2−ΔΔCt method and in relation to GAPDH.
Quantification of Chemokine/Cytokines
Supernatants for chemokine/cytokine analysis of cancer cells were collected 4 h post-treatment of the in vitro experiments. Supernatants were stored in 96-well plates at −80°C. For detection of the soluble inflammatory mediators (chemokines/cytokines), the LEGENDplex (BioLegend, San Diego, USA) bead-based immunoassay was utilized. The experiments were carried out according to the manufacturer’s instructions. The targets of the assay were the following: interleukin (IL) 1β, IL6, IL8, IL10, and IL12p70, free-active tumor growth factor β (TGFβ), tumor necrosis factor α (TNFα), interferon γ (IFNγ), C-X-C motif chemokine ligand 1 (CXCL1), CXCL10, arginase, C-C motif ligand 17 (CCL17/TARC), and vascular endothelial growth factor (VEGF). All 13 targets were quantified simultaneously, each with specific standards and limits of detection. Staining and measurement of samples were done in v-bottom 96-well plates (Eppendorf, Hamburg Deutschland), from which the fluorescent beads were directly acquired with a flow cytometer (CytoFlex; Beckman Coulter, Brea, USA). The discrimination between the 13 different beads was done using differences in forward and side scatter (FSC, SSC) and fluorescent intensity at λex 638 nm and λem 640–680 nm. By analyzing the fluorescence intensity of PE-labeled antibodies (λex 561 nm and λem 564–606 nm) detecting the targets bound to the beads, the absolute concentration of all factors was interpolated using polynomial functions of the 5th degree and dedicated data analysis software (Vigene Tech, Carlisle, USA).

Statistical Analysis
Data are from two to six experiments with several technical replicates. For statistical analysis and graphing, Prism 8.4.2 (GraphPad, San Diego, USA) was utilized. Multiple comparisons

(B) DAPI and TUNEL-stained tissue from in ovo-grown MiaPaCa2 tumors that (I) were left untreated or (II) plasma-treated for 2 × 60 s, and (C) quantification of TUNEL+ apoptotic cells per mm² of tissue. (D) DAPI and TUNEL-stained tissue from in ovo-grown PaTuS tumors that (I) were left untreated or (II) plasma-treated for 2 × 60 s, and (E) quantification of TUNEL+ apoptotic cells per mm² of tissue. (F) DAPI and TUNEL-stained tissue from in ovo-grown PaTuT tumors that (I) were left untreated or (II) plasma-treated for 2 × 60 s, and (G) quantification of TUNEL+ apoptotic cells per mm² of tissue. (H) DAPI and TUNEL-stained tissue from in ovo-grown Panc01 tumors that (I) were left untreated or (II) plasma-treated for 2 × 60 s, and (I) quantification of TUNEL+ apoptotic cells per mm² of tissue. Arrows in the images indicate a significant (↑↑), and a moderate (↑) increase of apoptosis. The data display the distribution of the values with their mean (red line) as well as 25 and 75% quartiles (dotted lines). The magnification of all images was 20×. The data are from at least 4–5 eggs per group. Scale bar is 500 µm.
were done with ANOVA (with Welch’s correction). For comparison between two adjacent groups, the Welch’s t-test was used. The levels of significance are indicated in the figures as asterisks: $\alpha = 0.05$ (*), $\alpha = 0.01$ (**), and $\alpha = 0.001$ (**).

RESULTS

Plasma Treatment Partly Elicited Apoptosis of Pancreatic Cancer Cells Grown in ovo

To test the anticancer efficacy of cold physical plasma generated via the kINPen, different pancreatic cancer cell lines (MiaPaCa2, PaTuS, PaTuT, and Panc01) were seeded on the chorion-allantois membrane of fertilized chicken eggs (TUM-CAM model) to grow solid tumors before these were plasma-treated twice for 60 s on two consecutive days (Figure 1A). The induction of apoptosis was different among the cell lines tested. A significant effect ($p < 0.044$) of plasma treatment was observed in MiaPaCa2 tumors (Figures 1B,C). An apparent increase in the apoptosis rate (TUNEL+ cells) was visible in the tumor surface region, and to a lower amount also in deep tissue layers (Figure 1B). In contrast, PaTuS cells did not show large rates of apoptosis after plasma treatment ($p < 0.764$; Figures 1D,E). Similar results were obtained for PaTuT cells ($p < 0.331$) (Figures 1F,G). For Panc01 tumors, a modest increase ($p < 0.082$) of apoptotic cells was observed in the plasma treatment conditions, especially at the tumor margins (Figures 1H,I).

Plasma Treatment Did Not Affect the Adhesion Marker Profile of in ovo-Grown Tumors

Cellular adhesion is a critical factor in tumor metastasis. In addition to the mechanical spread of tumor cells through invasive measures, endogenous metastasis occurs when cells actively detach from their mass and migrate into blood vessels and lymph nodes. Therefore, the expression of adhesion molecules in untreated and plasma-treated tumors was investigated. Tissue sections were prepared, and tissue slides were stained for the cell adhesion markers integrin alpha-2 (CD49b; Figure 2A), E-cadherin (CD324; Figure 2B), and Ep-CAM (CD326; Figure 2C). It was found that CD49b was expressed across all different tumor cell lines, albeit to a different extent. CD324 was highly expressed only in PaTuS but not in the three
other tumor cell lines. CD326 expression was found in MiaPaCa2 and PaTuS tumors, but only to a negligible extent in PaTuT and Panc01 tumors. Interestingly, the growth pattern of PaTuS tumors was changed following the treatment with plasma to a more glandular, epithelial phenotype. A decrease in E-cadherin and Ep-CAM is a known indicator of pro-metastatic cancer phenotypes, suggesting plasma treatment not to interfere with such processes.

**Plasma Treatment Neither Promoted Cell Detachment Nor Expression of ZEB1**

After analyzing the toxicity and adhesion-related receptor expression in solid pancreatic cancer tissue, the next question was whether plasma treatment actively engaged the dislodgement of individual cells from the main tumor. This might occur due to, e.g., argon gas pressure, electrical discharges, drying of the outer tumor surface, and ROS-mediated breakage of cell-cell connections. The experiment was done by plasma treatment of the tumors and washing the tumors immediately afterward. The cells that were contained in the washing solution (cell culture medium) were then seeded into cell culture plastic and allowed to grow for 6 days (144 h). This was necessary, as the number of cells retrieved directly in the washing solution was too low to perform intelligent imaging analysis. After 6 days, the cell growth was calculated using a software-based method that was utilizing a filtered image to detect the area of these cell floaters (Figure 3A). In MiaPaCa2 cells, it was found that the cell growth non-significantly decreased with plasma treatment, while PaTuS and PaTuT cells contained in the washing liquid overall failed to proliferate significantly in vitro (Figure 3B). In both cell lines, the growth area was similar or smaller in the plasma treatment condition. This does not suggest that these cells do not grow in vitro, but rather the cells detached from the original tumor mass were mostly not viable or too low in numbers. Panc01 cells, in contrast, had a large growth area in the control group, which significantly declined in the plasma treatment group (Figure 3B). These results suggest that plasma treatment either did not promote the detachment of pancreatic tumor cells from the bulk tumor mass or that detachment was promoted, but the cells were dead, unable to proliferate, or both. The next question was whether the cells that grew in vitro changed their expression levels of the zinc finger e-box binding homeobox 1 (ZEB1) transcription factor, known to be associated with the mesenchymal transition of cancer cells [18]. ZEB1 was detected in the highest amount in MiaPaCa2 and Panc01 cells, and both of these cell lines showed a reduction of ZEB1 expression in the cells initially detached from the plasma-treated bulk tumor mass (Figure 3C), suggesting a decreased EMT phenotype.

**Plasma Treatment Modulated the Inflammatory Profile in vitro and in ovo**

Inflammation is one key aspect in tumor metastasis, and cytokines and chemokines are the major regulators of inflammation. Therefore, 13 different soluble mediators of inflammation were quantified in supernatants of in vitro and in ovo experiments (Figure 4). All data were normalized to that of untreated controls, while crossed out boxes indicate concentrations above or below the detection limit of the assay. Arrows indicate a 2-fold up or downregulation. Three is an only partial agreement between the in vitro and in vivo results, exemplifying the need to address research questions in both systems. Panc01 showed a consistent downregulation of almost all cytokines investigated in vitro and in ovo, except VEGF and IL8. By contrast, in vitro supernatant analysis of MiaPaCa2 and PaTuT revealed only upregulation of cytokines for IL6 and TNFα in both cell lines, and IL1β and TNFα in MiaPaCa2. The results for PaTuS were mainly analogous to those retrieved for PaTuT, except for an increase in CCL17 and a decrease in IL8 and CXCL1. While some of the results were similar to those seen in the ovo samples (e.g., for IL6 and TNFα), some were different either in amplitude or direction of regulation. This was expected, as the CAM provided a nutritious and vascularized tumor microenvironment in which the cells modulate the expression of several genes associated with, e.g., extracellular matrix generation, differentiation, and
Plasma Treatment Did Not Induce an EMT Phenotype in Pancreatic Cancer Cells

In vitro

PaTuT and PaTuS cells only showed few cell detachment in the in ovo experiments. However, they had the most vital changes in cytokine expression among the tested cancer cell lines. Hence, it was tested if the plasma treatment induced a more invasive mesenchymal phenotype (EMT) that is associated with tumor cell metastasis and growth. The expression of α-smooth-muscle actin (αSMA), was unaffected, while vimentin was slightly increased ($p < 0.1$; Figures 5A, B) in PaTuS cells. ZEB1 was not found to be expressed in PaTuS cells (Figures 5A, B). In PaTuT cells, αSMA did not show any change in the cells after exposure to plasma (Figures 5A, C). Vimentin and ZEB1 gave a modest, non-significant upregulation after plasma treatment (Figures 5A, C). Another marker that is protective against tumor invasion and angiogenesis is the Tissue inhibitor of metalloproteinases 2 (TIMP2) [39]. Therefore, the expression of TIMP2 was investigated among all pancreatic cancer cell lines that were tested in this study. PaTuS cells showed the highest gene expression of TIMP2, followed by MiaPaCa2. The expression in both of the cell lines was significantly different compared to PaTuT and Panc01 cells, which had low levels of TIMP2 (Figure 5D).

Plasma Treatment Reduced the Cancer Cell Outgrowth in a Stellate Cell-Matrix-3D-Model

To provide a tumor microenvironment that could be monitored via fluorescence microscopy, a co-culture of human pancreatic stellate and cancer cells was setup. The former are myofibroblasts contributing to matrix formation and remodeling. The 3D tumor spheroid mixtures were exposed to plasma and embedded into a basement membrane matrix (growth factor reduced Matrigel) containing mainly laminin and vimentin collagens providing growth conditions for the cells [34] that allow the analysis of the evasion of the fluorescently labeled cells from the bulk tumor over time using quantitative multicolor fluorescence live-cell microscopy. MiaPaCa2 and Panc01 cells showed the highest release of floaters that had detached from the bulk tumor and grown in vitro (Figure 3B). Therefore, these two cell lines were used in this model as we expected a high degree of motility. Plasma treatment reduced the size area of the core spheroid in both cancer cell types co-cultured with stellate cells (Figure 6A). Interestingly, the stellate cells had a higher capacity of exiting the core spheroid into the extracellular matrix (Figures 6B, E, orange cells). Quantification of the absolute number (Figure 6F) as well as their mean migration distance (Figure 6G) significantly decreased with plasma treatment of Panc01 cells co-cultured with stellate cells in 3D spheroids.
DISCUSSION

Pancreatic cancer is an aggressive and fast-growing tumor entity [40, 41]. It is often diagnosed at very late stages after there are already metastases in the liver or lungs. Peritoneal metastases may also be present at this time [41, 42]. Even with surgery in a resectable tumor, the number of R0 resections (no tumor tissue in the respective margins) remains low [43, 44]. Pancreatic cancer has a poor prognosis, and the importance of cell residuals is outlined by the median survival that drops from 25.1 months (for R0) to only 15.3 months with R1 resection [16]. A combination with plasma treatment might become an additive approach to existing surgical and chemotherapeutic strategies to tackle the tumor cell residuals at the surgical margins of the pancreas. Additional treatment of these cancer cell residuals might be able to decelerate the rapid course of cancer remission observed in most patients. Plasma treatment showed promising effects against pancreatic cancer cells in vitro [45–48] and in vivo [49–52]. However, the possibility of inducing a more metastatic phenotype in the cells surviving the treatment is underexplored. Early studies with experimental plasma jets showed an increase in cellular detachment [53–55]. Recent investigations did not report any cellular detachment in the TUM-CAM or spheroid model [28, 34], or a lack of EMT marker modulation after cellular exposure to plasma-oxidized medium [23].

In our previous work, it was shown that plasma treatment introduced cellular toxicity in vitro and reduced the tumor mass of tumors grown on the chorion-allantois membrane of fertilized...
FIGURE 6 | Plasma treatment reduced cancer cell outgrowth in a matrix-3D-tumor model. chicken eggs (TUM-CAM in ovo model) [28]. The TUM-CAM model provides a realistic setting for the growth of solid tumors. It supplies an extracellular matrix, as well as a supply of blood and nutrients through the chicken embryo’s blood vessels [56]. Argon gas flow alone did not alter the metabolic activity of the tested cancer cell in the same setting, and more importantly, did also not significantly detach cells from the in ovo grown tumors. The role of mechanical stress that is applied through a similar plasma treatment can therefore be neglected, indicating the changes in EMT and adhesion marker profile to be more important for the initiation of metastasis. These investigations were now expanded to further downstream analysis of the tumor tissue. Despite a modest to substantial induction of apoptosis in plasma-treated tumor tissue, a change in some of the main cell adhesion molecules was not observed. Cells, including tumor cells, usually firmly adhere to the bulk mass via adhesion molecules, such as CD49b (integrin α-2), CD324 (E-cadherin), and CD326 (Ep-CAM) [15, 28, 57–59].

CD49b is an integrin involved in cellular contacts with laminin and collagen of extracellular matrices. Early work reported MiaPaCa2 cells to be void of CD49b [60], but similar to other studies [28] we found the molecule to be expressed in these and all other cell types. Ep-CAM plays a controversial role in the progression of epithelial tumors. This molecule is an adhesion molecule often found to be overexpressed in non-malignant epithelial. CD326 is also associated with tumor cell signaling (mandatory function in tumor cell invasion) and is—because of its higher expression in cancers—described as a tumor-antigen [61, 62]. Novel therapy approaches also use targeted-therapies against Ep-CAM to prevent tumor growth [63]. However, Ep-CAM was only found expressed in tissue from MiaPaCa2 and PaTuS tumors and was not modulated by their treatment with plasma. Cell-cell contacts are mediated via E-cadherin (CD324), which has a crucial function in preserving tissue stability [58]. Reduced expression or loss of CD324 is associated with a more motile, invasive cancer cell phenotype [64]. In our study, CD324 was only expressed in PaTuS and in PaTuT cells to a modest extent. This corresponds to our finding that both cell lines released the lowest number of viable floaters from in ovo-grown tumors to proliferate in vitro. MiaPaCa2 and Panc01 cells showed only background level of E-cadherin staining in tumor tissues. Subsequently, they showed more in vitro growth from cellular floaters initially detached from the in ovo-grown tumor. Importantly, plasma treatment reduced the amount of MiaPaCa2 and Panc01 cells grown in vitro after in ovo treatment of tumors. Similar findings were made for ZEB1 expression levels in the in vitro cultures. ZEB1 is a transcription factor highly associated with tumor progression and metastasis [65]. It is known that this factor is associated with EMT in pancreatic cancer and leads to signaling cascades changing the cellular polarity and reducing the expression of adhesion markers such as E-cadherin [18, 66, 67]. It is also associated with decreased prognosis in various types of tumors [68]. Besides ZEB1, another EMT marker is the TIMP2, which is involved in the suppression...
of matrix metalloproteinase (MMP) activity and vascularization [39]. MiaPaCa2 and PaTuS cells had higher levels of TIMP2 than PaTuT and Panc01 cells, suggesting these to be vulnerable to cellular outgrowth. Indeed, PaTuT showed more ZEB1 and vimentin expression than PaTuS cells. Also, other markers that are associated with the mesenchymal-like phenotype, such as αSMA, were not changed due to the treatment. These data suggest that plasma treatment was not promoting EMT and metastatic potential of human pancreatic cancer cells in vitro and in ovo. Even more, tumor cells with a more mesenchymal profile, such as Panc01, were particularly sensitive to plasma treatment in terms of reduced outgrowth, as seen in tumor spheroid experiments. In general, spheroids are utilized in several studies utilizing plasma treatments, while most of them are using plasma-oxidized media or lacked an additional extracellular matrix so that no outgrowth was monitored, but showed a strong reduction in the growth of these 3D-models [23, 28, 34, 69–76].

The inflammatory profile in the tumor microenvironment—especially regarding the crosstalk with stromal cells—is decisive in tumor metastasis ever since the discovery of the link between chronic inflammation and tumorigenesis by Rudolf Virchow in 1863 [77–79]. However, the specific traits of inflammation are as heterogeneous as are different tumor types and stages [80], but some universal findings include the pro-angiogenic property of TGFβ and VEGF [81]. While in vitro changes in both molecules were rather modest, we identified an increase in VEGF with plasma treatment in ovo with PaTuS and PaTuT, while VEGF was decreased in MiaPaCa2 and Panc01. It has to be stated, however, that the origin of targets measured in samples from in ovo experiments cannot be explicitly determined (due to, e.g., angiogenesis provided by the chicken embryo as well). Noteworthy, none of the 13 molecules investigated followed the same tendency after plasma treatment, neither in vitro nor in ovo. By contrast, for each cell line, there were clear and consistent patterns. For Panc01, the majority of targets were either similar or markedly decreased, especially in vitro. This supports other findings of this study, pointing to cellular senescence. This pathway has been recently unraveled in Panc01 cells, with miR-137 as a central switch [82] that may have also been activated with plasma treatment but warrants further studies. PaTuS and PaTuT, two sister cell lines with different metastatic potential, showed a similar regulation of chemokines and cytokines release (especially IL6, IL8, CXCL1, and VEGF) despite their different sensitivity to plasma treatment. VEGF production may be a consequence of hypoxia-inducible factor 1α (HIF1α) activation with IL8 serving as another molecule to support angiogenesis [83] and tumor growth [84]. By contrast, IL8 also is positively associated with oxidative immunogenic cancer cell death (ICD) in melanoma cells, together with the activation of dendritic cells [85]. This was similar to the increased levels of IL6 in that study. IL6 is a potent attractor of monocytes/macrophages [86], which can, in turn, be supportive or detrimental for tumor growth, depending on microenvironmental factors [87]. Being the ligand for CXCR2 [88] and a neutrophil chemoattractant [89], CXCL1 is associated with poor prognosis in cancer due to its growth-stimulating, pro-angiogenic properties [90], also in pancreatic cancer [91], by encouraging tumor-stromal interactions. Increased levels of this chemokine were found in PaTuS and PaTuT cells, which at least for PaTuS might explain the different tissue morphology observed for E-cadherin compared to that of PaTuS. Also, an increased release of IFNγ and TNFα was identified following plasma treatment. Both molecules were previously linked to antiproliferative effects in pancreatic cancer cells [92].

CONCLUSION

The results provide valuable insights into the effect of plasma treatment on metastasis-related properties of cancer cells in vitro and in ovo and did not suggest EMT-promoting effects of this novel cancer therapy. For future research, a detailed investigation of the EMT modulation through specific reactive species should be carried out. Although being technically challenging, future studies using in vivo models on cancer metastasis after plasma treatment are needed to validate our findings and the investigations should be extended to other tumor fields and clinical applications also. In addition, plasma treatment should be combined with existing therapies to identify its adjuvant potential.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

Ethical review and approval was not required for the animal study because experiments with chicken embryos were terminated before day 15 from which on these experiments need to be declared to an ethics committee according to national regulations.

AUTHOR CONTRIBUTIONS

SB and AK designed the study. EF, CS, AS, and AP-M performed the experiments. EF and SB analyzed the data and prepared the figures and the manuscript draft. L-IP, AK, and SB supervised the study. AB, TVW, K-DW, C-DH, and SB provided funding and contributed to reagents and models. All authors have contributed the final manuscript.

FUNDING

This work was supported by the German Federal Ministry of Education and Research (grant numbers 03Z22DN11 and 03Z22Di1).

ACKNOWLEDGMENTS

We thankfully acknowledge the technical support by Felix Niessner and Antje Janetzko. We also thank Jonas Van Audenaerde and Evelien Smits for generating the transduced cell lines used in this study.
