ABSTRACT

Understanding the molecular content of galaxies is a critical problem in star formation and galactic evolution. Here we present a new method, based on a Strömgren-type analysis, to calculate the amount of H\textsc{i} that surrounds a molecular cloud irradiated by an isotropic radiation field. We consider both planar and spherical clouds, and H\textsubscript{2} formation either in the gas phase or catalyzed by dust grains. Under the assumption that the transition from atomic to molecular gas is sharp, our method gives the solution without any reference to the photodissociation cross section. We test our results for the planar case against those of a photodissociation region code and find typical accuracies of about 10%. Our results are also consistent with the scaling relations found in Paper I of this series, but they apply to a wider range of physical conditions. We present simple, accurate analytic fits to our results that are suitable for comparison to observations and to implementation in numerical and semi-analytic models.

Key words: ISM: clouds – ISM: molecules – molecular processes – radiative transfer – stars: formation

1. INTRODUCTION

1.1. Description of the Problem

Stars form in molecular gas. It is therefore of central importance to understand how molecular gas forms in the interstellar medium (ISM) of galaxies, which are pervaded by far ultraviolet (FUV) radiation that destroys the molecules by photodissociation. In the diffuse ISM of galaxies like the Milky Way, this radiation is sufficient to maintain the gas occupying most of the volume in an atomic or ionized state. Sufficient concentrations of gas are able to exclude the dissociating radiation, both by self-shielding and by dust absorption, and thereby become molecular; these are the molecular clouds. Regions in and around molecular clouds in which the thermal and chemical state of the gas is determined by FUV radiation are termed photodissociation regions (PDRs; e.g. Hollenbach & Tielens 1999). The surface density of atomic gas in a PDR, $\Sigma_{\text{H}\textsc{i}}$, sets the threshold for gas to become molecular and thus to be able to form stars.

The study of PDRs is a vast field, but the majority of the work that has been done is not suited to the problem of making general statements about the thicknesses of H\textsc{i} layers. Most of it is highly numerical (Federman et al. 1979; van Dishoeck & Black 1986; Black & van Dishoeck 1987; Draine & Bertoldi 1996; Neufeld & Spaans 1996; Spaans & Neufeld 1997; Liszt & Lucas 2000; Liszt 2002; Browning et al. 2003), which is useful for trying to match detailed properties of particular regions, but makes it difficult to draw general conclusions that allow extrapolation beyond the particular numerical parameters selected for a calculation. The same problem of how to draw general conclusions from particular results arises with galactic-scale simulations that model H\textsubscript{2} formation and dissociation as one of many processes occurring in a galaxy (Robertson & Kravtsov 2008; Gnedin et al. 2009). In contrast, the analytic work preceding this series of papers has been limited to the comparatively simple one-dimensional cases of a unidirectional beam of radiation impinging on a slab (Draine & Bertoldi 1996; Sternberg 1988) or a radially converging radiation field striking the surface of a sphere (Elmegreen 1993); the beam and slab case is a reasonable approximation for a PDR irradiated by a single star, but not for a cloud immersed in the interstellar radiation field produced by the ensemble of many stars. Since these authors assumed that the radiation is beamed, they were able to introduce a shielding function that describes the attenuation of the dissociating radiation with depth; this does not appear to be possible for isotropic incident radiation, particularly for spherical clouds. Moreover, these treatments did not identify the important dimensionless numbers that characterize the problem of a spherical cloud immersed in an isotropic radiation field. Perhaps the paper that is closest in spirit to the present series of papers is that of Sternberg (1988), who determined scaling laws for infrared fluorescent emission lines of H\textsubscript{2} emitted by an irradiated slab. He assumed that the radiation was beamed, so that he could use a shielding function. His results do not offer clear guidance on how the results scale with metallicity.

We determined the dimensionless quantities that characterize irradiated spherical clouds for the first time in Krumholz et al. (2008, hereafter Paper I), where we also gave an approximate solution for the atomic-to-molecular ratio of an irradiated gas cloud in terms of these numbers. In this paper, we extend this analysis by introducing a new and more accurate method for solving the equations of radiative transfer and photodissociation. We also extend our treatment to the case of primordial H\textsubscript{2} formation, where there is no dust and H\textsubscript{2} instead forms via the H\textsuperscript{+} channel. Finally, we apply our results to the determination of the molecular fraction in atomic–molecular complexes.

1.2. The Strömgren Analysis

PDRs are one example of a general class of problem in which one must find the chemical state of a gas cloud that simultaneously obeys coupled conditions of chemical and radiative equilibrium. The most famous example of this type of problem is that of determining the structure of an H\textsc{ii} region, and the structure of PDRs and similar problems can be solved by adapting the classic solution to the H\textsc{ii} region problem by Strömgren (1939). In the absence of dust, the thickness of the layer of ionized gas created by an incident flux of ionizing photons $F^*$ is
\[ \ell_{\text{St}} = \frac{F_{\text{ion}}^*}{\alpha n_e^2}, \]  
(1)

where the superscript * indicates photon quantities, \( n_e \) is the density of electrons, and \( \alpha \) is the radiative recombination coefficient. Similarly, for a point source of ionizing radiation, the radius of the ionized gas (the Strömgren radius) is given by

\[ R_{\text{St}} = \left( \frac{3L_{\text{ion}}^*}{4\pi \alpha n_e^2} \right)^{1/3}. \]  
(2)

Note that these results are independent of the value of the cross section, \( \sigma_{\text{ion}} \), for absorption of the ionizing radiation, which is the process that actually produces the ionized gas. However, in order for this simple Strömgren analysis to be useful in determining \( R_{\text{St}} \), it is necessary for the thickness of the layer in which the gas switches from primarily ionized to primarily atomic to be thin: \( R_{\text{St}} \gg 1/n(\text{H})\sigma_{\text{ion}} \), which is generally satisfied for \( \text{H} \) regions around OB stars (Strömgren 1939). If this condition is not satisfied, the Strömgren analysis still provides the total volume emission measure, \( \int n_i^2 dV = L_{\text{ion}}^*/\alpha \). The effects of dust absorption on Strömgren layers and spheres can be readily included (Petrosian et al. 1972).

The same type of analysis can be applied to the atomic gas in a PDR (Paper I). This is particularly useful because, whereas photoionization in an \( \text{H} \) \ region is a relatively simple continuum absorption process, photodissociation is a line absorption process; sophisticated calculations (e.g., Draine & Bertoldi 1996) are needed to follow the absorption as the lines become opaque and even overlap. Only a fraction \( f_{\text{diss}} \) of the line absorptions result in dissociation of the H\(_2\) molecule; the rest result in the emission of fluorescence radiation. \( f_{\text{diss}} \) is a weak function of frequency and of the level populations of the \( \text{H}_2 \) molecules; the average value is in the range 0.12 (Draine & Bertoldi 1996) to 0.11 (Browning et al. 2003), although it may be higher in regions within a PDR where a large fraction of the \( \text{H}_2 \) molecules are in excited states.) The process that is analogous to radiative recombination is molecule formation, which occurs at a rate \( f_1 n_\text{H}^2 \mathcal{R} \), where \( n_\text{H} \) is the number density of hydrogen nuclei, \( f_1 \equiv n(\text{H})/n_\text{H} \) is the \( \text{H} \) \ fraction, and \( \mathcal{R} \) is the rate coefficient for \( \text{H}_2 \) formation. In the Galaxy, \( \text{H}_2 \) forms on dust grains and the rate coefficient is \( R \simeq 10^{-16.5} \text{cm}^3 \text{s}^{-1} \) (Draine & Bertoldi 1996). In primordial, metal-free gas, \( \text{H}_2 \) forms via the \( \text{H}^- \) process or the three-body process, which can be described similarly (Section 3). In the absence of dust absorption, a point source with a photon luminosity \( L^* \) in the Lyman–Werner (LW) bands between 91.2 nm and 110.8 nm that is embedded in a medium of constant density, \( n_\text{H} \), can create a sphere of atomic gas with a total number of neutral hydrogen atoms

\[ N_{\text{H},\text{tot}} = \int f_1 n_\text{H} dV = \frac{f_{\text{diss}} L^*}{R n_\text{H}}. \]  
(3)

In the absence of dust, the transition between the atomic and molecular gas is not sharp (Paper I); nonetheless, we can define a characteristic radius of the atomic gas by setting \( f_1 = 1 \), obtaining

\[ R_{\text{H}} = \left( \frac{3f_{\text{diss}} L^*}{4\pi n_\text{H}^2 \mathcal{R}} \right)^{1/3}, \]  
(4)

which has the same form as the Strömgren radius. Similarly, a dissociating photon flux \( F_{\text{inc}}^* \) incident on the surface of a slab of gas can maintain an \( \text{H} \) \ column density

\[ N_{\text{H},\text{tot}} = \int f_1 n_\text{H} d\ell = \frac{f_{\text{diss}} F_{\text{inc}}^*}{n_\text{H} \mathcal{R}}. \]  
(5)

Setting \( f_1 = 1 \) gives the characteristic size of this layer,

\[ \ell_{\text{H},\text{slab}} = \frac{f_{\text{diss}} F_{\text{inc}}^*}{n_\text{H} \mathcal{R}}. \]  
(6)

An important limitation of the Strömgren analysis is that the bandwidth of the dissociating radiation must be known in advance. As shown by Sternberg (1988), the effective bandwidth begins to shrink for metallicities \( Z \gtrsim Z_\odot \), where dust absorption is sufficiently strong that the individual absorption lines no longer overlap. For the cases of greatest interest, however, \( Z \lesssim Z_\odot \) and the results presented here are applicable.

1.3. Summary of Previous Papers in this Series

In Paper I, we gave an approximate determination of the thickness of the \( \text{H} \) \ layer in a sphere irradiated from the outside by isotropic radiation. For such a sphere, the incident flux is unknown, since the flux due to radiation striking the surface from outside the sphere can be compensated in part by the flux due to radiation that passes through the sphere. It is therefore advantageous to characterize the radiation field by the ambient value of the mean density of dissociating photons. If we let \( E \) be the energy density of photodissociation radiation, then \( E^* \) is the corresponding photon density; let \( E_0^* \) be the corresponding ambient value. We define the characteristic value of the thickness of the \( \text{H} \) \ layer as \( \ell_{\text{H},\text{slab}} \) with \( F_{\text{inc}}^* \) replaced by \( cE_0^* \):

\[ \ell_{\text{ch}} \equiv \frac{f_{\text{diss}} cE_0^*}{n_\text{H}^2 \mathcal{R}}. \]  
(7)

For an opaque slab embedded in an isotropic radiation field, the energy density just outside the slab is half the ambient value and the flux is half that, or \( F_{\text{inc}}^* = \frac{1}{2}cE_0^* \); as a result, \( \ell_{\text{H},\text{slab}} \simeq \frac{1}{2} \ell_{\text{ch}} \) in this case. The importance of dust is measured by the characteristic dust optical depth,

\[ \tau_{\text{ch}} = n_\text{H} \sigma_d \ell_{\text{ch}} = \frac{f_{\text{diss}} \sigma_d cE_0^*}{n_\text{H} \mathcal{R}} \equiv \chi, \]  
(8)

where \( \chi \) is one of the two dimensionless parameters introduced in Paper I. PDRs are often characterized by the ratio \( G_0^*/n_{\text{H}} \), where \( G_0^* \) is the ratio of the dissociating radiation field, \( E_0^* \), to the typical value in the Milky Way, which is \( 7.5 \times 10^{-4} \) photons cm\(^{-3} \) s\(^{-1} \) from Draine (1978). In terms of this ratio, \( \chi \) is

\[ \chi = 71 \left( \frac{\sigma_d}{R_{-16.5}} \right) G_0^*/n_{\text{H}}. \]  
(9)

Physically, \( \chi/f_1 \) is the ratio of the number of LW photons absorbed by dust to the number absorbed by H\(_2\) molecules. Thus, dust has a significant impact on the structure of the \( \text{H} \) \ layer for \( \chi \gtrsim 1 \). The parameter \( \chi \) is of order unity in the Milky Way (Krumholz et al. 2009b, hereafter Paper II; see Equation (13)). Clumps in the PDRs discussed by Hollenbach & Tielens (1999) have \( \chi \sim 0.3 \text{–} 10 \); while the interclump gas in those PDRs has values about 100 times larger. Observe that for the case in which \( \text{H}_2 \) forms on dust grains, both \( \sigma_d \) and \( \mathcal{R} \) are effectively measures of the total surface area of dust grains mixed into the gas; \( \sigma_d \) measures the area available for absorbing photons, and \( \mathcal{R} \) the area available for adsorbing hydrogen atoms. Thus, their ratio should be independent of metallicity, dust-to-gas ratio, density, and other most quantities. For an opaque slab, we have seen that the incident flux \( F_{\text{inc}}^* = \frac{1}{2}cE_0^* \), so that \( \ell_{\text{H},\text{slab}} = \frac{1}{4} \ell_{\text{ch}} \) and

\[ \ell_{\text{H},\text{slab}} = n_\text{H} \sigma_d \ell_{\text{H},\text{slab}} = \frac{1}{4} \chi, \]  
(10)
keep in mind that these simple estimates are based on neglecting absorption of the incident FUV radiation by dust. For future reference, we note that this implies that the total $H_1$ column density in a dust-free slab (Equation (5)) is $N_{H_{1,\text{min}}} = \chi / (4\sigma_d)$. Finally, we note that the ratio of $\ell_{\text{ch}}$ to the cloud radius, $R$, is

$$\frac{\ell_{\text{ch}}}{R} = \frac{E_0^*}{n_{H_1}^2 R^2} = \frac{\chi}{R^2},$$

(11)

where $\tau_R = n_H \sigma_d R$, the dust optical depth associated with the cloud radius, is the other dimensionless parameter in Paper I.

As in the case of $H\alpha$ regions, a Strömgren-type analysis is particularly useful if the transition from atomic to molecular gas is sharp, $\ell_{H_1} \gg 1/(n_H \sigma_H \ell_{\text{ch}})$. In Paper I, we showed that this transition is indeed relatively sharp for $\chi \gtrsim 1$, so that in that case it is possible to infer the size of the atomic gas by setting $f_1 \approx 1$. For the case with dust, we make this approximation here; this is the principal approximation in our work. In the absence of dust, we can determine the total mass of $H_1$ (in the spherical case) or column of $H_1$ (in the slab case) without making this approximation.

The advance made in Paper II was to recognize that the density in the atomic gas in the transition region is set by the requirement that it be in two-phase equilibrium (Wolfire et al. 2003). The latter authors showed that the minimum density of cold $H_1$ (the cold neutral medium (CNM)) in galaxies is

$$n_{H_1,\text{min}} = \frac{31}{1 + 3.1 Z^* 0.365} \left( \frac{E_0^*}{7.5 \times 10^{-4} \text{ cm}^{-3}} \right) \text{ cm}^{-3},$$

(12)

where $E_0^*$ and $Z^*$ are the radiation field and metallicity normalized to the local Milky Way value. If the density is several times the minimum value ($n_H = \phi_{\text{CNM}} n_{H_1,\text{min}}$ with $\phi_{\text{CNM}} \sim 3$), then

$$\chi = 3.1 \left[ \frac{\sigma_{d,-21}}{R_{16.5} \phi_{\text{CNM}} / 3} \right] \left( 1 + 3.1 Z^* 0.365 \right) \frac{4.1}{1 + 3.1 Z^* 0.365} \tag{13}$$

depends primarily on metallicity, and weakly at that; here $\sigma_{d,-21} = \sigma_d / (10^{-21} \text{ cm}^2)$, etc. The surface density of $H_1$ in a galaxy, assuming that it is in a slab and neglecting dust absorption, is then

$$\Sigma_{H_1} = \frac{\mu_H}{\sigma_d} \tau_{H_1,\text{slab}}, \quad \Sigma_{H_1} \approx \frac{8.8}{Z^* (\phi_{\text{CNM}} / 3)} \frac{1 + 3.1 Z^* 0.365}{4.1} M_\odot \text{ pc}^{-2} \tag{14}$$

for $R_{16.5} / \sigma_d = 1$; here, $\mu_H = 2.34 \times 10^{-24} \text{ g}$ is the mass per hydrogen for a gas of cosmic abundances. Paper II showed that dust absorption reduces this by about a factor of 2. On the other hand, if the slab of gas is illuminated from both sides, then the total column of $H_1$ is increased by a factor of 2. Paper II generalized these results to the case of finite clouds and demonstrated that the results were in good agreement with existing observations. Indeed, since the theory applies to individual cloud complexes, predictions were made on how the results would change as the resolution of the observations improves.

Krumholz et al. (2009c) applied the results of Papers I and II together with the earlier work of Krumholz & McKee (2005) to determine the star formation rate in galaxies as a function of metallicity. For low surface densities ($\Sigma \lesssim 10/Z^* M_\odot \text{ pc}^{-2}$), the rate is dominated by the transition from $H_1$ to $H_2$; for intermediate columns ($10/Z^* M_\odot \text{ pc}^{-2} \lesssim \Sigma \lesssim 85 M_\odot \text{ pc}^{-2}$), it is determined by the properties of giant molecular clouds (GMC); and for larger column densities it is determined by the pressure of the galactic ISM. Similarly, Krumholz et al. (2009a) showed how the results of Papers I and II can be used to explain the observed absence of damped Ly$\alpha$ systems with high column densities and metallicities. The treatment of the $H_1$–$H_2$ transition in both these papers relied on an analysis that is more broadly applicable than the one developed in Paper I. We provide that analysis here.

In Section 2, we present the general formalism for determining the thickness of the $H_1$ shielding layer for spherical molecular clouds. This formalism is based on a Strömgren-type analysis. In Section 3, we present the results for both slabs and spheres in the absence of dust; this is relevant to the study of primordial clouds. Section 4 gives the results including dust absorption. Section 5 shows how these results can be generalized to the case of clouds in which the atomic and molecular regions have differing densities, and the conclusions are given in Section 6.

2. FORMALISM

2.1. Basic Equations

Consider a spherical cloud of radius $R$ and uniform density exposed to an isotropic UV radiation field. We describe the radiation field in terms of the specific intensity in photon units, $I^* = I_e / h \nu$. Let $\kappa_{2v} = n_2 \sigma_{2v}$ be the opacity due to absorption by $H_2$ molecules, where $n_2$ is the density of $H_2$ molecules and $\sigma_{2v}$ is the $H_2$ absorption cross section at frequency $\nu$. Let $\kappa_d = n_1 \sigma_d$ be the opacity due to absorption by dust, where $n_1$ is the density of $H$ nuclei and $\sigma_d$ is the dust absorption cross section per $H$ in the photodissociation part of the spectrum, from 91.2 to 110.8 nm; we ignore the weak frequency dependence of this cross section. The equation of transfer is then

$$\hat{e} \cdot \nabla I^* = - (\kappa_{2v} + \kappa_d) I^* = -(n_2 \sigma_{2v} + n_1 \sigma_d) \tag{15}$$

for the intensity in the $\hat{e}$ direction. The opacity $\kappa_{2v}$ depends on position, but we have suppressed the argument for clarity. For a cloud bathed in a uniform radiation field of intensity $I^*_0$, the intensity at a point inside the cloud is

$$I^*_v = I^*_0 \exp(-\tau_{2v}) \tag{16}$$

where the optical depths are proportional to the column density: the dust optical depth is

$$\tau = \int n_1 \sigma_d ds \tag{17}$$

and the $H_2$ optical depth is

$$\tau_{2v} = \int n_2 \sigma_{2v} ds = N_2 \sigma_{2v}. \tag{18}$$

where the range of integration extends along the ray from where the ray enters the cloud to the point in question and $N_2$ is the corresponding $H_2$ column density along the ray.

We next integrate over the range of frequencies that can photodissociate $H_2$, $\nu_2 \gtrsim \nu \gtrsim \nu_1$, corresponding to wavelengths 91.2 nm $\lesssim \lambda \lesssim 110.8$ nm. The frequency-integrated equation of transfer is

$$\hat{e} \cdot \nabla I^* = -[\kappa_f (\hat{e}) + \kappa_d] I^*, \tag{19}$$

where

$$\kappa_f (\hat{e}) = \kappa_{2v} + \int n_2 \sigma_{2v} d\nu$$

is the total $H_2$ optical depth, and $\kappa_d$ is the dust optical depth.
where
\[
\kappa_I(\hat{e}) = \frac{1}{I^*} \int_{\nu_1}^{\nu_2} \kappa_{2\nu} I_{\nu}^* d\nu.
\]

(20)

We include the argument \(\hat{e}\) in \(\kappa_I\) to emphasize that this opacity depends on angle through its dependence on \(I_{\nu}^*\); \(\kappa_I\) also depends on position. The intensity-weighted \(H_2\) opacity is then a function of \(N_2\),
\[
\kappa_I = \frac{\int_{\nu_1}^{\nu_2} \kappa_{2\nu} \exp(-\tau_{2\nu}) d\nu}{\int_{\nu_1}^{\nu_2} \exp(-\tau_{2\nu}) d\nu} = \kappa_f(N_2).
\]

(21)

The dependence of \(\kappa_f\) on \(N_2\) is governed by two countervailing factors. On one hand, as \(N_2\) increases more and more photons at frequencies near line centers are absorbed. Since \(\sigma_{2\nu}\) decreases away from line center, the mean opacity per \(H_2\) molecule is reduced. On the other hand, \(\kappa_{2\nu}\) is also proportional to the density of \(H_2\) molecules \(n_2\), which increases with \(N_2\). The intensity-weighted optical depth that determines the attenuation of \(I^*\) is \(\tau_I = \int \kappa_I ds\), so that
\[
I^* = I_0^* \exp[-\tau_I + \tau].
\]

(22)

In terms of the first three angular moments of the radiation field,
\[
E_{\nu}^* = \int d\Omega I_{\nu}^*, \quad F_{\nu}^* = \int d\Omega \hat{e} I_{\nu}^*, \quad P = \frac{1}{c} \int d\Omega \hat{e} \hat{e} I_{\nu}^*,
\]

(23)

the first two angular moments of the equation of radiative transfer are
\[
\nabla \cdot F_{\nu}^* = -c(\kappa_{2\nu} + \kappa_d) E_{\nu}^*, \quad \nabla \cdot P_{\nu}^* = -c(\kappa_{2\nu} + \kappa_d) F_{\nu}^*.
\]

(24)

(25)

Integrating over frequency gives
\[
\nabla \cdot E^* = -c(\kappa_E + \kappa_d) E^*, \quad \nabla \cdot P^* = -c(\kappa_E + \kappa_d) F^*,
\]

(26)

(27)

where
\[
\kappa_E = \frac{1}{E^*} \int_{\nu_1}^{\nu_2} d\nu \kappa_{2\nu} E_{\nu}^* = \frac{1}{E^*} \int d\Omega \int_{\nu_1}^{\nu_2} d\nu \kappa_{2\nu} I_{\nu}^* = \frac{1}{E^*} \int d\Omega \kappa_I I^*.
\]

(28)

We have assumed that the direction of \(F_{\nu}^*\) is independent of frequency; as a result, \(\kappa_E\) is given by an expression like that for \(\kappa_E\) with \(E^*\) replaced by \(|F^*|\) and with a factor \(\mu\) in the angular integrals. Writing out Equations (26) and (27) in the case of spherical symmetry, we obtain
\[
\frac{1}{r^2} \frac{d}{dr} r^2 F^* = c(\kappa_E + \kappa_d) E^*,
\]

(29)

\[
\frac{d P^*}{dr} + \frac{3 P^* - E^*}{r} = \frac{1}{c}(\kappa_E + \kappa_d) F^*.
\]

(30)

where \(F^* \equiv |F^*| = -F_{\nu}^*\) and \(P^* = P_{rr}^*\) is the rr component of the radiation pressure tensor.

Now define the characteristic flux
\[
F_{\text{ch}}^* \equiv \frac{n_H^2 \mathcal{R}_R}{f_{\text{diss}}},
\]

(31)

which is the flux required to photodissociate a layer of thickness \(R\), as discussed in Section I. The solution is determined by the two quantities defined in Paper I,
\[
\chi \equiv \frac{f_{\text{diss}} \sigma_d E_0^*}{n_H \mathcal{R}}, \quad \tau_R \equiv \frac{n_H \sigma_d R},
\]

(32)

(33)

where \(E_0^*\) is the number density of dissociating photons far from the cloud. In terms of these parameters, we have
\[
F_{\text{ch}}^* \equiv \left(\frac{\tau_R}{\chi}\right) c E_0^*.
\]

(34)

We define the normalized flux and photon density by
\[
\tilde{F}^* \equiv \frac{F^*}{F_{\text{ch}}}, \quad \tilde{E}^* \equiv \frac{c E^*}{F_{\text{ch}}},
\]

(35)

The normalized photon density far from the cloud is then
\[
\tilde{E}_0^* = \frac{\chi}{\tau_R}.
\]

(36)

We now use the assumption that the formation and destruction of \(H_2\) are in balance in order to determine the opacity \(\kappa_E\); this is the essence of the Strömgren argument. Observe that it is difficult to calculate \(\kappa_E\) explicitly, since it involves first a frequency integration over the cross section and the specific intensity, both of which are complicated functions of frequency due to line absorption, and then an average over angle. Balancing the rates of formation and destruction of \(H_2\) gives
\[
f_1 n_H^2 \mathcal{R} = f_{\text{diss}} \int d\Omega \int_{\nu_1}^{\nu_2} d\nu \kappa_{2\nu} I_{\nu}^*,
\]

(37)

\[
= f_{\text{diss}} c \kappa_E E^*,
\]

(38)

where \(f_1 \equiv n(\text{HI})/n_H\) is the atomic fraction and \(\mathcal{R}\) is the rate coefficient for \(H_2\) formation. The principal approximation in our analysis is to assume that the transition from atomic to molecular gas is sharp, so that \(f_1 \simeq 1\) in the atomic gas. The balance equation then implies that
\[
\kappa_E = \frac{n_H^2 \mathcal{R}}{c f_{\text{diss}} E^*} = \frac{1}{\mathcal{R} E^*}.
\]

(39)

Our second approximation is to relate the flux-weighted opacity to \(\kappa_E\) by
\[
\kappa_F = \phi_e \kappa_E,
\]

(40)

where \(\phi_e\) is a constant. The results for the one-dimensional case below verify that this is a good approximation. We expect \(\phi_e\) to exceed unity since the rays that carry the flux are closer to the radial direction and have therefore undergone less attenuation and interact with a larger cross section, as mentioned below Equation (21).
To close the moment equations of radiative transfer, we introduce a variable Eddington factor,

\[ f^{*}_{\text{Edd}} \equiv \frac{\hat{P}^{*}}{E^{*}}. \]  

Expressing Equations (29) and (30) in dimensionless form and using Equation (39) to eliminate \( \kappa_{E} \), we obtain

\[ \frac{d \hat{E}^{*}}{dx} + \frac{2 \hat{E}^{*}}{x} = f_{1} + \tau_{R} \hat{E}^{*}, \]

\[ \frac{d}{dx} \left( f^{*}_{\text{Edd}} \hat{E}^{*} \right) + \left( \frac{3 f^{*}_{\text{Edd}} - 1}{x} \hat{E}^{*} \right) \frac{\phi_{E} f_{1} \hat{E}^{*}}{E^{*}} + \tau_{R} \hat{E}^{*}, \]

where \( x \equiv r/R \). These equations must be solved subject to the boundary conditions that both the photon density and the flux vanish at \( x_{H_{2}} \), the transition point from atomic to molecular gas; i.e., \( \hat{E}^{*}(x_{H_{2}}) = \hat{F}^{*}(x_{H_{1}}) = 0 \). The values of the photon density and flux at the surface are not known, except in the case in which the cloud is completely opaque.

2.2. Approximate Determination of the Eddington Factor \( f^{*}_{\text{Edd}} \)

Many astrophysical problems are characterized by a central source of radiation in an opaque region, where the radiation is nearly isotropic, surrounded by a less opaque region in which the radiation is beamed outward. Shu (1991) writes a general form for a relation to close the moment equations of radiative transfer as

\[ E^{*} = 3 P^{*} - \frac{q_{F}}{c} F^{*}. \]

He points out that the choice \( q_{F} = 2 \) makes a smooth transition from the isotropic case \( E^{*} = 3 P^{*}, F^{*} \to 0 \) to the beamed case \( E^{*} = P^{*}, F^{*}/c \). Our problem is quite different, however: the radiation is isotropic at large distances from the cloud, but close to the cloud there is a “hole” in the radiation field since radiation cannot pass through the molecular core. We therefore need to develop a different approach to closure.

As remarked above, we close the moment equations by using variable Eddington factor, \( f^{*}_{\text{Edd}} \). Our approximation for \( f^{*}_{\text{Edd}} \) at any point inside the cloud is based on representing the main qualitative feature of the radiation field—that the intensity decreases for rays at larger angles to the outward normal and vanishes for rays that have intersected the molecular core—by a step function decrease at some angle \( \theta_{f} \). (We adopt the convention in Paper I that \( \theta \) is the angle between the outward normal and the direction from which the photon originates—see Figure 1.) We thus approximate the radiation field as being of constant intensity for \( 0 \leq \theta < \theta_{f} \) (corresponding to \( 0 \leq x_{f} / R \leq 1 \)) and vanishing for \( \theta_{f} < \theta \leq \pi \) (corresponding to \( x_{f} > R \)). We then obtain

\[ f^{*}_{\text{Edd}} \equiv \frac{P^{*}}{E^{*}} = \frac{\int_{1}^{\mu_{f}} \mu^{2} d\mu}{\int_{1}^{\mu_{f}} d\mu} = \frac{1}{3} (1 + \mu_{f} + \mu_{f}^{2}). \]

It remains to adopt an ansatz for \( \mu_{f} \). First consider the dust-free case. For points close to the molecular core \( (x \to x_{H_{2}}) \), we assume that \( 2 \theta_{f} \) is the angle subtended by the molecular core, so that \( \sin \theta_{f} \approx x_{H_{2}} / R \). In the opposite limit, in which the molecular core is assumed to be small \( (x_{H_{2}} \ll 1) \) and the point is far from the core, we assume that a ray at \( \theta_{f} \) intersects the midplane at a distance \( x_{f} R \) from the center of the cloud, so that \( \tan \theta_{f} \approx x_{f} / R \). We combine these two limits by assuming that \( \tan^{2} \theta_{f} \) is the sum of the squares of the tangents in the two limiting cases,

\[ \tan^{2} \theta_{f} \equiv \frac{x_{H_{2}}^{2}}{x^{2} - x_{H_{2}}^{2}} + \frac{x_{f}^{2}}{x^{2}}. \]

The corresponding cosine is \( \mu_{f} = -1/(1 + \tan^{2} \theta_{f})^{1/2} \), where the minus sign reflects the fact that the angle is in the second quadrant:

\[ \mu_{f}(x) = \frac{x^{2} (x^{2} - x_{H_{2}}^{2})}{x^{4} + x_{f}^{2} (x^{2} - x_{H_{2}}^{2})}, \]

and \( \theta_{f} \) is an eigenvalue of the problem, which is adjusted to give the correct net flux at the surface.

How does this compare with Shu’s (1991) closure approximation? Using the model that the radiation field is uniform for \( \mu \geq \mu_{f} \) and zero for \( \mu < \mu_{f} \) implies that the flux is \( \frac{1}{2} E^{*}(1 - \mu_{f}^{2})^{1/2} \). Solving for the closure factor \( q_{F} \) in Equation (44), we find \( q_{F} \approx 2 \mu_{f} \). Since \( \mu_{f} \) is negative, it follows that the closure factor is negative, which is qualitatively different than the standard case. The fact that \( \mu_{f} < 0 \) implies that \( f^{*}_{\text{Edd}} \) in Equation (45) is always less than \( \frac{1}{3} \), it is in the range \( \frac{1}{3} \geq f^{*}_{\text{Edd}} \).

Next, consider the case in which dust is included. For a dusty slab, the dissociating photon density at an optical depth \( \tau \) from the surface is

\[ E^{*} = \frac{1}{2} E_{0}^{*} \int_{0}^{1} \exp(-\tau / \mu) d\mu \] (dusty slab).

Evaluation of the integral gives

\[ E^{*} = \frac{1}{2} E_{0}^{*} E_{2}(\tau) \approx \frac{1}{2} E_{0}^{*} \frac{e^{-\tau}}{1 + \tau}, \]

where \( E_{2} \) is an exponential integral and where the approximation is accurate to about 25%. The advantage of the approximation
is that it shows that the photon density is as if the intensity along
the normal filled a solid angle corresponding to
\[ \Delta \Omega = 2 \pi \Delta \mu = 2 \pi (1 - \mu_d) \text{ with } 1 - \mu_d = 1/(1 + \tau), \]
so that
\[ \mu_d = \frac{\tau}{1 + \tau}. \]  
(50)

For the spherical case, we take \( \tau = (1 - x) \tau_R \), where \( \tau_R \) is the
dust optical depth from the cloud center to edge. To join the case
where dust dominates the opacity onto the case where molecular
absorption dominates it, we use the simple ansatz
\[ f_{Edd} = \frac{1}{3} (1 + \mu_f + \mu_d^2) \]  
(51)

with \( \mu_f = \mu_f + \mu_d. \) Note that whereas \( \mu_f \) is always negative in
the dust-free case, it can be positive when dust is important.

2.3. Boundary Conditions for the Spherical Case

As in Paper I, we use the solution of the radiative transfer equation at the cloud surface to constrain the solution. At the
surface \( (x = 1) \), photons at \( \mu > 0 \) are unattenuated, those that
traverse the cloud outside the molecular core, \( 0 > \mu > \mu_2 \), with
\[ \mu_2 = - \left( 1 - \chi H_2 \right)^{1/2}, \]  
(52)

are attenuated, and those that strike the molecular core \( (\mu < \mu_2) \)
are absorbed. Integration of Equation (22) then gives
\[ \hat{E}^*(\tau_R) = \frac{1}{2} \hat{E}_0^* \left[ 1 + \int_{\mu_2}^0 d\mu \, e^{-(\tau_I + \tau_R)} \right]. \]  
(53)

We then introduce our next approximation: we replace \( \tau_I = \int k_I(r, \mu) ds \), with \( \tau_E = \int k_E(r) ds \) (see Equation (28)). Note
that the error introduced by this approximation is limited, since
the term in which it is made contributes at most half the total.
Proceeding in the same fashion with the evaluation of the flux at
the surface, we obtain
\[ \hat{E}^*(\tau_R) = \frac{1}{2} \hat{E}_0^* \left[ 1 + \int_{\mu_2}^0 d\mu \, e^{-(\tau_I + \tau_R)} \right]. \]  
(54)

where the factor 2 in front arises since the unattenuated intensity is \( \frac{1}{2} E_0^* \) whereas the unattenuated flux is \( \frac{1}{2} c E_0^* \). The optical depth is
given by
\[ \tau_E = 2 \int_{\sin \theta}^1 \frac{x' dx'}{(x'^2 - \sin^2 \theta)^{1/2}} \hat{E}_0^*, \]  
(55)

where \( \sin \theta \) is the value of \( \theta \) of closest approach to the center of
the cloud for a ray at an angle \( \theta \).

The equations we have now written down constitute a complete set
that fully determines the solution. For a given choice of \( \chi \) and \( \tau_R \), a solution consists of two unknown numbers, \( \mu_f \) (or equivalently \( f_{Edd} \), since the two are related by
Equation (51)) and \( \chi H_2 \), and two unknown functions, \( \hat{E}^* \) and \( \hat{F}^* \).

The two functions are constrained by the ordinary differential
equations (ODEs), Equations (42) and (43), while the two
numbers are constrained by the algebraic equations \( \hat{E}^*(\chi H_2) = 0 \) and the consistency condition (Equation (54)). We
must choose a fixed value of \( \phi \), since we lack an equation to
determine an additional parameter. We discuss how to choose this
value in Section 2.4, and we defer discussion of how to
obtain the solution numerically once we have chosen \( \phi \) until
Sections 3.2 and 4.2.

2.4. The Semi-infinite Slab Limit

The normalization we have used for the spherical case, which is
based on \( F_{Edd}^* \propto R \), breaks down for a one-dimensional, semi-infinite slab, which corresponds to the limit \( R \to \infty \).
We therefore normalize with respect to the ambient radiation
field, \( E_0^* \) by defining
\[ F_1 = \frac{F^*}{c E_0^*}, \quad E_1 = \frac{E^*}{E_0^*}, \]  
thus, \( F_1(0) = \frac{1}{4} \) and \( E_1(0) = \frac{1}{4} \) at the surface of the slab. The first two moments of the radiative transfer equation become
\[ \frac{dF_1}{d\tau} = - \chi F_1 - E_1, \]  
(57)

\[ \frac{d(F_{Edd} E_1)}{d\tau} = - \phi \chi F_1 - F_1, \]  
(58)

where \( d\tau = \eta \sigma_T dz \), with \( z \) zero at the surface and increasing inward. In the one-dimensional limit \( (x, \chi H_2 \to 1) \), the angle \( \mu_f \) that enters the Eddington factor approaches zero (Equation (47)). The Eddington factor thus becomes
\[ f_{Edd} = \frac{1}{3} (1 + \mu_f + \mu_d^2). \]  
(59)

For small \( \tau \) (i.e., close to the surface), \( f_{Edd} \to \frac{1}{4} \) as it should, since the radiation is approximately isotropic in the half-space \( \mu > 0 \). For large \( \tau \), we have \( \mu_d = \tau/(1 + \tau) \to 1 \), and \( f_{Edd} \to 1 \); this too is as it should be, since highly extincted radiation is beamed so that \( F^* \propto E^* \).

As with the spherical case, we have now written down enough
equations to close the system. The independent parameter that
determines the solution is the dimensionless radiation intensity \( \chi \).
For a given \( \chi \), a solution consists of two numbers, the ratio \( \phi \), of the flux-mean opacity to the energy-mean opacity and the
dust optical depth \( \chi H_2 \), at which the molecular transition occurs,
plus two functions, \( E_1^* \) and \( F_1^* \). These quantities are constrained by two algebraic equations, \( E_1^*(\chi H_2) = F_1^*(\chi H_2) = 0 \),
and the two ODEs (Equations (57) and (58)). These ODEs are subject to the boundary conditions \( E_1^*(0) = 1/2 \) and \( F_1^*(0) = 1/4 \). This set of constraints therefore fully specifies the system. We defer
discussion of our solution algorithm to Sections 3.1 and 4.1. We pause here to point out an important distinction between the spherical and slab cases: for the spherical case, the angle \( \theta_f \) at which we transition from zero flux to finite flux represents an extra parameter to be determined that is not present in the slab
case. As a result, for the slab case we can use our constraint
equations to determine \( \phi \), and we can then use the resulting
value of \( \phi \) in the spherical case. As we shall see, a single value of \( \phi \) works quite well over a very broad range of radiation
fields.

3. THE DUST-FREE CASE: PRIMORDIAL CLOUDS

Although the motivation for this series of papers was to understand the atomic–molecular transition in galaxies today,
where \( H_2 \) is formed on grains, our methodology applies to
primordial gas clouds also, where \( H_2 \) is formed via gas phase
reactions. The effective values of \( R \) for gas-phase production
of \( H_2 \) are given in the Appendix. The results obtained here are also useful for comparison with the results for dusty clouds in the following section.
3.1. Semi-infinite Slab

In the limit that $\kappa_d \rightarrow 0$, Equations (57) and (58) for the one-dimensional case become

$$\frac{dF_1^*}{dN_{H_1}} = -\frac{1}{4}, \quad (60)$$

$$\frac{df_{\text{edd}}E_1^*}{dN_{H_1}} = -\frac{\phi_c F_1^*}{4E_1^*}, \quad (61)$$

where we used the fact that $\kappa_d/\chi = n_H\sigma_d/\chi = n_H/(4N_{H_1,\text{tot}})$ (see below Equation (10)) and defined

$$\hat{N}_{H_1} \equiv \frac{N_{H_1}}{N_{H_1,\text{tot}}}, \quad (62)$$

which varies from 0 at the surface of the slab to 1 at the point that the slab becomes fully molecular. Note that we have not assumed anything about the spatial variation of the $H_1$ fraction, $f_1$. As pointed out in Section 2.4, the boundary conditions are $F_1^*(1) = 1/4$ and $E_1^* = 1/4$; we also pointed out that for small $\tau$, the Eddington factor approaches $f_{\text{edd}} = 1/4$. In the dust-free case, the use of $f_{\text{edd}} = 1/4$ at large optical depths in the $H_2$ lines is justified by the fact that the photons that dominate the photodissociation are in the line wings; they are not highly extinguished and therefore are not beamed. Integration of the equations then gives

$$F_1^* = \frac{1}{4}(1 - \hat{N}_{H_1}), \quad (63)$$

$$E_1^{*2} = \frac{1}{4} - \frac{3\phi_c}{8}\left(\hat{N}_{H_1} - \frac{1}{2}\hat{N}_{H_1}^2\right). \quad (64)$$

Since $E_1^*$ must vanish at the same point that $F_1^*$ does (i.e., at $\hat{N}_{H_1} = 1$), it follows that

$$\phi_c = \frac{4}{3}. \quad (65)$$

We shall see in Section 4.1 that this remains a good approximation in the dusty case for all physically relevant values of $\tau$.

3.2. Spherical Clouds

The problem of the dust-free spherical cloud does not have an exact solution with the Strömgren method because the net incident flux, $F^*_\text{inc}$, depends on the structure of the molecular hydrogen in the transition zone; some of the rays that strike the cloud will penetrate all the way through, reducing the incident flux by an amount that depends on the unknown spatial distribution of the $H_2$. We therefore consider two complementary approximations: in the first method, we assume that the gas is entirely atomic in the transition zone ($f_1 = 1$) and calculate the incident flux self-consistently. In the second method, we allow for the fact that molecular gas exists in the transition zone ($f_1 < 1$), but assume that the transition zone is thin enough that the incident flux has the value appropriate for an opaque cloud, $F^*_\text{inc} = 1/4cE^*_0$. We shall see that the results overlap, giving a self-consistent determination of the region of validity of our results.

In general, both $\chi$ and $\tau_R$ go to zero for dust-free spherical clouds, since both are proportional to the dust cross section $\sigma_d$. However, the ratio

$$\xi \equiv \frac{\chi}{\tau_R} = \frac{\ell_{\text{ch}}}{R} = \frac{f_{\text{diss}}cE^*_0}{n_H^2RR} \quad (66)$$

remains finite, and this becomes the independent parameter describing the normalized radiation intensity in the dust-free case. We anticipate that the cloud will be fully atomic at high values of $\xi$, whereas the atomic gas will be confined to a thin shell at low $\xi$.

3.2.1. Method 1: $f_1 = 1$

With $\tau_R = 0$ and $f_1 = 1$, Equation (42) reduces to

$$\frac{dF^*}{dx} + \frac{2F^*}{x} = 1 \quad (67)$$

which may be integrated analytically, subject to the boundary condition $F^*(x_{H_1}) = 0$, to obtain

$$F^* = \frac{x}{3}\left[1 - \left(\frac{x_{H_1}}{x}\right)^3\right]. \quad (68)$$

Substituting this into Equation (43) gives

$$\frac{d}{dx}\left(f_{\text{edd}}F^*\right) + \frac{(3f_{\text{edd}} - 1)E^*}{x} = \frac{\phi_c x\left[1 - (x_{H_1}/x)^3\right]}{E^*}. \quad (69)$$

We can now obtain the relationship between $x_{H_1}$ and $\xi$ via the following algorithm:

1. Select a value for $x_{H_1}$. Our algorithm will determine the corresponding $\xi$.
2. Pick a trial value of the parameter $x_f$. (The value of $\phi_c$ is fixed to 4/3, as discussed in Section 3.1.) The choice of $x_f$ determines the Eddington factor $f_{\text{edd}}$ via Equation (45).
3. Given $f_{\text{edd}}$, determine the function $\hat{F}^*$ by integrating the ODE, Equation (69), from $x = x_{H_1}$ to $x = 1$, using the boundary condition that $\hat{F}^*(x_{H_1}) = 0$.
4. Check whether the solution for $\hat{F}^*$ obeys the integral constraint Equation (54) to within some specified tolerance. If not, repeat steps 2–4, using Newton–Raphson iteration to find a value of $x_f$ that minimizes the difference between the two sides of Equation (54).
5. If the solution does satisfy the constraint Equation (54), Equation (36) tells us that $\xi = \hat{F}^*(1)$.

Applying this algorithm yields the curve for $x_{H_1}$ versus $\xi$ shown in Figure 2. Note that in this approximation, $x_{H_1}$ goes to zero exactly for $\xi = 2$. In an exact calculation with $f_1 < 1$, the gas would not be fully atomic at this point, but this result shows that clouds with $\xi > 2$ are substantially atomic. The formula

$$x_{H_1}^3 \sim 1 - \left(\frac{3}{4}\right)\frac{\xi}{1 + 0.0712\xi^{2/8}} \quad (70)$$

matches the numerical solution to within 11% in the range $x_{H_1} > 0.01$, and may be used in place of a numerical evaluation for most practical calculations.
3.2.2. Method 2: $F_{\text{inc}}^* = \frac{1}{2} c E_0^*$

If we retain the dependence on $f_1$ but assume that the incident flux is known, an analytic solution is possible. In this case, Equation (42) reduces to

$$\frac{d \hat{F}^*}{d \xi} + \frac{2 \hat{F}^*}{\xi} = f_1.$$  

(71)

The boundary condition $F_{\text{inc}}^* = F^*(1) = \frac{1}{2} c E_0^*$ becomes

$$\hat{F}^*(1) = \frac{1}{2} \xi$$

(72)

with the aid of Equation (36). Integration of Equation (71) gives

$$3 \int_1^\xi \frac{1}{\chi^2} f_1 d\chi = \frac{N_{H_1}}{N_{H_1, \text{cloud}}} = 3 \left( \frac{\xi}{4} - \frac{x^2 \hat{F}^*}{2} \right),$$  

(73)

where $N_{H_1}$ is the number of H\textsc{i} atoms outside $r = x R$ and $N_{H_1, \text{cloud}} = 4\pi R^3 n_{H}/3$ is the total number of H nuclei in the cloud. To relate this result to that from the first method, we define an effective value of $x_{H_1}$ such that

$$x_{H_1, \text{eff}}^3 = 1 - \frac{N_{H_1, \text{tot}}}{N_{H_1, \text{cloud}}}.$$  

(74)

where $N_{H_1, \text{tot}}$, the total number of H\textsc{i} atoms, is evaluated at $x^2 \hat{F}^*/(\xi/4) \to 0$. Equation (73) then implies

$$x_{H_1, \text{eff}}^3 = 1 - \frac{3}{4} \xi.$$  

(75)

This has the same form as Equation (70), which is based on the first method, for $\xi \lesssim 1$. Since the first method properly accounts for the flux that penetrates through the cloud, we conclude that the total number of H\textsc{i} atoms in a spherical, dust-free cloud is

$$N_{H_1, \text{tot}} = \frac{3}{4} \xi N_{H_1, \text{cloud}}$$  

(76)

for $\xi \lesssim 1$. Since Method 1 showed that the cloud becomes fully atomic for $\xi \gtrsim 2$ and both methods agree for $\xi \lesssim 1$, we conclude that the results of this section are valid everywhere except where the cloud is close to being fully atomic.

4. DUSTY CLOUDS ($F_1 = 1$)

4.1. Semi-infinite Slab

We now consider the case of clouds with dust, $\sigma_d > 0$, beginning with the semi-infinite slab. As discussed in Section 1, the presence of dust sharpens the transition between atomic and molecular gas, enabling us to make the approximation that $f_1 = 1$ in the atomic gas. Our goal is to determine the relationship between the imposed dimensionless radiation field $\chi$ and the dust optical depth $\tau_d$, at which the transition from atomic to molecular occurs. In the process we must determine the unknown parameter $\phi_\epsilon$. We do so using an algorithm slightly modified from that in Section 3.2.2:

1. Select a value for $\chi$. Our algorithm will determine the corresponding $\tau_d$.
2. Pick a trial value of the parameter $\phi_\epsilon$.
3. Given $\phi_\epsilon$, integrate the ODEs, Equations (57) and (58), using the boundary conditions that $E_1^*(0) = 1/2$ and $F_1^*(0) = 1/4$. Integrate in the direction of increasing $\tau_0$, stopping once we reach a value $\tau_0 = \tau_0$ for which $F_1^*(\tau_0) = 0$ or $E_1^*(\tau_0) = 0$.
4. If $F_1^*(\tau_0) > 0$, repeat steps 2–4 using Newton–Raphson iteration on $\phi_\epsilon$ to minimize the value of $E_1^*(\tau_0)$ or $F_1^*(\tau_0)$.
5. If $E_1^*(\tau_0) = F_1^*(\tau_0) = 0$ to within the specified tolerance, then $\tau_{H_1} = \tau_0$.

Applying this algorithm produces the curve for $\tau_{H_1}$ as a function of $\chi$ shown in Figure 3. The formula

$$\tau_{H_1} \approx \ln \left[ 1 + \frac{\chi}{4(1 + \epsilon)} \right],$$  

(77)

with $\epsilon = 0.122 \chi^{0.62}$, reproduces the numerical solution to within 2% for $\log \chi < 2.5$.

It is interesting to compare our result with that of Sternberg (1988), who wrote the chemical balance Equation (38) as

$$f_1 n_{H_1}^2 \mathcal{R} = D f_{\text{shield}}(N_2) n_2 e^{-(N_1 + 2N_2) \sigma_d},$$  

(78)

where $D n_2(0) = f_{\text{diss}}(C_2K_2)(E^*(0)$ is the dissociation rate at the cloud surface (this is a slight change from Sternberg 1988, who defined $D$ as the rate for the Draine 1978 radiation field). Integration of this equation, without the assumption that $f_1 \approx 1$, gives

$$\sigma_d \int_0^\infty n_1 d\xi = \ln \left( 1 + \frac{DG}{n_{H_1} \mathcal{R}} \right),$$  

(79)

where $n_1$ is the atomic hydrogen number density and

$$G \equiv \sigma_d \int_0^\infty f_{\text{shield}}(N_2) e^{-2N_1 \sigma_d} dN_2.$$  

(80)
molecular clouds have \( \chi \), then the left-hand side of Equation (79) is just consistent with those of Sternberg. Photodissociation and found good agreement. Our results are which is a good approximation in the dusty case when \( \chi \). Provided the transition from atomic to molecular gas is sharp, which is a good approximation in the dusty case when \( \chi \gtrsim 1 \) (Paper I), then the left-hand side of Equation (79) is just \( \tau_{\text{H}_2} \). Sternberg’s result then has the same form as ours, although it requires knowledge of the shielding function \( f_{\text{shield}} \) in order to evaluate it accurately. Furthermore, Sternberg considered the case of beamed radiation, whereas in our problem the ambient radiation is isotropic far from the cloud. For beamed radiation, \( F^* = cE^* \), so that Equation (77) becomes \( \tau_{\text{H}_2} \approx \ln(1 + \chi) \) (neglecting \( \epsilon \)); Sternberg’s factor \( DG/n_{\text{H}}/R \) is thus comparable to our factor \( \chi \), and it is possible to show this directly (A. Sternberg 2009, private communication). In Paper I, we compared the results from our Strömgren analysis for beamed radiation with those from a detailed numerical calculation of \( \text{H}_2 \) photodissociation and found good agreement. Our results are therefore consistent with those of Sternberg.

It is also interesting to examine the value of \( \phi_\epsilon \) determined by our procedure. For the dust-free case \( \phi_\epsilon = 4/3 \) exactly, and the lower panel of Figure 3 shows that this remains a very reasonable approximation even when \( \chi \) is significant, meaning that dust opacity plays an important role in shielding molecules. The approximation \( \phi_\epsilon = 4/3 \) is good to better than 10% for \( \chi < 12.6 \), and good to within 50% for \( \chi < 50 \). Since typical molecular clouds have \( \chi \approx 1 \) (Paper II), this means that we can adopt \( \phi_\epsilon = 4/3 \) in general without significant error for the parameters that describe real clouds.

4.1.1. Comparison to Numerical Results

The dusty slab case is a useful one to consider because there are a number of PDR codes that solve for the transition for HI to \( \text{H}_2 \) in an infinite slab exposed to an isotropic external radiation field using brute-force frequency-dependent radiative transfer through the LW bands, coupled to explicit calculation of the \( \text{H}_2 \) level populations. These codes also include a number of physical processes that our treatment omits, such as H I production by cosmic rays, temperature dependence of the \( \text{H}_2 \) formation rate coefficient, and variations in density and temperature through the PDR. By checking our simple analytic model against these much more sophisticated (and computationally costly) calculations, we can estimate the likely level of error in our method.

For this comparison we examine a series of calculations performed by M. G. Wolfire (2009, private communication) using the Meudon PDR code (Le Petit et al. 2006; Kaufman et al. 2006). In these models the radiation field outside the slab is set to \( G_0 = 0.3, 0.5, 1.5, 3, 10, 30, \) or 100, where \( G_0 \) is measured in units of the Draine (1978) field. The dust cross section in the Meudon runs is \( \sigma_d = 1.1 \times 10^{-21} \text{ cm}^2 \). The \( \text{H}_2 \) formation rate coefficient varies with temperature, but a rough mean value is \( R = 3 \times 10^{-17} \text{ cm}^3 \text{ s}^{-1} \). Most runs use a cosmic ray ionization rate \( \xi = 10^{-17} \text{ s}^{-1} \) (the canonical Milky Way value), but one also uses \( \xi = 10^{-16} \text{ s}^{-1} \), a factor of 10 higher. The gas density in the Meudon code can be set to a constant value, but to provide a more stringent test for how our method fares when there is a realistic level of density variation, we instead compare to runs where the density is determined in one of two self-consistent ways. In some runs the density is determined by requiring that the thermal pressure in every cell has a constant value \( P_{\text{H}_2}/k_B = 10^4 \) or \( 10^5 \text{ K cm}^{-3} \); the density and temperature are then obtained iteratively by requiring that the gas be in mechanical and thermal equilibrium at this pressure. In the second group of runs, the mean density as a function of depth in the molecular cloud is determined by requiring that the gas be in hydrostatic equilibrium with the self-gravity of a molecular cloud of a specified mass \( M_{\text{d}} \). In these models, the median density also differs from the mean density due to the effects of turbulence-induced clumping. For these models the density at a given depth is fully determined by the cloud mass \( M_{\text{d}} \), which varies \( 10^5 \) to \( 10^6 \text{ M}_{\odot} \). Full details of the models are given in M. G. Wolfire et al. (2010, in preparation).

In order to compare the numerical results to our analytic predictions, we must choose definitions for ambiguous quantities. First, our model is for constant-density gas, but the density is not constant in the numerical runs. Thus, we must choose some sort of average density to plug into our analytic formula for \( \chi \). This choice is non-trivial because the density rises sharply as gas converts from HI to \( \text{H}_2 \) in the numerical runs, increasing by an order of magnitude between the predominantly atomic and predominantly molecular region. Clearly our predictions will depend on whether we take the gas density to be the atomic density, the molecular density, or some intermediate value. Second, the atomic-to-molecular transition is fairly sharp, but the atomic fraction never falls to zero exactly in the numerical calculations. Thus, we must decide how to define the column density or optical depth of the atomic layer.

We consider two schemes for how to define these two quantities. First, following our approach in Paper I, we can use an integral definition of the optical depth of the shielding layer:

\[
\tau_{\text{H}_2} \equiv \sigma_d \int n_1 \, dz,
\]

where \( n_1 \) is the number density of atomic hydrogen. In the limit of an infinitely sharp transition from atomic to molecular,
this clearly gives the correct optical depth for the H\textsubscript{1} layer, and this definition has the advantage that we need not choose an arbitrary molecular fraction at which to declare that the transition has occurred. Since the H\textsubscript{1} fraction falls off faster than exponentially, the integral is guaranteed to converge (neglecting the tiny amount of H\textsubscript{1} produced by cosmic rays). For this definition of \(\tau\), since we are sampling the entire gas column where the atomic-to-molecular transition occurs, we choose to define the density to be the mass-averaged density of all computational cells with \(f_{\text{H}_2} < 0.9\), where \(f_{\text{H}_2} \equiv 2n_2/n_{\text{H}_1}\) is the fraction of the gas in the molecular phase. Thus, our definition takes the density to be the average density considering both the predominantly atomic gas and the gas in the transition zone where the molecular fraction is below 90\%. However, we also considered alternate methods to compute the mean density, ranging from considering only cells with \(f_{\text{H}_2} < 0.5\) (i.e., excluding more of the transition zone) up to allowing all cells with \(f_{\text{H}_2} < 0.95\) (i.e., going further into the molecule-dominated region). These alternate definitions do not change the predicted value of \(\tau\) by more than a few percent.

The second option we consider is to define \(\tau\) as the dust optical depth from the edge of the slab up to the point where the \(f_{\text{H}_2} = 0.5\). We refer to this as the point definition, since we are choosing to measure the column up to some specific point. The choice of 0.5 is rather arbitrary, but picking a particular point allows us to study how big an error we might make by assuming that the atomic-to-molecular transition is sharp, something that an integral definition such as Equation (81) might obscure. For this point definition of \(\tau\), we need to define the density differently than we did using the integral definition—clearly the density of gas in which \(f_{\text{H}_2}\) is in the range 0.5–0.9, which we include in our averaging for the integral definition, cannot affect the propagation of radiation in the region where \(f_{\text{H}_2} \leq 0.5\). Instead, since the point where \(f_{\text{H}_2} = 0.5\) is primarily determined by how much radiation is absorbed in the predominantly atomic region, we estimate the density in this case by computing the mass-averaged density of gas in which \(f_{\text{H}_2} < 0.05\) (i.e., in the mainly atomic region). If we instead consider gas with \(f_{\text{H}_2} < 0.025\) or gas with \(f_{\text{H}_2} < 0.1\), our predicted optical depths \(\tau\) change by \(\sim 50\%\).

Now that we have defined a mean density \(n_{\text{H}_1}\), we must compute the other quantities that determine \(\chi\): the radiation field \(E_0^*\) and the H\textsubscript{2} formation rate coefficient \(R\). For the radiation field, the photon number density \(E_0^*\) corresponding to a radiation intensity \(G_0^*\) at the cloud surface is \(E_0^* = 2G_0^*/(7.5 \times 10^{-4} \text{ cm}\text{ s}^{-1})\), where \(7.5 \times 10^{-4} \text{ cm}^{-3}\) is the LW photon density corresponding to the Draine (1978) field, and the factor of 2 arises because the free-space value of the radiation field, \(E_0\), is twice the value at the surface of an infinite slab. For the H\textsubscript{2} formation rate coefficient, we use \(R = 3 \times 10^{-17} \text{ cm}^3 \text{ s}^{-1}\), the rough mean value given the temperature variation within the PDR. Finally, we have \(\sigma = 1.1 \times 10^{-21} \text{ cm}^2\) and \(f_{\text{diss}} = 0.11\). Given these values, we compute \(\chi\) for each Meudon run, and then we compute the dust optical depth of the H\textsubscript{1}–H\textsubscript{2} transition predicted by our analytic model using Equation (77).

The circles in the upper panel of Figure 3 show \(\tau\) versus \(\chi\) for the integral definition for \(\tau\) and density, while the triangles show the results if we instead adopt the point definition. In the range \(\chi > 1\), the choice of definition matters little and the errors are small. In this region, the largest absolute difference between our analytic model and any of the numerical results is 23\% or 28\% and the median absolute differences are 4\% and 9\% for the integral and point definitions, respectively. Overall our \(\sim 10\%\) error level is comparable to the intrinsic uncertainty in the numerical models arising from our imperfect knowledge of input parameters such as the H\textsubscript{2} formation rate coefficient and the dust cross section for LW photons.

In the region \(\chi \ll 1\), the two definitions begin to diverge. Our analytic model still tracks the integral definition reasonably well, reaching a maximum error of 40\% at \(\chi = 0.078\), the lowest \(\chi\) numerical run. In contrast, our model becomes increasingly inaccurate in estimating the location of the 50\% molecular point as \(\chi \to 0\). This is not a surprising result. For \(\chi \ll 1\), we found in Paper I and we find again here that the transition between the atomic and molecular regions ceases to be sharp, and a majority of the atomic column is located in regions where the molecular fraction is \(> 50\%\). One can no longer identify a single meaningful location for the atomic-to-molecular transition. In this case, our analytic model remains reasonably accurate in estimating the total atomic column, but, since we do not track the atomic fraction through the transition region, it does not provide a good estimate of where the atomic fraction reaches some specified value. This is analogous to the case of a Str"omgren analysis for ionizing radiation applied to a situation where the ionization front is not sharp (e.g., for ionization by X-rays rather than EUV photons). In such a case there is no well-defined ionization front, and the Str"omgren analysis does not give a good estimate for where the ionization fraction reaches 50\% or some other specified value. However, it does still provide a good estimate for the total emission measure, much as our method still gives a reasonably good estimate for the total H\textsubscript{1} column.

We emphasize again that in Paper II we showed that \(\chi \sim 2–3\) for any cloud, GMC or diffuse, in a region where two-phase equilibrium of the H\textsubscript{1} gas prevails. Values of \(\chi \ll 1\), where our method fails, can only be found in regions where the pressure is either too low (e.g., well off the galactic plane, or in the far outskirts of galactic disks) or too high (e.g., in the nuclei of starburst galaxies) for two-phase equilibrium to be possible.

### 4.2. Spherical Clouds

Our algorithm for the spherical case with dust is a slightly more complex version of the ones described in Sections 3.2 and 4.1. We proceed as follows:

1. Select values for \(\tau\) and \(x_{\text{H}_2}\). Our algorithm will determine the corresponding \(\chi\).
2. Pick a trial value of the parameter \(x_{\text{H}_1}\). (The value of \(\phi_1\) is fixed to 4/3, as discussed in Section 3.1.) The choice of \(x_{\text{H}_1}\) determines the Eddington factor \(f_{\text{edd}}\) via Equation (51).
3. Given \(f_{\text{edd}}\), determine the function \(\hat{E}^*\) by integrating the ODEs, Equations (42) and (43), from \(x = x_{\text{H}_1}\) to \(x = 1\), using the boundary condition that \(\hat{E}^*(x_{\text{H}_1}) = 0\).
4. Check whether the solution obeys the integral constraint Equation (54) to within some specified tolerance. If not, repeat steps 2–4 using Newton–Raphson iteration to search for a value of \(x_{\text{H}_1}\) that minimizes the difference between the left- and right-hand sides of Equation (54).
5. If the solution does satisfy the constraint Equation (54), determine \(\chi\) from \(\hat{E}^*(1)\) and \(\tau\) using Equation (36).

We use this procedure to calculate values of \(\chi\) on a grid of values running from \(\tau = 0.01–100\) and \(x_{\text{H}_2} = 0.01–0.99\), and we use this table to construct contours of the molecular volume \(x_{\text{H}_2}^3\) in terms of \(\chi\) and \(\tau\). The results are shown in Figure 4. As illustrated in the figure, the numerical result is well
have different densities, since this is a more realistic representation of an atomic–molecular complex. Given a method to calculate \( x_{\text{H}_2} \) as a function of \( \xi_d \) and \( \tau_R \), we solved the problem of determining the molecular mass fraction in such a cloud in Paper II. In that paper, we used the approximate form for \( x_{\text{H}_2}(\chi, \tau_R) \) determined in Paper I; in this section, we apply the same approach to calculate the mass fraction for our new, improved determination of \( x_{\text{H}_2}(\chi, \tau_R) \).

As discussed in Paper II, in a cloud where the atomic and molecular gas have differing densities, determining the molecular mass fraction requires an additional constraint beyond the one imposed by radiative and chemical equilibrium. The most natural constraint is to require that the atomic and molecular gas be in pressure balance. In an atomic–molecular complex of total (atomic plus molecular) surface density \( \Sigma_{\text{mol}} \equiv \Sigma_{\text{comp}} \), we can approximate it. Re-arranging Equation (85), we find

\[
\tau_c = \tau_R \left[ 1 + (\phi_{\text{mol}} - 1)x_{\text{H}_2}^3 \right],
\]

where

\[
\phi_{\text{mol}} \approx 10 \text{ is the ratio of molecular to atomic gas volume densities, and } \mu_\text{H} \text{ is the mean mass per H nucleus. Given either an analytic approximation for } x_{\text{H}_2}(\chi, \tau_R) \text{ (e.g., Equation (82)), or a numerical algorithm to calculate } x_{\text{H}_2}(\chi, \tau_R) \text{ (e.g., Section 4.2), Equation (85) implicitly determines the effective optical depth } \tau_R \text{ as a function of } \chi. \text{ It is then simple to calculate } \tau_R \text{ and } x_{\text{H}_2}(\chi, \tau_R) \text{ for a given value of } \chi, \text{ and then to compute the corresponding molecular mass fraction}
\]

\[
f_{\text{H}_2, \text{comp}} = \frac{\phi_{\text{mol}}x_{\text{H}_2}^3}{1 + (\phi_{\text{mol}} - 1)x_{\text{H}_2}^3}.
\]

5. MOLECULAR MASS FRACTIONS IN ATOMIC–MOLECULAR COMPLEXES

Thus far we have calculated molecular fractions under the assumption of uniform-density gas. However, it is convenient to generalize to the case where the atomic and molecular regions
and experimentation with numerical solutions to this equation shows that 0.0712ξd^2.8 ≈ 0.25σ for φ_{max} ≈ 10. Substituting this into Equation (90), we arrive at our approximate solution:

\[ f_{H_2, \text{comp}} \simeq 1 - \left( \frac{3}{4} \right) \frac{s}{1 + 0.25s}. \] (93)

We apply this only for \( s < 2 \); for \( s \geq 2 \), we have \( f_{H_2, \text{comp}} = 0 \).

Following Paper II, we can estimate \( \chi \) for a two-phase atomic medium using Equation (13). Similarly, we can write \( \tau_c \) in terms of the complex surface density and the metallicity as \( \tau_c = 0.066\Sigma_{\text{comp},0}Z' \), where \( \Sigma_{\text{comp},0} = \Sigma_{\text{comp}}/(1 M_\odot pc^{-2}) \) and \( Z' \) is the metallicity relative to Solar. In writing this relationship, we have assumed the \( \sigma_d \propto R \propto Z' \). With these estimates for \( \chi \) and \( \tau_c \), we obtain the relationship between \( H_2 \) mass fraction and \( \Sigma_{\text{comp}} \) shown in Figure 5. The difference between the approximate solution given by Equation (93) and the numerical solution is less than 5% for all \( \Sigma_{\text{comp}} \) and metallicities between log \( Z' = -2 \) and log \( Z' = 1 \), where the difference between the approximate and numerical solutions is defined to be \( |f_{H_2, \text{approx}} - f_{H_2, \text{num}}|/\max(f_{H_2, \text{num}}, 1 - f_{H_2, \text{num}}) \).

6. CONCLUSIONS

Using a Strömgren-type analysis, we have evaluated the thickness of the H1 layer around molecular clouds for both planar and spherical geometry, and both without and with dust. We have assumed that the density of the H1 layer is constant. In contrast with most treatments of PDRs, we have assumed that the radiation incident upon the cloud is isotropic. The results of our analysis are based on several approximations. The major physical approximation is that the gas in the layer is entirely atomic, \( f_1 = 1 \). We also assumed that the metallicity \( Z \lesssim Z_{\odot} \), so that the individual absorption lines in the Lyman–Werner bands overlap and the dissociating radiation covers most of the band 91.2–710.8 nm (Sternberg 1988). The principal methodological approximation is the treatment of the variable Eddington factor, \( f_{\text{edd}} \), as described in Section 2.2. In the absence of dust, \( f_{\text{edd}} \) for a spherical cloud has the unusual property that it is generally less than the isotropic value of \( \frac{1}{3} \). In addition, we assumed that the opacity associated with the flux was related to that associated with the number density by a constant, \( \phi_c \). In the one case in which we could determine \( \phi_c \) as an eigenvalue of the solution (Section 3.1), we found that this was a good approximation. Finally, in calculating the optical depth needed to obtain a constraint equation, we replaced the optical depth for individual rays, \( \tau_c \), with the angle-averaged value, \( \tau_E \). The accuracy of our approximations for the planar case has been tested by comparison with the results of the Meudon PDR code, which were kindly supplied by Wolfire. The analytic fit to our results (Equation (77)) typically agrees with the results of the PDR code to within 10%, with the maximum error of about 30%.

Our results for the scaling behavior of the solutions are consistent with those of Paper I. In the planar, dust-free case, the solution depends only on the characteristic Strömgren length, \( \ell_{ch} \propto \dot{E}_0/n_{H_2}/R \). When dust is included, the solution depends only on the dust optical depth associated with this length scale, \( \chi = n_H\sigma_d\ell_{ch} \propto G_0/n_{H} \). In the spherical case, an additional parameter enters, the dust opacity associated with the cloud radius: \( \tau_d = n_H\sigma_dR \). In the dust-free case, the solution depends only on the ratio of these two parameters, \( \xi = \chi/\tau_d = \ell_{ch}/R \propto G_0/(n_{H}n_{R}) \). We have presented simple analytic approximations for our results that should be useful for applications.

We thank Jason Tumlinson for his contributions to the previous papers in this series and Mark Wolfire for providing the results from the Meudon PDR code so that we could test our results. We particularly thank Amiel Sternberg for a number of helpful comments that significantly improved the paper. Support for this work was provided by the National Science Foundation through grants AST-0606831 (C.F.M.), AST-0908553 (C.F.M.), and AST-0807739 (M.R.K.), by NASA through the Spitzer Space Telescope Theoretical Research Program, provided by a contract issued by the Jet Propulsion Laboratory (M.R.K.), and by the Alfred P. Sloan Foundation (M.R.K.).

APPENDIX

PRIMORDIAL FORMATION OF H2

In the simplest case, H2 formation in low-density primordial gas is governed by just two reactions, the formation of H−,

\[ H + e^- \rightarrow H^- + hv, \] (A1)

and the formation of H2,

\[ H^- + H \rightarrow H_2 + e^-. \] (A2)

The reaction rates for number of important reactions in primordial gas have been summarized recently by Glover & Abel (2008). The rate coefficient they cite for H− formation is within 15% of the simple expression

\[ k_- = 1.83 \times 10^{-18} T^{0.88} \text{cm}^3 \text{s}^{-1} \] (A3)

given by Hutchins (1976). They indicate that the rate coefficient they give for formation of H2,

\[ k_2 = 1.3 \times 10^{-9} \text{cm}^3 \text{s}^{-1}, \] (A4)

is uncertain by at least a factor of 2. If these two reactions are the only ones governing the abundance of H−—in particular, if
photodetachment by infrared radiation is negligible—then the equilibrium abundance of $\mathrm{H}^-$ is

$$n^- = \left(\frac{k_-}{k_2}\right) n_e.$$  

(A5)

The formation rate coefficient $\mathcal{R}_-$ that is analogous to the rate coefficient $\mathcal{R}$ for $\mathrm{H}_2$ formation on dust grains,

$$n_\mathrm{H}^2 \mathcal{R}_- = k_2 n_- n_\mathrm{H},$$  

(A6)

is then given by

$$\mathcal{R}_- = 8 \times 10^{-19} x_e^{-3} T^{0.88} \text{ cm}^3 \text{ s}^{-1},$$  

(A7)

where the normalized ionization, $x_e^{-3} \equiv n_e/(10^{-3} n_\mathrm{H})$, is typical of regions of primordial star formation (e.g., Abel et al. 2002; Bromm et al. 2002).

While this analysis shows that in principle our formalism can apply to $\mathrm{H}_2$ formation in primordial clouds via the $\mathrm{H}^-$ process, it is not clear whether it can do so in practice. For temperatures $\sim 10^3$ K, the $\mathrm{H}^-$ rate coefficient is about 30 times less than the rate coefficient for $\mathrm{H}_2$ formation in the Milky Way. As a result, the timescale for $\mathrm{H}_2$ formation is very long unless the density is high, but if the density is high it is likely that the ionization will be less than the assumed value of $10^{-3}$ and that the formation-rate coefficient will be correspondingly reduced. For example, in their calculations of radiative feedback by the first stars, Ahn & Shapiro (2007) found that the $\mathrm{H}_2$ concentrations were generally less than about 1%, whereas our analysis determines the condition for the concentration to approach 100%

At higher densities, $\mathrm{H}_2$ can form via three-body collisions at a rate

$$n_\mathrm{H}^2 \mathcal{R}_{3b} = n_\mathrm{H}^3 k_{3b},$$  

(A8)

so that the rate coefficient $\mathcal{R}_{3b}$ is proportional to the density. The three-body formation rate is uncertain by 2 orders of magnitude (Glover & Abel 2008); the geometric mean of the high and low rates they cite is $k_{3b} = 2.4 \times 10^{-28} T^{-1.27} \text{ cm}^6 \text{ s}^{-1}$ for $T > 300$ K, corresponding to $\mathcal{R}_{3b} = 3.7 \times 10^{-22} (n_\mathrm{H}/10^{10} \text{ cm}^{-3}) T_2^{-1.27} \text{ cm}^3 \text{ s}^{-1}$. Since three-body formation is important only at high densities, high UV fluxes, such as those in circumstellar disks or in close binaries, are required to create significant photodissociation zones. Such calculations have yet to be carried out.
