Helicase-like transcription factor: a new marker of well-differentiated thyroid cancers

Vanessa Arcolia1, Paula Paci1,2,7, Ludovic Dhont2, Gilbert Chantrain3, Nicolas Sirtaine4, Christine Decaestecker5, Myriam Remmelink6, Alexandra Belayew2† and Sven Saussez1†

Abstract

Background: The preoperative characterization of thyroid nodules is a challenge for the clinicians. Fine-needle aspiration (FNA) is the commonly used pre-operative technique for diagnosis of malignant thyroid tumor. However, many benign lesions, with indeterminate diagnosis following FNA, are referred to surgery. There is an urgent need to identify biomarkers that could be used with the FNA to distinguish benign thyroid nodules from malignant tumors. The purpose of the study is to examine the level of expression of the helicase-like transcription factor (HLTF) in relation to neoplastic progression of thyroid carcinomas.

Methods: The presence of HLTF was investigated using quantitative and semi-quantitative immunohistochemistry in a series of 149 thyroid lesion specimens. Our first clinical series was composed of 80 patients, including 20 patients presenting thyroid adenoma, 40 patients presenting thyroid papillary carcinoma, 12 patients presenting thyroid follicular carcinoma and 8 patients presenting anaplastic carcinoma. These specimens were assessed quantitatively using computer assisted microscopy. Our initial results were validated on a second clinical series composed of 40 benign thyroid lesions and 29 malignant thyroid lesions using a semi-quantitative approach. Finally, the HLTF protein expression was investigated by Western blotting in four thyroid cancer cell lines.

Results: The decrease of HLTF staining was statistically significant during thyroid tumor progression in terms of both the percentage of mean optical density (MOD), which corresponds to the mean staining intensity (Kruskall-Wallis: p < 0.0005), and the labelling index (LI), which corresponds to the percentage of immunopositive cells (Kruskall-Wallis: p < 10−6). Adenomas presented very pronounced nuclear HLTF immunostaining, whereas papillary carcinomas exhibited HLTF only in the cytoplasm. The number of HLTF positive nuclei was clearly higher in the adenomas group (30%) than in the papillary carcinomas group (5%). The 115-kDa full size HLTF protein was immunodetected in four studied thyroid cancer cell lines. Moreover, three truncated HLTF forms (95-kDa, 80-kDa and 70-kDa) were also found in these tumor cells.

Conclusions: This study reveals an association between HLTF expression level and thyroid neoplastic progression. Nuclear HLTF immunostaining could be used with FNA in an attempt to better distinguish benign thyroid nodules from malignant tumors.

Keywords: Biomarker, HLTF, Diagnosis, Tumor suppressor, Thyroid lesions, Cancer
Background
Thyroid cancer is the most common malignant endocrine tumor with an estimated annual incidence of 122,803 cases worldwide [1]. Well-differentiated thyroid carcinomas (papillary and follicular carcinomas) have an excellent prognosis, with 85 to 90% cure rates thanks to early detection and appropriate treatment. Until now, fine-needle aspiration (FNA) was the most commonly used pre-operative technique for diagnosis of a malignant thyroid tumor. However, using ultrasound-guided FNA, this technique showed inconclusive biopsy results in 10-20% of all cases, even with the best hands of radiologist and/or pathologist. Thus, there is an urgent need to identify new biomarkers that could be used in conjunction with the FNA to distinguish benign thyroid nodules from malignant tumors. Such biomarkers may provide crucial knowledge about the biology of well-differentiated thyroid cancers and, most likely, new directions for targeted therapies.

Helicase-like Transcription Factor (HLTF) is a SWI/SNF (mating-type switching/sucrose non-fermenting) protein that presents 7 DNA helicase domains that use the energy of ATP hydrolysis to remodel chromatin in a variety of cellular processes; it was initially characterized for its role in cancer. Moreover, H. Ding et al. [23], suggesting that HLTF is hypermethylated in human colorectal [11-19], gastric [13,20,21], esophageal [13,22] and uterine cancers [13,20,21], esophageal [13,22] and uterine cancers [13,20,21] and after her delineation, the pathological area was analyzed quantitatively by computer-assisted morphometry. In a different model, HLTF induction was detected very early in small pre-neoplastic buds of hamster kidney tumors induced by diethylstilbestrol [25]. Recently, we studied the immunohistochemical expression of HLTF in relation to head and neck squamous cell carcinoma (HNSCC) tumor progression. We showed that HLTF expression increases significantly when comparing carcinomas to normal epithelia or dysplasias [26]. Moreover, high levels of HLTF expression were found to be associated with rapid recurrence rates in a series of 100 hypopharyngeal squamous cell carcinomas (SCC) [26].

We characterized the HLTF mRNAs from HeLa cells by RT-PCR and identified 6 protein forms. One of these forms, the 95-kDa HLTF, was detected along with the 115-kDa full-length protein in both head and neck SCC biopsies. The 95-kDa variant did not contain the 3 carboxyl-terminal helicase domains that are involved in DNA repair [26]. Similarly, the immunoexpression of the 115-kDa full-size HLTF protein increased during carcinogenesis of the uterine cervix but was replaced by truncated forms (95 or 83-kDa) in squamous cell carcinoma [27]. These observations suggested that HLTF expression could also be altered in thyroid carcinogenesis.

Methods
The first part of the study was conducted using thyroid tumor surgical specimens. Immunohistochemical HLTF expression was studied in a clinical series of 149 patients with benign and malignant thyroid lesions. The pathological area was analyzed quantitatively by computer assisted morphometry in 80 cases (in addition to a nuclear assessment) and semi-quantitatively in 69 additional cases. These data were submitted to statistical analysis (Figure 1).

The second part of the study was performed using thyroid cancer cell lines (B-CPAP, TPC-1, FTC133, 8505C and HeLa). Immunocytochemical HLTF expression was examined by immunofluorescence and Western blotting (Figure 1).

Patient’ characteristics
The immunohistochemical HLTF expression was first studied in a clinical series of 80 patients (23 males and 57 females), including 20 patients with thyroid adenoma, 40 patients presenting with thyroid papillary carcinoma, 12 patients presenting with thyroid follicular carcinoma and 8 patients presenting with anaplastic carcinoma. This series was selected by a pathologist (Prof. M. Remmelink, Erasme hospital, Department of Pathology, ULB, Belgium), and after her delineation, the pathological area was analyzed quantitatively by computer-assisted morphometry.

For the second part, we extended our analysis to a series of 40 patients (9 males and 60 females) with benign thyroid lesions, including 10 colloid nodules, 16 follicular adenomas, 7 Hashimoto’s thyroiditis, and 7 Grave’s disease, and to a series of 29 patients with malignant thyroid lesions including 17 papillary carcinomas and 12 follicular variant of papillary carcinomas. These series were selected by the same pathologist (Prof. M. Remmelink, Erasme hospital, Department of Pathology, ULB, Belgium), and
after selection, the pathological area was analyzed semi-
quantitatively.

Ethics Statement
These clinical studies were approved by the Faculty of Medicine and Pharmacy (University of Mons, Belgium) ethics committee (OM 004). A written informed consent was obtained from all patients.

Anti-HLTF antibodies
Two human HLTF protein forms are expressed from the same open reading frame and differ only in the translation start site (Met1 or Met123) [2]. The ART2 rabbit anti-serum was raised against a peptide in the HLTF amino-terminal sequence specific of the full length Met1 form, as previously described in Debauve et al. [25].

The anti-COOH rabbit serum (Eurogentec) is specific to the wild type HLTF proteins (Met1 and Met123) and was raised against a peptide (CFGTKKPNADEMKQAX) that is missing in the HLTF truncated variants.

The anti-HLTF rabbit serum (HPA015284, Sigma) detects all HLTF protein forms and was raised against a peptide extending from residues 164 to 300 (LKKHG...MGLGK).

Cell Culture
Four cell lines derived from human thyroid cancers were studied: B-CPAP and TPC-1 derived from papillary carcinoma (Dr. C.Paulin, Laboratory of Anatomy and Cytology-Pathology, University of Lyon, Lyon, France and Prof. C.Maenhout, IRIBHM ULB, Brussels, Belgium, respectively), FTC-133 derived from follicular carcinoma (Dr. Köhrle, Institute of Experimental Endocrinology of the Charité, Humboldt University, Berlin, Germany) and 8505C derived from anaplastic carcinoma (Dr. Akiyama, Radiation Effects Research Foundation, Hiroshima). The HeLa cell line was used as the positive control. HeLa cells are derived from cervical carcinoma and are routinely cultivated in the laboratory of Molecular Biology (UMons). The cell lines HeLa, FTC-133, TPC-1, B-CPAP and 8505C were grow in Dulbecco’s Modified Essential Medium–F12 (DMEM-F12, Lonza) and RPMI 1640 (Lonza) with 10% fetal bovine serum (FBS, PAA Laboratories) and 1% antibiotics and antimycotics (PAA Laboratories). The cells were incubated at 37°C with 5% CO₂. The culture medium was changed once every 3 days. For routine subculture and cell plating in preparation for immunofluorescence studies, cells were detached by incubation with Accutase (PAA Laboratories), resuspended and counted using a hemocytometer.

Immunofluorescence Staining of Cultured Cells
Six-well culture plates containing sterile round glass coverslips were seeded at a density of 5x10⁵ cells/well and grown for 24 h. Cell cultures were rinsed with phosphate-buffered saline (PBS: 0.04 M Na₂HPO₄, 0.01 M KH₂PO₄ and 0.12 M NaCl, pH 7.4) and fixed in 4% paraformaldehyde for 10 min at 4°C and 5 min at room temperature (RT). The fixed cells were rinsed in PBS and blocked by incubation with bovine serum albumin (PBS plus 0.2% Triton X-100 and 5% BSA) for 30 min at RT. The fixed cells were incubated in the ART2 primary antibody diluted 1/100 in the blocking buffer for 1 h at RT, rinsed in PBS and incubated with Alexa Fluor 555 goat anti-rabbit IgG (Invitrogen) for 30 min. The immunostained sections were rinsed in PBS, mounted in Vectashield (Vector Laboratories), examined under a LeitzOrthoplan fluorescence microscope (Ploem system) and representative fields were recorded with a digital camera (Leica DC 300 F). Controls for the immunostaining specificity included the omission of the primary antibody or the substitution of non-immune sera for the primary antibodies. The specificity of anti-HLTF immunostaining was also examined with primary antibodies previously incubated with the synthetic peptide used as an antigen. In each case, these controls were negative (data not shown).
Immunohistochemistry of Benign and Malignant Thyroid Tumors
All tumor samples were fixed for 24 h in 10% buffered formaldehyde, dehydrated and then embedded in paraffin. Immunohistochemistry was performed on 5 μm-thick sections that were mounted on silane-coated glass slides. Before initiating the immunohistochemistry, tissue sections were briefly exposed to microwave pre-treatment in a 0.01 M citrate buffer (pH 6.2) for 2 x 5 min at 900 W. The sections were then incubated in a 0.06% hydrogen peroxide solution for 4 min to block endogenous peroxidase activity, rinsed in PBS and successively exposed for 5 min to solutions containing avidin (0.1 mg/ml PBS) and biotin (0.1 mg/ml PBS) to avoid false-positive staining reactions from endogenous biotin. After a washing step with PBS, the sections were incubated for 15 min with a solution of 0.5% casein in PBS and sequentially exposed at RT to solutions of i) specific primary anti-HLTF antibody (1/50); ii) corresponding biotinylated secondary antibody (polyclonal goat anti-rabbit IgG, 1/50, Vector Laboratories, Burlingame, CA); and iii) avidin-biotin-peroxidase complex (ABC Kit, Vector Laboratories, Burlingame, CA). The incubation steps were alternated with washing steps to remove unbound proteins. Antigen-dependent presence of the peroxidase complex in the sections was visualized by incubation with chromogenic substrates containing diamino benzidine and H2O2. After rinsing, the sections were counterstained with Luxol fast blue and mounted with a synthetic medium. To exclude antigen-independent staining, the incubation step with primary antibodies was omitted from the protocol in negative controls. In all cases, these controls were negative (data not shown).

Immunohistochemical Quantitative Analysis using a Computer-assisted microscopy
After the immunohistochemical steps, the levels of HLTF protein expression were quantitatively determined in our initial clinical series using a computer-assisted KS 400 imaging system (Carl Zeiss Vision, Hallbergmoos, Germany) connected to a Zeiss Axioplan microscope. For each section, 10 fields were analyzed at a 20X magnification and a picture was recorded for each of them by the ProgRes-CapturePro 2.1 program. The morphometric analysis was focused on selected pathological areas where two variables were measured: the labelling index (LI) and the mean optical density (MOD). The median was calculated for each section and for each tumor type.

Nuclear assessment by Optical Microscopy
For each specimen, 10 fields were analyzed at a 40X magnification to count the immunopositive nuclei and also the total number of nuclei in a gate of 0.084 mm². The mean of positive nuclei was assessed for each specimen.

Immunohistochemical Semi-quantitative Analysis
After the immunohistochemical steps, the levels of HLTF expression were semi-quantitatively determined on the second clinical series in collaboration with a pathologist (M.R) using an optical microscope (Leitz). The mean intensity (MI) was defined as follows: 0 (negative), 1 (low), 2 (moderate), and 3 (strong). The percentages of immunopositive tissue areas (Labelling index, LI) were categorized as follows: 0 (0% positive cells), 1 (1-25%), 2 (26-75%), and 3 (76-100%).

Western blotting
Total cell, nuclear and cytoplasmic extracts were used for all cell lines. To obtain total cell extracts, cells were recovered on ice with a scraper in 1 ml of PBS. The cell suspension was centrifuged at 4000 rpm for 5 min at 4°C. We resuspended the pellet in 100 μl of lysis buffer (BugBuster Protein Extraction Reagent, Novagen) for protein extraction. Nuclear and cytoplasmic extractions were performed using the NE-PER Nuclear and Cytoplasmic Extraction kit (Thermo Fisher Scientific) according to the manufacturer’s instructions.

Cells were homogenized at 4°C in hypertonic buffer (Tris 50 mM pH 7, NaCl 500 mM and NP40 0.1%) with added anti-proteases (Protease Inhibitor Cocktail, Sigma) and 1 mM DTT. Protein concentrations were measured using the Bio-Rad protein assay (BioRad Laboratories). 40 μg (for nuclear and cytoplasmic extracts) or 60 μg (for total cell extracts) of protein were diluted in 5 μl 4X LDS sample buffer (NuPAGE LDS sample buffer 4X, Invitrogen), 1 μl 20X reducing reagent (Fermentas) and up to 20 μl water, heated to 95°C for 5 min and separated by 4-12% PAGE-SDS (NuPAGE 4%-12% Bis-Tris Gel, Novex). After electrophoresis, the proteins were electrotransferred from the gel onto a nitrocellulose membrane (Hybond ECL, Amersham Pharmacia Biotech) using an electrophoretic transfer cell (Bio-Rad) at 260 mA for 1 h 45 min at 4°C. The transfer efficiency was controlled by Ponceau red staining (Ponceau S Solution, Sigma). Non-specific protein binding sites on the membrane were blocked by incubation with PBS 5% non-fat milk (Bio-Rad) for 1 h at RT. The membrane was incubated at 4°C overnight in the anti-HLTF primary antibody (Sigma) diluted 1/500 (for nuclear and cytoplasmic extracts) or 1/1000 (for total cell extracts) in the blocking buffer. After incubation, the membrane was washed three times with PBS and incubated for 1 h at RT with HRP-conjugated goat anti-rabbit IgG antibodies (Amersham Pharmacia Biotech) diluted 1/5000 in 0.5% Albumin bovine fraction V (BSA, MP Biomedicals). After treatment with Super Signal West Femto Chemiluminescent Substrate (Thermo Scientific), the membrane was exposed for 15 min on a photosensitive film (Hyperfilm ECL, Amersham Pharmacia Biotech). Molecular weight markers were analyzed in
parallel for internal calibration (PAGE Ruler Prestained Proteins, Fermentas).

**Statistical Analysis**
Independent groups of quantitative and semi-quantitative data were compared using the nonparametric Kruskall-Wallis test (for comparison of more than two groups). In the case of more than two groups, post-hoc tests (Dunn procedure) were used to compare pairs of groups (to avoid multiple comparison effects).

**Results**

**HLTF immunostaining decreases with tumor progression and shifts from the nucleus to the cytoplasm**

The first aim of our study was to quantitatively investigate HLTF expression in a series of 80 thyroid tumors. Moreover, the HLTF sub-location (nuclear staining) was also assessed by cell counting. In adenomas, the HLTF staining was moderate in the cytoplasm, but a pronounced nuclear staining was clearly observed (Figure 2A, B). In contrast, in papillary carcinomas, the HLTF staining was limited to the cytoplasm (Figure 2D, E), whereas follicular and anaplastic carcinomas exhibited weak cytoplasmic and nuclear immunostaining (Figure 2C, F, respectively).

To clearly present our data, we first compared all groups (Adenomas: Ad; Papillary Carcinomas: PC; Follicular Carcinomas: FC; and Anaplastic carcinomas: AC) using a nonparametric Kruskall-Wallis test (Figure 3). The decrease in HLTF staining was statistically significant during thyroid tumor progression in terms of both MOD, which corresponds to the mean staining intensity (Kruskall-Wallis: \( p < 0.0005 \), Figure 3A), and the LI, which corresponds to the percentage of immunopositive cells (Kruskall-Wallis: \( p < 10^{-6} \), Figure 3B). Using a post-hoc comparison for pairs of groups, we observed that HLTF expression decreased when comparing adenomas to anaplastic carcinomas (MOD: \( p = 0.03 \), Figure 3A; LI: \( p = 0.05 \), Figure 3B), adenomas to follicular carcinomas (LI: \( p = 0.02 \), Figure 3B), papillary carcinomas to follicular carcinomas (MOD: \( p = 0.02 \), Figure 2A; LI: \( p = 0.000003 \), Figure 2B) and papillary carcinomas to anaplastic carcinomas (MOD: \( p = 0.002 \), Figure 3A; LI: \( p = 0.00006 \), Figure 3B).

In addition, the percentage of HLTF positive nuclei differed significantly among the 4 tumor groups (Kruskall-Wallis \( p < 10^{-6} \), Figure 3C). More precisely, this difference is significant when comparing adenomas to papillary carcinomas (\( p = 0.000004 \), post-hoc test, Figure 3C). Indeed, the median value of the number of HLTF positive nuclei in the adenoma group (30%) is clearly higher than that in the papillary carcinoma group (5%).

**HLTF immunostaining is detected in benign thyroid lesions**

Figure 4A-F illustrates the HLTF immunohistochemical expression in a series of 40 benign thyroid lesions including 10 with colloid nodules (CN), 16 with adenomas (Ad), 7 with Hashimoto’s thyroiditis (HT) and 7 with...
Grave’s disease (GD). In colloid nodules and adenomas, HLTF is localized in both the nucleus and the cytoplasm of follicular cells, but with a significantly higher staining intensity at the nuclear level (Figure 4A, B). In Hashimoto’s thyroiditis (HT) and Grave’s disease (GD), a decrease in nuclear staining was observed (Figure 4C, D, respectively). All of the specimens were assessed using a semi-quantitative analysis with one pathologist (MR) because the quantitative assessment could not be proposed in a routine examination. We compared all groups (CN, Ad, HT, GD) using a nonparametric Kruskal-Wallis test and obtained a significant difference in terms of both the percentage of the mean immunopositive nuclei (LI nuc: $p = 0.007$; Kruskal-Wallis) (Figure 4E) and the mean staining intensity of the immunopositive nuclei (MI nuc: $p = 0.02$; Kruskal-Wallis) (Figure 4F). These two parameters were decreased in Hashimoto’s thyroiditis (HT) and Grave’s disease (GD) when compared to colloid nodules (CN) and adenomas (Ad). Then, using a post-hoc comparisons for pairs of groups, we determined that the percentage of immunopositive epithelial cells was higher in colloid nodules than in Grave’s Disease (LI nuc: $p = 0.04$, post-hoc test) (Figure 4A, D, E). We also observed that the staining intensity of the immunopositive epithelial cells of colloid nodules was stronger than that in Hashimoto’s thyroiditis, where the nuclear staining was moderate (MI nuc: $p = 0.04$, post-hoc test) (Figure 4A, C, F). These results show that the HLTF expression level decreases in thyroid autoimmune diseases, which can develop into thyroid carcinomas, suggesting a potential role in early diagnosis.

**HLTF nuclear immunostaining profile during thyroid tumor progression**

The immunohistochemical expression of HLTF was investigated in a series of normal thyroid tissue as well as in benign and malignant lesions, more specifically, 4 normal thyroid tissue (N), 10 colloid nodules (CN), 16 adenomas
Ad, 7 Hashimoto's thyroiditis (HT), 7 Grave's disease (GD), 17 papillary carcinomas (PC) and 12 follicular variant of papillary carcinomas (FVPC). In adenomas, HLTF was localized in both the nucleus and the cytoplasm of cells but with significantly higher staining intensity at the nuclear level (Figure 5A). In papillary carcinomas, the HLTF protein was detected in both compartments but with a more pronounced staining at the nuclear periphery (Figure 5B). The intensity of nuclear staining by our anti-HLTF antibody was compared between these 7 groups for which a significant difference was detected (MI nuc: p < 10^{-6}, Kruskal-Wallis) (Figure 5C). Post-hoc comparisons detected a significant difference between papillary carcinomas and normal tissue (MI nuc: p = 0.02; post-hoc test) and adenomas (MI nuc: p = 0.0002; post-hoc test) and colloid nodules (MI nuc: p = 0.0002; post-hoc test) (Figure 5C). We also observed a significant difference when we compared FVPC with adenomas (MI nuc: p = 0.003) or colloid nodules (MI nuc: p = 0.002) (Figure 5C). The intensity of the HLTF nuclear staining was strong in adenomas (MI nuc: median = 2.5) and decreased in papillary carcinomas (MI nuc: median = 1). These results corroborate the first observation in which HLTF expression decreased during thyroid tumor progression with a gradual shift of HLTF staining from the nucleus to the cytoplasm in malignant cells.

Truncated HLTF protein forms are expressed in adenomas and papillary carcinomas

HLTF immunohistochemical expression was investigated in biopsies of adenomas and papillary carcinomas using two different anti-HLTF antibodies. The ART2 serum targets the amino-terminal domain of full-length HLTF and two truncated HLTF forms (83- and 95- kDa) [26], whereas the anti-COOH serum targets the carboxy-terminal domain of wild-type HLTF that is missing in...
the truncated forms (see Methods). Using the ART2 antibody, HLTF was detected in both the nucleus and the cytoplasm of follicular cells in adenomas (Figure 6A). In papillary carcinomas, the staining was limited to the cytoplasm (Figure 6C). By contrast, with the anti-COOH antibody, HLTF staining was abolished both in adenomas and papillary carcinomas (Figure 6B, D), demonstrating the expression of truncated forms that lack DNA repair ability.

**HLTF staining pattern in thyroid cancer cell lines**

We also studied the expression of HLTF protein by immunocytofluorescence in 3 different transformed thyroid cell lines, B-CPAP, FTC-133 and 8505C, derived from human papillary carcinoma, follicular carcinoma and anaplastic carcinoma, respectively. The rabbit antisem (ART2) specific for the HLTFMet1 variant was used to determine the localization of HLTF in these cells. HLTF expression was exclusively localized to the nuclear compartment in all cell lines (Figure 7A-C).

We also determined the molecular size of the HLTF protein by Western blotting followed by immunodetection in these cell lines. HeLa cells were used as a positive control because the cancer-associated truncated HLTF protein variants were discovered in these cells [26]. In total cell extracts, a band was detected at approximately 120-kDa in TPC-1, FTC-133, 8505C and HeLa cells (Figure 7D; lanes 1, 3–5). These signals correspond to the HLTF wild-type full-length protein (HLTFMet1). In addition, a second band at 95-kDa, which corresponds to the HLTFMet1ΔB variant, was observed in the TPC1, FTC133 and 8505C thyroid cell lines (Figure 7D; lanes 1, 3–4). Finally, a band at ~80-kDa corresponding to the HLTFMet1ΔA variant was detected in the TPC-1 and FTC-133 thyroid cell lines (Figure 7D; lanes 1 and 3).

In the nuclear extracts, the ~120-kDa band was observed in all of the cell lines except for BCPAP (Figure 7E; lanes 1, 3–5). The 95-kDa band was observed in FTC133, 8505C and HeLa cells (Figure 7E; lanes 3–5). We also observed a band at 80-kDa in FTC-133 cells (Figure 7E; lane 3). Finally, a protein was detected at 70-kDa in all cell lines, which may correspond to the HLTFMet123Δ form, i.e., the translation initiation at the Met 123 codon and the carboxyl-terminal truncation of 274 residues (Figure 7E; lanes 1–5). In the cytoplasmic extracts, two bands were detected at 120- and 95-kDa in all cell lines (Figure 7F,

---

**Figure 5** Immunohistochemical staining of HLTF in benign and malignant thyroid tumors and statistical analysis of HLTF staining in benign and malignant thyroid lesions. (A-B) A: follicular adenoma and B: papillary carcinoma. The scale bar is 50 μm. (C) N: normal tissues. Ad: adenomas, HT: Hashimoto’s Thyroiditis, GD: Graves’ Diseases, CN: colloid nodules, PC: papillary carcinomas and FVPC: follicular variant of papillary carcinomas. The immunohistochemical expression was semi-quantitatively assessed in the nuclear compartment using the MI (MI nuc). The threshold of significance associated with the global multigroup comparison (Kruskal-Wallis test) is located in the higher right corner. Horizontal arrows represent the post-hoc comparison for the pairs of groups, with corresponding p-values.
lanes 1–5). In the whole cell extracts, we also observed a 60-kDa band that does not correspond to any known HLTF protein variant (Figure 7D-F; lanes 1–5).

**Discussion**

The present study shows for the first time that follicular adenomas present specific nuclear HLTF immunostaining (using the ART2 rabbit anti-serum recognizing the HLTF wild type protein as well as the two HLTF variants, HLTFMet1ΔA and HLTFMet1ΔB), whereas papillary carcinomas exhibit cytoplasmic expression. This observation has been confirmed in a second clinical series of benign and malignant thyroid lesions, allowing us to propose HLTF as a new potential marker of follicular adenomas. This observation could be of major interest for FNAB diagnosis in pathology. In fact, both parameters, LI and MOD, could also be assessed on smeared cells from FNA, but this immunohistochemical quantitative analysis requires computer-assisted microscopy, which is not available in all pathology departments. In this context, we propose further testing of HLTF as a new potential marker of follicular adenomas on FNA using a threshold of 30% HLTF-positive nuclei. In such case, the pathologist could perform a semi-quantitative assessment of HLTF-positive nuclei on smeared cells.

Concerning the difficult differential diagnosis of follicular adenomas from follicular carcinomas, our study showed that HLTF staining was moderate in the cytoplasm and pronounced in the nuclei of follicular adenomas, whereas follicular carcinomas exhibited weak cytoplasmic and nuclear immunostaining. Using quantitative analysis, we demonstrated that HLTF expression decreased significantly when comparing follicular adenomas to follicular carcinomas. However, our results are preliminary, and HLTF expression should be studied in a larger series of follicular adenomas versus carcinomas.

Moreover, our *in vivo* study revealed that the expression of one or more truncated HLTF protein variants (HLTFMet1ΔA and HLTFMet1ΔB) was associated with thyroid tumorigenesis. This observation is in agreement with our previous study, which showed that cervical cancers exhibited a significant increase in HLTF expression from normal epithelia to invasive squamous cell carcinoma [27]. We identified the 115-kDa HLTF wild-type protein in cervical intraepithelial neoplasia I-III samples by Western blotting, but only the truncated 83-kDa and 95-kDa proteins were detected in invasive squamous cell carcinoma samples. The 83-kDa and 95-kDa proteins have similar sizes to the HLTF variants Met1ΔA and Met1ΔB, respectively, which were previously characterized in HeLa cells and lack the domains that are
involved in DNA repair [26]. In invasive hypopharyngeal squamous-cell carcinomas [26], we also showed that truncated HLTF protein variants increase during tumor progression when comparing carcinomas to normal epithelia or dysplasia and that HLTF overexpression was associated with a worse prognosis.

Considering these data, we propose that these truncated HLTF proteins, having lost important domains that are involved in DNA repair, may contribute to thyrocyte progression in carcinogenesis.

Using immunocytochemistry on several thyroid cancer cell lines, we visualized the HLTF protein exclusively in the nucleus. Nevertheless, wild-type HLTF protein (115-kDa) was present both in the nuclear and cytoplasmic compartments in addition to a truncated form(s) (70-kDa, 83-kDa and/or 95-kDa). Therefore, thyroid cancer cells might utilize various mechanisms to suppress HLTF DNA repair activity: i) mutations affecting the wild type protein activity without excluding it from the nucleus; ii) mutations that shift the end of the reading frame, causing truncated variants; and iii) mutations that alter the nuclear localization signal, causing HLTF exclusion from the nucleus. These alterations could occur by alternative HLTF mRNA splicing, as we have previously observed [26]. In this way, these proteins are unable to perform DNA repair, which would provide an advantage to cell growth in cancer.

Indeed, we have previously shown that truncated HLTF variants are progressively overexpressed during carcinogenesis (head and neck cancer [26] as well as cervical cancer [27]) and replace the wild-type protein. In the immunoblotting experiments presented here, we could not discriminate one type of thyroid cancer from another because all of the cell lines shared the same expression profile of HLTF protein forms. In this regard, van Staveren et al. [28] and Saiselet et al. [29] have shown by mRNA profiling studies that, regardless of where the cancer originated, thyroid cancer cell lines appear to be the most similar to dedifferentiated thyroid cancer in vivo (anaplastic, the most aggressive). Thus, these tumor cell lines are not reliable in vitro tools for studying differentiated thyroid tumors because they have progressively acquired characteristics of dedifferentiated cells in culture. However, these cells could be used to identify genes involved in this process of tumor dedifferentiation. Papillary and follicular thyroid cancer cells may have lost their DNA synthesis/replication regulation mechanisms during their in vitro cell adaptation, according to the studies cited above [28,29].

Finally, we know that HLTF is implicated in post-replication DNA repair, a mechanism that could be disturbed in thyroid cancer cells [20]. To better understand the role of HLTF in thyroid cancer progression, we would like to study HLTF expression profiles, both at
the mRNA level (by RT-PCR) to identify potential mutations and at the protein level.

Conclusions

This study demonstrates a correlation between HLTF expression level and thyroid neoplastic progression. Nuclear HLTF immunostaining may therefore represent a new marker in thyroid tumors that could be used with FNA in an attempt to better distinguish benign thyroid nodules from malignant tumors. Three truncated HLTF forms lacking the domains that are involved in DNA repair were detected in thyroid carcinomas, strengthening the role of HLTF as a tumor suppressor.

The authors declare that they have no competing interests.

Authors' contributions

SS and AB conceived and designed the experiments. VA, PP, and LD performed the experiments. VA, PP, LD, CD and MR analyzed the data. GC and NS contributed materials. VA, PP, LD, AB, and SS wrote the paper. All authors read and approved the final manuscript.

Authors' information

Alexandra Belayew and Sven Saussez contributed equally to this work as co-senior authors.

Acknowledgements

This study was supported by the Hainaut Medical Research Fund (FRMH), and LD held a doctoral fellowship from the National Fund for Scientific Research (FNRS).

Author details

1 Laboratory of Anatomical and Cell Biology, Faculty of Medicine and Pharmacy, Research Institute for Health Sciences and Technology, University of Mons, 7000 Mons, Belgium. 2 Laboratory of Molecular Biology, Faculty of Medicine and Pharmacy, Research Institute for Health Sciences and Technology, University of Mons, 7000 Mons, Belgium. 3 Department of Oto-Rhino-Laryngology, CHU Saint-Pierre, Free University of Brussels, Brussels, Belgium. 4 Department of Pathology, Institut Bordaet, Free University of Brussels, Brussels, Belgium. 5 Laboratory of Image, Signal Processing and Acoustics (LISA), Ecole Polytechnique de Bruxelles, Free University of Brussels, Brussels, Belgium. 6 Department of Pathology, Hospital Erasme, Free University of Brussels, Brussels, Belgium. 7 Present address: Laboratory of Neurosciences, Faculty of Medicine and Pharmacy, Research Institute for Health Sciences and Technology, University of Mons, 7000 Mons, Belgium.
