Domain Walls in QCD

Michael McNeil Forbes and Ariel R. Zhitnitsky

ABSTRACT: QCD was shown to have a nontrivial vacuum structure due to the topology of the $\theta \equiv \theta + 2\pi n$ parameter. As a result of this nontrivial topology, in the large $N_c$ limit, quasi-stable QCD domain walls appear, characterized by a transition in the singlet $\eta'$ field. We discuss the physics of these QCD domain walls as well as related axion domain walls and we present a new type of axion wall which also contains an $\eta'$ transition. These domain walls are absolutely stable in the limit $N_c \to \infty$ and classically stable for large $N_c$, but can decay through a tunneling process. We argue that the qualitative features of these QCD domain walls—namely their classical stability—persist to the realistic case of $N_c = 3$ and that it is at least possible that their lifetime could be macroscopically large. If it is, then QCD domain walls could play an important role in the evolution of early universe and may be detectable in energetic collisions such as those at the Relativistic Heavy Ion Collider (RHIC).

1. Introduction

Color confinement, spontaneous breaking of chiral symmetry, the $U(1)$ problem, $\theta$ dependence, and the classification of vacuum states are some of the most interesting questions in QCD. Unfortunately, the progress in our understanding of them is extremely slow. At the end of the 1970s A. M. Polyakov [1] demonstrated color confinement in 3-dimensional QED (QED$_3$): this was the first example in which non-trivial dynamics of the ground state played a key role. Many papers were written
regarding the ground state structure of gauge theories in the strong coupling regime, but there were many unanswered questions. Almost 20 years passed before the next important piece of the puzzle was solved [2, 3]. Seiberg and Witten demonstrated that confinement occurs in supersymmetric (SUSY) QCD due to the condensation of monopoles: a similar mechanism was suggested many years ago by ’t Hooft and Mandelstam (see [4] for a review). Furthermore, condensation of dyons together with oblique confinement for nonzero vacuum angle $\theta$ was also discovered in SUSY models [5] (this phenomenon was also argued to take place in ordinary QCD. See [4]).

In addition to providing solid demonstration of earlier ideas, the recent progress in SUSY models has introduced many new phenomena, such as the existence of rich vacuum state structure and the existence of domain walls [6]: topologically stable interpolations connecting the same vacuum state. The same conclusion was reached by Witten in [7, 8] based on a D-brane construction in the limit of large $N_c$. In fact, one can see that in both approaches, the number of states in the vacuum family is $N_c$. Motivated by this development in SUSY gauge theories D-brane construction, we ask how this applies to QCD. The issue of classifying the vacuum states for a given parameter $\theta$ as well as the phenomenological consequences (domain walls and their decay etc.) is the subject of this work. In separate publications [9] we shall apply these results to analyze the physics after the QCD phase transition in evolution of early Universe. In particular, we discuss the possibility of generation of primordial magnetic fields due to the existence of short-lived QCD domain walls discussed in this paper.

The starting point of our analysis is an effective Lagrangian approach. Experience with SUSY models demonstrates that the effective Lagrangian approach is a very effective tool for the analysis of large distance dynamics in the strong coupling regime. There are two different definitions of an effective Lagrangian in quantum field theory. One of them is the Wilsonian effective Lagrangian describing the low energy dynamics of the lightest particles in the theory. In QCD, this is implemented by effective chiral Lagrangians for the pseudoscalar mesons. Another type of effective Lagrangian is defined by taking the Legendre transform of the generating functional for connected Green’s functions to obtain an effective potential. This object is useful in addressing questions about the vacuum structure of the theory in terms of vacuum expectation values (VEVs) of composite operators—these VEVs minimize the effective action. The latter approach is well suited for studying the dependence of the vacuum state on external parameters such as the light quark masses or the vacuum angle $\theta$. However, it is not, for example, useful for studying $S$-matrix elements because the kinetic term cannot be recovered through this approach. The utility of the second approach for gauge theories had been recognized long ago for supersymmetric models, where the anomalous effective potential was found for both the pure supersymmetric gluodynamics [10] and supersymmetric QCD (SQCD) [11] models. Properties of the vacuum structure in the SUSY models were correctly understood
only after analyzing this kind of effective potential.

This paper contains many of the details mentioned in the letter [9] and is organized as follows:

**Section 2:** Here we review the properties of the QCD effective Lagrangian [12, 13] which is a generalization of the Di Vecchia-Veneziano-Witten (VVW) Lagrangian [14, 15] to include terms subleading in $1/N_c$ as well as to account for a constraint due to the quantization topological charge\(^1\). One should emphasize from the very beginning that the specific form of the effective potential used in this paper is not critical for the present analysis: only the topological structure and winding $\theta \rightarrow \theta + 2\pi n$—a consequence of the topological charge quantization—is essential.

**Section 3:** Here we review the idea of topological charge conservation and show how, in the limit $N_c \rightarrow \infty$, the QCD effective Lagrangian admits stable domain walls. We then discuss how these walls are metastable on the quantum level due to the tunneling decay mode allowed when we consider heavier degrees of freedom to the next order in $1/N_c$.

**Section 4:** Here we present the classical domain wall solutions for QCD domain walls both with and without a dynamical axion field.

**Section 5:** Here we show that the QCD domain walls are not stable on the quantum level due to the tunneling phenomena as discussed in Section 3. In this section we also discuss the validity of the large $N_c$ approximation when $N_c = 3$ and argue that the realistic case is qualitatively the same as the large $N_c$ limit. We estimate the lifetime of the QCD domain walls when $N_c = 3$ and show that it is potentially macroscopically large. Thus, these domain walls may play an important role in various physical processes.

**Section 6:** This is our conclusion.

### 2. Effective Lagrangian and $\theta$ dependence in QCD

Our analysis begins with the effective low energy QCD action derived in [12, 13], which allows the $\theta$-dependence of the ground state to be analyzed. Within this approach, the pseudo-Goldstone fields and $\eta'$ field are described by the unitary matrix $U_{ij}$, which correspond to the $\gamma_5$ phases of the chiral condensate: $\langle \bar{\Psi}_L \Psi_R \rangle = -|\langle \bar{\Psi}_L \Psi_R \rangle| U_{ij}$ with

$$U = \exp \left[ i \sqrt{2} \frac{\pi^a \lambda^a}{f_\pi} + i \frac{2}{\sqrt{N_f}} \frac{\eta'}{f_{\eta'}} \right], \quad U U^\dagger = 1, \quad (2.1)$$

\(^1\)Such a generalization was also motivated by SUSY consideration [16], see also [6] for a review.
where $\lambda^a$ are the Gell-Mann matrices of $SU(N_f)$, $\pi^a$ is the pseudoscalar octet, and $f_\pi = 133$ MeV. In terms of $U$ the low-energy effective potential is given by $\llbracket 12, 13 \rrbracket$:

$$W_{\text{QCD}}(\theta, U) = -\lim_{V \to \infty} \frac{1}{V} \log \sum_{l=0}^{N_c-1} \exp \left\{ \frac{V}{2} \text{Tr}(MU + \text{H.c.}) + VE \cos \left( \frac{2\pi l + i \log \text{Det} U - \theta}{N_c} \right) \right\}.$$  

(2.2)

All dimensional parameters in this potential are expressed in terms of the QCD vacuum condensates, and are well known: $M = \text{diag}(m_q |\langle \bar{\Psi}^i \Psi^i \rangle|)$; and the constant $E$ is related to the QCD gluon condensate $E = \langle b_\alpha s^3 2\pi G_2 \rangle$, where numerically $3b = 11N_c - 2N_f$; quark condensate $\langle \bar{\Psi}^i \Psi^i \rangle \simeq - (240 \text{ MeV})^3$, gluon condensate $\langle \frac{b_\alpha}{(32\pi)} G_2 \rangle \simeq 1.2 \times 10^{-2}\text{GeV}^4$.

It is possible to argue that equation (2.2) represents the anomalous effective Lagrangian realizing broken conformal and chiral symmetries of QCD. The arguments are that Equation (2.2):

1. correctly reproduces the VVW effective chiral Lagrangian, $\llbracket 14, 15 \rrbracket$ in the large $N_c$ limit,  

   [ For small values of $(\theta - i \log \text{Det} U)$, the term with $l = 0$ dominates the infinite volume limit. Expanding the cosine (this corresponds to the expansion in $1/N_c$), we recover exactly the VVW effective potential $\llbracket 14, 15 \rrbracket$ together with the constant term $-E = -\langle b_\alpha s/(32\pi) G_2^2 \rangle$ required by the conformal anomaly:  

   $$W_{\text{VVW}}(\theta, U, U^\dagger) = -E - \frac{1}{2} \text{Tr}(MU + \text{H.c.}) + \frac{1}{2} \langle \nu^2 \rangle_{YM} (i \log \text{Det} U - \theta)^2 \ldots,$$  

   (2.3)  

   where we used the fact that at large $N_c$, $E/N_c^2 = -\langle \nu^2 \rangle_{YM}$ is the topological susceptibility in pure YM theory. Corrections in $1/N_c$ stemming from Equation (2.2) constitute a new result of $\llbracket 12, 13 \rrbracket$.]

2. reproduces the anomalous conformal and chiral Ward identities of QCD,  

   [ Let us check that the anomalous Ward Identities (WI’s) in QCD are reproduced from Equation (2.2). The anomalous chiral WI’s are automatically satisfied with the substitution $\theta \to (\theta - i \log \text{Det} U)$ for any $N_c$, in accord with $\llbracket 14, 15 \rrbracket$. Furthermore, it can be seen that the anomalous conformal WI’s of $\llbracket 17 \rrbracket$ for zero momentum correlation functions of the operator $G_{\mu\nu}^2$ in the chiral limit $m_q \to 0$ are also satisfied when $E$ is chosen as above. As another important example of WI’s, the topological susceptibility in QCD near the chiral limit will be calculated from Equation (2.2). For simplicity, the limit of $SU(N_f)$]
isospin symmetry with $N_f$ light quarks, $m_q \ll \Lambda_{\text{QCD}}$ will be considered. For the vacuum energy for small $\theta$ one obtains [12, 13]

$$E_{\text{vac}}(\theta) = -E + m_q \langle \bar{\Psi} \Psi \rangle N_f \cos \left( \frac{\theta}{N_f} \right) + O(m_q^2). \quad (2.4)$$

Differentiating this expression twice with respect to $\theta$ reproduces the chiral Ward identities [18, 19]:

$$\lim_{q \to 0} i \int dx e^{i qx} \langle 0 | T \left\{ \frac{a_s}{8\pi} G \bar{G}(x) \frac{a_s}{8\pi} G \bar{G}(0) \right\} | 0 \rangle = -\frac{\partial^2 E_{\text{vac}}(\theta)}{\partial \theta^2} = \frac{1}{N_f} m_q \langle \bar{\Psi} \Psi \rangle + O(m_q^2). \quad (2.5)$$

Other known anomalous WI’s of QCD can be reproduced from Equation (2.2) in a similar fashion. Consequently, Equation (2.2) reproduces the anomalous conformal and chiral Ward identities of QCD, and in this sense passes the test for it to be the effective anomalous potential for QCD.

3. reproduces the known $\theta$ dependence [14, 15].

[As mentioned earlier, our results are similar to those found in [14, 15]. A new element which was not discussed in 80’s, is the procedure of summation over $l$ in (2.2). As we shall discuss in a moment, this leads to the cusp structure of the effective potential which seems to be an unavoidable consequence of the topological charge quantization$^2$. These singularities are analogous to the ones arising in SUSY models and show the non-analyticity of phases at certain values of $\theta$. The origin of this non-analyticity is clear, it appears when the topological charge quantization is imposed explicitly at the effective Lagrangian level.]

An interesting note is that, in general, the $\theta$ dependence appears in the combination $\theta/N_c$, (see Equation (2.2)) which naïvely does not provide the desired $2\pi$ periodicity for the physical observables; Equation (2.2), however, explicitly demonstrates the $2\pi$ periodicity of the partition function. This seeming contradiction is resolved by noting that in the thermodynamic limit, $V \to \infty$, only the term of lowest energy in the summation over $l$ is retained for a particular value of $\theta$, creating the illusion of $\theta/N_c$ periodicity in the observables. Of course, the values $\theta$ and $\theta + 2\pi$ are physically equivalent for the entire set of states, but relative transitions—switching branches—between different $\theta$ states have physical significance. Exactly this important property will be used in what follows for the construction of the domain walls which are classically stable, non-trivial interpolations between physically equivalent

$^2$This element was not explicitly imposed in the approach of [14, 15]: the procedure was suggested much later to cure some problems in SUSY models (see [16] and references therein). Analogous constructions were discussed for gluodynamics and QCD in [12, 13].
vacuum states (see below). Consequently, the $\theta$ dependence in the infinite volume limit appearing in the combination $\theta/N_c$ is a result of being stuck in a particular state: The local geometry give the impression of $\theta/N_c$ periodicity but the topology gives the true $\theta$ periodicity. The reader is referred to the original papers [12, 13] for more detailed discussions of the properties of the effective potential (2.2).

Our final remark regarding (2.2). The appearance of the cosine interaction, $\cos(\theta/N_c)$, implies\(^3\) the following scenario in pure gluodynamics ($\phi_i$‘s frozen): the $(2k)^{th}$ derivative of the vacuum energy with respect to $\theta$, as $\theta \to 0$, is expressed solely in terms of one parameter, $1/N_c$, for arbitrary $k$:

$$\left. \frac{\partial^{2k} E_{\text{vac}}(\theta)}{\partial \theta^{2k}} \right|_{\theta=0} \sim \int \prod_{i=1}^{2k} d^4 x_i \langle Q(x_1)\ldots Q(x_{2k}) \rangle \sim \left( \frac{i}{N_c} \right)^{2k},$$

(2.6)

where, $Q = \frac{\alpha_s}{8\pi} G \tilde{G}$. This property was seen as a consequence of Veneziano’s solution of the $U(1)$ problem [20]. The reason that only one factor appears in Veneziano’s calculation is that the corresponding correlation function, $\sim \int \prod_{i=1}^{2k} d^4 x_i \langle Q(x_1)\ldots Q(x_{2k}) \rangle$, becomes saturated at large distances by the Veneziano ghosts whose contributions factorize exactly, and was subsequently interpreted as a manifestation of the $\theta/N_c$ dependence in gluodynamics at small $\theta$. However, at that time it was incorrectly assumed that such a dependence indicates that the periodicity in $\theta$ is proportional to $2\pi N_c$. We now know that the standard $2\pi$ periodicity in gluodynamics is restored by the summation over $l$ in (2.2) such that one jumps from one branch to another at $\theta = \pi$.

2.1 Vacuum States

In the next section we shall discuss different types of domain walls which interpolate between various vacuum states, but first we should study the classification of vacuum states themselves. In order to do so, it is convenient to parameterize the fields $U$ as

$$U = \begin{pmatrix} e^{i\phi_1} & 0 & \ldots & 0 \\ 0 & e^{i\phi_2} & \ldots & 0 \\ \vdots & \vdots & \ddots & 0 \\ 0 & 0 & \ldots & e^{i\phi_{N_f}} \end{pmatrix}$$

(2.7)

such that the potential (2.2) takes the form

$$V(\phi_1, \theta) = -E \cos \left( \frac{1}{N_c} \theta - \frac{1}{N_c} \sum \phi_i \right) - \sum M_i \cos \phi_i.$$

(2.8)

\(^3\)As we noticed in the introduction, the specific form of the potential is not very essential for what follows. However, this form is very appealing for the present study because with it, we can describe some of the domain walls in the analytical form (see below, for example (4.12)).
The minimum of this potential is determined by the following equation:

\[
\frac{1}{N_c} \sin \left( \frac{1}{N_c} \theta - \frac{1}{N_c} \sum \phi_i \right) = \frac{M_i}{E} \sin \phi_i, \quad i = 1, \ldots, N_f. \tag{2.9}
\]

At lowest order in \(1/N_c\) this equation coincides with that of [14, 15]. For general values of \(M_i/E\), it is not possible to solve Equation (2.9) analytically, however, in the realistic case \(\varepsilon_u, \varepsilon_d \ll 1, \varepsilon_s \sim 1\) where \(\varepsilon_i = N_c M_i/E\), the approximate solution can be found:

\[
\sin \phi_u = \frac{m_d \sin \theta}{\left[ m_u^2 + m_d^2 + 2m_u m_d \cos \theta \right]^{1/2}} + O(\varepsilon_u, \varepsilon_d),
\]

\[
\sin \phi_d = \frac{m_u \sin \theta}{\left[ m_u^2 + m_d^2 + 2m_u m_d \cos \theta \right]^{1/2}} + O(\varepsilon_u, \varepsilon_d),
\]

\[
\sin \phi_s = O(\varepsilon_u, \varepsilon_d). \tag{2.10}
\]

This solution coincides with the one of [14, 15] to leading order in \(\varepsilon_u, \varepsilon_d\). In what follows for the numerical estimates and for simplicity we shall use the \(SU(2)\) limit \(m_u = m_d \ll m_s\) where the solution \(2.10\) can be approximated as:

\[
\phi_u \simeq \theta/2, \quad \phi_d \simeq \theta/2, \quad \phi_s \simeq 0, \quad 0 \leq \theta < \pi, \tag{2.11}
\]

\[
\phi_u \simeq (\theta + 2\pi)/2, \quad \phi_d \simeq (\theta - 2\pi)/2, \quad \phi_s \simeq 0, \quad \pi \leq \theta < 2\pi, \quad \text{etc.}
\]

Once solution (2.11) is known, one can calculate the vacuum energy and topological charge density \(Q = \langle 0| \bar{\Psi} \sigma G \tilde{G} |0 \rangle\) as a function of \(\theta\). In the limit \(m_u = m_d \equiv m, \langle \bar{d}d \rangle = \langle \bar{u}u \rangle \equiv \langle \bar{\Psi} \Psi \rangle\) one has:

\[
V_{\text{vac}}(\theta) \simeq V_{\theta=0} + 2m \langle \bar{\Psi} \Psi \rangle \left( 1 - \cos \frac{\theta}{2} \right)
\]

\[
\langle \theta | \bar{\Psi} \sigma G \tilde{G} | \theta \rangle = -\frac{\partial V_{\text{vac}}(\theta)}{\partial \theta} = -m \langle 0| \bar{\Psi} \Psi |0 \rangle \sin \frac{\theta}{2}. \tag{2.12}
\]

As expected, the \(\theta\) dependence appears only in combination with \(m\) and goes away in the chiral limit. One can also calculate the chiral condensate \(\langle \bar{\Psi} L \Psi \rangle\) in the \(\theta\) vacua using solution (2.11) for vacuum phases:

\[
\langle \theta | \bar{\Psi} L \Psi | \theta \rangle = \cos \frac{\theta}{2} \langle 0| \bar{\Psi} \Psi |0 \rangle_{\theta=0}, \tag{2.13a}
\]

\[
\langle \theta | \bar{\Psi} i\gamma_5 \Psi | \theta \rangle = -\sin \frac{\theta}{2} \langle 0| \bar{\Psi} \Psi |0 \rangle_{\theta=0}. \tag{2.13b}
\]

A remark is in order. As is well known, in thermal equilibrium and in the limit of infinite volume, the \(|\theta\rangle\) vacuum state is a stable state for all values of \(\theta\). Thus, it is possible to conceive of a world with ground state \(|0\rangle\) where \(\theta \neq 0\). The physics of this world would be quite different from that of our own: In particular, P and CP symmetries would be strongly violated due to the non-zero value of the P and CP violating condensates (2.1, 2.13). Despite the fact that the state \(|\theta\rangle\) has a higher
energy than \(|0\rangle\) (2.1), it is stable because of a superselection rule: There exists no gauge invariant observable \(\mathcal{A}\) in QCD that can communicate between different \(|\theta\rangle\) states, i.e. \(\langle \theta'|\mathcal{A}|\theta\rangle \sim \delta(\theta - \theta')\) for all gauge invariant observables \(\mathcal{A}\). Therefore, there are no possible transitions between these states [21, 22, 23] and any such state \(|\theta\rangle\) may happen to be the ground state for our world.

On account of this superselection rule, one might ask why \(\theta = 0\) is so finely tuned in our universe. Indeed, within standard QCD, there is no reason to prefer any particular value of \(\theta\). This is known as the strong CP problem. One of the best solutions to this problem has been known for many years: introduce a spontaneously broken symmetry (Peccei-Quinn symmetry [24]). The corresponding pseudo-Goldstone particle—the axion [19, 25, 26, 27, 28, 29, 30, 31, 32]—behaves exactly like the parameter \(\theta\) but is now a dynamical field, thus we can absorb the parameter \(\theta\) by redefining the axion field \(a(x)\) and set \(\theta = 0\). The axion is now dynamical and so the corresponding states \(|\theta\rangle \sim |a(x)\rangle\) are no longer stable: the axion field relaxes to the true minimum \(\theta \sim a(x) = 0\) (2.1). The axion is included in the potential (2.2) through the Yukawa interaction

\[
\frac{1}{2} V \text{Tr}(MU + \text{H.c.}) \rightarrow \frac{1}{2} V \text{Tr}(MUe^{ia} + \text{H.c.})
\]

and kinetic term \(f_a^2(\partial_\mu a)^2/4\). Examining the potential (2.2) we see that the parameter \(\theta\) can be absorbed into the \(U(1)\) phase of \(U\) which in turn can be removed by a redefinition of the axion field \(a \rightarrow a + \theta/N_f\). Although axions have not been detected and experiments have ruled out the possibility of the original electroweak scale axion [25, 26], there is still an allowed window with very small coupling constant \(f_\pi/f_a \ll 1\) emphasizing that the axion arises from a very different scale than the electroweak or QCD. Axions with this scale, however, are strong dark matter candidates (see for example [30, 31, 32, 33]). The axion thus provides a way for the vacuum state to relax to the lowest energy state \(|\theta = 0\rangle\) (2.1). In the following we shall consider two types of domain walls: Axion domain walls where \(\theta\) is the dynamical axion field \(a\) and QCD domain walls where \(\theta\) is the fundamental parameter of the theory. In the latter case, we assume that the strong CP problem has been solved by some means and take \(\theta = 0\) to be fixed.

The effective potential (2.2) can be used to study the vacuum ground state (2.1, 2.13) as well as the pseudo-Goldstone bosons as its lowest energy excitations. In particular, one could study the spectrum as well as mixing angles of the pseudo-Goldstone bosons by analyzing the quadratic fluctuations in the background field (2.1, 2.13). We refer to the original papers [12, 13, 34] on the subject for details, but here we want to quote the following mass relationships for the \(\eta'\) meson to be used in the following discussions:

\[
f_\pi^2m_{\eta'}^2 = \frac{4N_f}{N_c} E + \frac{4}{N_f} \sum_i m_i |\langle 0|\bar{\psi}^i\psi^i|0\rangle| + O(m_q^2)
\]
where \( i \) runs over the three flavours \( \{u, d, s\} \). This relation is in a good agreement (on the level of 20\%) with phenomenology. In the chiral limit this formula takes especially simple form

\[
m_{\eta'}^2 = \frac{4N_f}{f_\pi^2 N_c^2} E,
\]

which demonstrates that, in the chiral limit, the \( \eta' \) mass is proportional to the gluon condensate, and is therefore related to the conformal anomaly. What is more important for us in this paper is that the combination on the right hand side of this equation exactly coincides with a combination describing the width of the QCD domain wall (see Equation (4.13)). For this reason, the properties of the QCD domain walls are dominated by the \( \eta' \) field.

2.2 Large \( N_c \) Limit

At this point, we pause to consider the large \( N_c \) limit first discussed by ‘t Hooft [35]. In order to define the limit, we must hold \( g^2 N_c \sim 1 \). From this it follows that \( \alpha_s \sim g^2 \sim N_c^{-1} \). Similarly, by analyzing the structure of the appropriate correlation functions, we find the following leading \( N_c \) dependences:

\[
\begin{align*}
\alpha_s &\sim N_c^{-1}, \\
b &\sim N_c, \\
E &\sim N_c^2, \\
f_\pi^2 &\sim N_c, \\
\langle \bar{\Psi}\Psi \rangle &\sim N_c.
\end{align*}
\]

(2.17)

Applying these to (2.16) we reproduce Witten’s famous result [36]

\[
\lim_{m_q \to 0} m_{\eta'} \sim N_c^{-1/2}.
\]

(2.18)

Here we have first taken the chiral limit \( m_q \to 0 \) and then the large \( N_c \) limit. In general, when \( m_q \neq 0 \), there are \( O(1) \) corrections arising from the second term in (2.13), but in reality, the chiral limit is good due to the small quark masses and we wish to preserve the qualitative behaviour of this limit as we take \( N_c \) to be large. Thus, in the following discussion, we always take the chiral limit first so that, to leading order in \( m_q \) and \( N_c \), the first term of (2.13) dominates and (2.18) holds. We shall return to this issue later in Section 5.4.

3. Topological Stability and Instabilities

The domain walls that we will discuss are examples of topological defects: classical solutions to the equations of motion which are stable due to the topological configurations of the fields. Examples of topological configurations abound in the literature, for example, Instantons, Skyrmions, Strings, Domain walls etc. [37, 38]

The basic idea is that the theory contains some conserved charge density \( q_\mu \) that is a total derivative \( q_\mu = \partial_\mu f(x) \). In this case, the total charge \( Q = \int q_0 d^3x \) is
quantized and represents some topological property of the fields such as winding or linking. Magnetic charge in the Georgi-Glashow model is an example (see [37] for details).

The essential point is that the charges $Q$ are exactly conserved quantities: the subspace of configurations with $Q = Q_1$ is orthogonal to the subspace with $Q = Q_2 \neq Q_1$. In particular, $Q_2 - Q_1 = n$ so there is no continuous way to vary a configuration from one subspace to the other and thus there is no overlap. Thus, objects with non-zero charges are absolutely stable: even if have an energy higher than the true vacuum state where $Q = 0$.

Referring back to our effective theory, we shall show that there is a conserved topological charge associated with domain wall configurations. Physically, the states $\theta = 0$ and $\theta = 2\pi n$ are identical: they represent the same state. However, as one can see from Equation (2.11), the solutions for the ground states corresponding to $\theta = 0$ and $\theta = 2\pi$ are not described in the same way: $\theta = 0$ corresponds to $\phi_u = \phi_d = 0$ while $\theta = 2\pi$ corresponds to $\phi_u = 2\pi$, $\phi_d = 0$. It clear that the physics in both these states is exactly the same: If we lived in one of these state and ignored the others, then we could assign an arbitrary phases $\sim 2\pi n$ for each $\phi_u$ or $\phi_d$ separately and independently. However, if we want to interpolate between these states to get feeling about both of them, the difference in phases between these states can no longer be a matter of choice, but rather is specified by Equation (2.11). This classification arises because the singlet combination $\phi_S = \sum \phi_i$ really lives on a $U(1)$ manifold which has the topology of a circle. The integer $n$ is only important if we are discussing transitions around the $U(1)$ circle: in this case, it is important to keep track of how many times the field winds around the center. Thus, $n$ is a topological winding number which plays an important role when the physics can interpolate around the entire $U(1)$ manifold. We illustrate this idea in Figure [1]. Here, we show three topologically distinct paths in a two-dimensional space with an impenetrable barrier in the center. The paths that wind around the barrier cannot be deformed into the other paths. Each path is characterized by a winding number $n$.

An example of the situation described above is the well-known 1+1 dimensional sine-Gordon model defined by the Lagrangian $L_{SG} = \frac{1}{2}(\partial_{\mu} \phi)^2 - \lambda \cos(\phi)$. Here, the topological current $q_{\mu} = \frac{1}{2\pi} \epsilon_{\mu\nu}\partial^\nu \phi$ and is related to the $\phi \rightarrow \phi + 2\pi n$ symmetry of the ground state. The well known soliton and antisoliton (kink) solutions are absolutely stable objects with topological charges $Q = \pm 1$. These cannot be recovered by the standard methods of quantum field theory when one starts from the vacuum state $\langle \phi \rangle = 0$ and ignores the topology.

In our case an analogous ground state symmetry is realized by the procedure of summation over $l$ in Equation (2.2), which makes symmetry $\theta \rightarrow \theta + 2\pi n$ explicit. Thus, in 1+1 spatial dimensions we have the analogous stable objects. The fact that we actually consider 3+1 dimensions means that the objects are not point-like solitons as they are in the sine-Gordon model, but rather, are two-dimensional...
Figure 1: Three examples of transitions that are topologically different. Paths $A$ and $B$ wind around the hold once ($n = 1$) and twice ($n = 2$) respectively whereas path $C$ does not wind ($n = 0$). Path $C$ can be shrunk to a point whereas the others cannot. Each path is said to belong to a different homotopy class. Only paths $A$ and $B$ are affected by the topology of the space. Path $C$ might imagine that it is living in a space with no hole.

domain walls with finite surface tension.

3.1 Higher Degrees of Freedom

What we have said up to this point is well known. In the sine-Gordon model, the solitons are absolutely stable objects as can be seen by the fact that they are associated with the conserved current $\frac{1}{2\pi} q_\mu = \epsilon_{\mu\nu} \partial^\nu \phi$ (here, the indices run over the $1 + 1$ dimensions $z$ and $t$). The conservation is trivial: $\partial^\mu q_\mu = \frac{1}{2\pi} \epsilon_{\mu\nu} \partial^\mu \partial^\nu \phi = 0$. The corresponding topological charge is $Q = \int q_\mu dz = \frac{1}{2\pi} \int -\partial_z \phi(z) dz = \frac{1}{2\pi}(\phi_{z=+\infty} - \phi_{z=-\infty}) = n_+ - n_-$ which is described by the winding number $n = n_+ - n_-$. Here, the field is in a vacuum state $\phi_{z=\pm\infty} = 2\pi n_\pm$ at infinity. Thus, we see that the charge is absolutely conserved and is integral.

In our effective theory (2.2), we consider an analogous conserved current

$$2\pi q_\mu = -i\epsilon_{\mu\nu} \text{Tr} \ U^\dagger \partial^\nu U = \epsilon_{\mu\nu} \partial^\nu \sum_i \phi_i = \epsilon_{\mu\nu} \partial^\nu \phi_S$$

(3.1)
where we have introduced the notation $\phi_S = \sum_i \phi_i \sim \eta'$ that we shall use later for the isotopical singlet ($\eta'$) field. By the same argument, we see that the two dimensional domain walls of the theory (2.2) are absolutely stable.

In the sine-Gordon model, this is the end of the story: the solitons are absolutely stable. In our effective Lagrangian (2.2), however, we have neglected the gluon degrees of freedom. In reality, however, the gluon degrees of freedom are not very heavy. Thus, we must consider these extra degrees and look at how they affect the charge conservation. What we find is that, when we account for the extra gluon degrees of freedom, the topology of the fields is no longer restricted to the $U(1)$ manifold. These extra degrees of freedom allow the domain walls to continuously deform and to decay so that the ground state exists everywhere.

To see how an extra degree of freedom can change the topology, consider Figure 4. Here we have added a third dimension to show that the barrier was actually a peg of finite height. Now that we can move in the extra dimension, we can use this degree of freedom to “lift” the paths over the peg: thus, they are no longer topologically stable. In the QCD analogue, paths $A$ and $B$ represents domain walls (path $C$ would is a trivial closed loop which would relax to a point representing the same vacuum state everywhere with no domain wall.). There is an energy cost to “lift” the path over the barrier and at low temperatures $T \ll \Lambda_{\text{QCD}}$ there is not enough energy to do this, so classically, the domain walls are stable. It is still possible, however, for the walls to overcome the barrier by tunneling through the barrier. The tunneling probability, however, could be low due to the height of the obstacle and hence the lifetime of the walls could be much larger than the $\Lambda_{\text{QCD}}^{-1}$ scale which one might naively expected for standard QCD fluctuations. See Section 5 for details of the dynamics of the gluon fields.

We should also remark that with each winding, the domain walls become more energetic. Walls with a large number of windings either have enough energy to rapidly unwind, or else separate spatially forming several domain walls of winding number $\sim \pm 1$. For this reason, we shall discuss in this paper only the simplest walls which wind once.

To tie this picture together, consider the formerly conserved current (3.1) and effective Lagrangian (2.2) and ask: from where do the phase field $\phi_i$ come? These phases arise from some sort of complex field $\Phi = \rho e^{i\phi_S}$. In general, we must consider the dynamics, not only of the phase $\phi_S$, but of the component $\rho = |\Phi|$. We assume that this field lives in some sort of Mexican-hat potential with approxi-

---

4One might think that, since the domain walls directly involve the $\eta'$ field, that the stability of the $\eta'$ particle might affect the stability of the domain walls. This is not so. Even in the effective theory (2.2), the $\eta'$ particle can be considered as unstable decaying $\eta' \rightarrow 2\gamma$ for instance. This instability is related to the fact that the $\eta'$ number charge is not conserved. Irrespective of this non-conservation, the current (3.1) is still perfectly conserved. The only way for these domain walls to decay is by violating the conservation of this current. This is what we consider next.
Figure 2: Here we show the same picture as in Figure 1 except that we show the third dimension. Here we can see that all the paths are now homotopically equivalent. We can deform the paths by “lifting” them over the obstacle so that we can unwind them. If the paths were strings with some weight, then it would require some energy to “lift” the strings over the obstacle. If this energy was not available, then we would say that, classically, the configurations that wind around the peg are stable. Quantum mechanically, however, the strings could still tunnel through the peg, and so the configurations are unstable quantum mechanically. The probability that one string could tunnel into another configuration would depend on the height of the peg.

mate symmetry $\phi_S \rightarrow \phi_S + \alpha$ and minimum valley where $\langle \rho \rangle = 1$. This symmetry is thus spontaneously broken by the vacuum expectation values of the condensate $\langle \Phi \rangle = \exp(i\langle \phi_S \rangle)$. To recover the effective Lagrangian: we “integrate” over the “heavy” $\rho$ degree of freedom by setting $\rho = \langle \rho \rangle = 1$ equal to its classical expectation value and ignoring the quantum fluctuations about this minimum. This must reproduce the effective potential (2.2) with the pseudo-Goldstone field $\phi_S$ ($\eta'$ and $\pi_i$ in the real theory). The appropriate Mexican-hat potential reproducing (2.2) is given in (5.7).

One can now consider an appropriate generalization of the current (3.1)

$$2\pi q_\mu = -i\epsilon_{\mu\nu} \text{Tr} \Phi^\dagger \partial^\nu \Phi = \epsilon_{\mu\nu} \left( -i\rho \partial^\nu \rho + \rho^2 \partial^\nu \phi_S \right)$$

which reduces to (3.1) when we set $\rho = \langle \rho \rangle = 1$. Now we have

$$\pi \partial^\mu q_\mu = \rho \epsilon_{\mu\nu} \partial^\mu \rho \partial^\nu \phi_S$$

which is no longer conserved as expected. This was only conserved in the effective theory (2.2) because we integrated out the heavy degrees of freedom by setting $\rho = 1$ so that $\partial^\mu \rho = 0$. Thus, the decay of the domain walls is directly related to the dynamics of the heavy degrees of freedom. We consider this effect in Section 5. The physical object responsible for this behaviour in (2.2) is the gluon condensate $E \sim \langle G^2 \rangle$, which is the most essential contribution to the mass $m_{\eta'}$ of the $\eta'$ particle\textsuperscript{5}.

\textsuperscript{5}If one assumes that all of the $\eta'$ physics comes exclusively from the phase of the chiral condensate
4. Domain Walls

In the rest of this paper we limit ourselves with the simplest case \( N_f = 2 \) and neglect the difference between \( f_\pi \) and \( f_\eta' \) which numerically are very close to each other. To describe the basic structure of the QCD domain walls as well as that of axion domain walls we replace the parameter \( \theta \) in Equation (2.2) by a dynamical axion field \( \theta \rightarrow \eta' \) (this corresponds to the so-called \( N = 2 \) axion model). We also introduce here the following dimensionless phases, \( \phi_S \) describing the isotopical “singlet” field, and \( \phi_T \) describing the isotopical “triplet” field. These fields correspond to the dynamical \( \eta' \) (singlet) and pion \( \pi^0 \) (triplet) fields defined in (2.1).

\[
\begin{align*}
\phi_S &= \phi_u + \phi_d, & \eta' &= \frac{f_\pi}{2\sqrt{2}} \phi_S, \\
\phi_T &= \phi_u - \phi_d, & \pi^0 &= \frac{f_\pi}{2\sqrt{2}} \phi_T.
\end{align*}
\]

(4.1a, b)

In what follows we also need to know the masses of the relevant fields in terms of parameters of the effective potential (2.2):

\[
m^2_\pi = \frac{4M}{f_\pi^2}, \quad m^2_a = \frac{4M}{f_a^2} \left(1 - \xi^2\right),
\]

(4.2)

and the \( \eta' \) mass relation

\[
m^2_{\eta'} = \frac{8}{N_c f_\pi^2} E + \frac{4M}{f_\pi^2}.
\]

(4.3)

follows from (2.15) with \( N_f = 2 \). Here we have neglected all possible mixing terms, and have introduced the following notations

\[
M \equiv \frac{M_u + M_d}{2} = \frac{m_u}{2} |\langle 0 | \bar{\Psi}_u \Psi_u | 0 \rangle | + \frac{m_d}{2} |\langle 0 | \bar{\Psi}_d \Psi_d | 0 \rangle |
\]

\[\xi = \frac{M_d - M_u}{M_d + M_u} \approx 0.3.\]

(4.4)

4.1 Domain Wall Equations

To study the structure of the domain wall we look at a simplified model where one half of the universe is in one ground state and the other half is in another. The fields will orient themselves in such a way as to minimize the energy density in space, forming a domain wall between the two regions. In this model, the domain walls are planar rather than from gluon condensate; then one might argue (using the linear sigma model) that the walls are classically unstable. Were this the case, then \( m_{\eta'} \sim m_q \rightarrow 0 \) in the chiral limit and the \( U(1) \) problem would remain unresolved [14, 15]. Thus, we see the importance of the gluon condensate \( E \sim \langle G^2 \rangle \gg m_q \) which ensures the classical stability of the domain walls for \( N_c \geq 3 \) as explained in Section 3.
and we shall neglect the $x$ and $y$ dimensions for now. Thus, a complete description of the wall is given by specifying the boundary conditions and by specifying how the fields vary along $z$.

The energy density of a domain wall is given by the following expression

$$
\sigma = \int_{-\infty}^{\infty} dz \left( \frac{f_a^2 \dot{a}^2}{4} + \frac{f_T^2 \dot{\phi}_T^2}{16} + \frac{f_S^2 \dot{\phi}_S^2}{16} + V(\phi_S, \phi_T, a) - V_{\text{min}} \right)
$$

(4.5)

where the first three terms are the kinetic contribution to the energy and the last term is the potential. The kinetic term is actually a four divergence, but we have assumed the wall to be a stationary solution—hence the time derivatives vanish—and symmetric in the $x$–$y$ plane. The only dependence remaining is the $z$ dependence.

Here, a dot signifies differentiation with respect to $z$: $\dot{a} = \frac{da}{dz}$.

Now, to find the form of the domain walls, it is convenient to use a form of the potential which follows from (2.8):

$$
V(\phi_S, \phi_T, a) = -2M \left( \cos\left(\frac{\phi_T}{2}\right) \cos\left(\frac{\phi_S}{2} + a\right) + \xi \sin\left(\frac{\phi_T}{2}\right) \sin\left(\frac{\phi_S}{2} + a\right) \right) - E \cos\left(\frac{\phi_S}{N_c}\right).
$$

(4.6)

Here we have redefined the fields $\phi_u \to \phi_u + a$ and $\phi_d \to \phi_d + a$ in order to remove the axion field from the last term $\sim E$ and to insert it into the term $\sim M$. To minimize these equations, we can apply a standard variational principle and arrive at the following equations of motion for the domain wall solutions:

$$
\frac{\ddot{a} f_a^2}{4M} = \cos\left(\frac{\phi_T}{2}\right) \sin\left(\frac{\phi_S}{2} + a\right) - \xi \sin\left(\frac{\phi_T}{2}\right) \cos\left(\frac{\phi_S}{2} + a\right),
$$

(4.7)

$$
\frac{\ddot{T} f_T^2}{8M} = \sin\left(\frac{\phi_T}{2}\right) \cos\left(\frac{\phi_S}{2} + a\right) - \xi \cos\left(\frac{\phi_T}{2}\right) \sin\left(\frac{\phi_S}{2} + a\right),
$$

(4.8)

$$
\frac{\ddot{S} f_S^2}{8M} = \cos\left(\frac{\phi_T}{2}\right) \sin\left(\frac{\phi_S}{2} + a\right) - \xi \sin\left(\frac{\phi_T}{2}\right) \cos\left(\frac{\phi_S}{2} + a\right) + \frac{E}{MN_c} \sin\left(\frac{\phi_S}{N_c}\right),
$$

(4.9)

where the last term of Equation (4.9) should be understood as the lowest branch of the multivalued function described by Equation (2.2). Namely, for $\phi_S \notin [0, \pi]$, this should be interpreted as $\sin((\phi_S - 2\pi l)/N_c)$ with the integer $l$ chosen to minimize the potential term $\cos((\phi_S - 2\pi l)/N_c)$. For example, with $\pi \leq \phi_S \leq 2\pi$, the last term should be of the form $\sin((\phi_S - 2\pi l)/N_c)$.

Notice the following features: first, the trigonometric terms on the right hand side are of, at most, order 1; thus the scale for the curvature (or rather, the second derivative) of the domain wall solutions is limited by $f_a^2/M$ and $f_T^2/M$ etc. In particular, the axion domain wall must have a characteristic scale larger than $m_a^{-1}/(1 - \xi^2)$ and the pion domain wall must have a scale larger than $m_\pi^{-1}$. The last term in
equation governing the $\phi_S$ field can potentially be somewhat larger than 1, hence the smallest scale for the $\phi_S$ field is related to the $\eta'$ mass. We see immediately that an axion domain wall must have a structure some thirteen orders of magnitude larger than the natural QCD scale and that the $\eta'$ field can have structure one order of magnitude smaller than that of the pion field.

4.2 QCD Domain Walls

Here we consider the most important case of the QCD domain wall solution which exists with or without an axion field. So we now set $a = 0$. The equations of motion become:

$$\frac{\ddot{\phi}_T f_\pi^2}{8M} = \sin\left(\frac{\phi_T}{2}\right) \cos\left(\frac{\phi_S}{2}\right) - \xi \cos\left(\frac{\phi_T}{2}\right) \sin\left(\frac{\phi_S}{2}\right),$$

$$\frac{\ddot{\phi}_S f_\pi^2}{8M} = \cos\left(\frac{\phi_T}{2}\right) \sin\left(\frac{\phi_S}{2}\right) - \xi \sin\left(\frac{\phi_T}{2}\right) \cos\left(\frac{\phi_S}{2}\right) + \frac{E}{M N_c} \sin\left(\frac{\phi_S}{N_c}\right). \quad (4.10)$$

For convenience, we shall label the vacuum states using the notation $(\phi_u, \phi_d)$. Thus, we have only one physical ground state $(\phi_u, \phi_d) = (0, 0)$; however, because of the conserved topological current (3.1), classically stable domain walls can form and interpolate from the ground state $(\phi_u, \phi_d) = (0, 0)$ along a path which is not homotopic to the null path. To classify the paths we use the redundant notation where $(0, 0)$ and $(2\pi, 0)$ etc. are considered as different states and we talk about the field interpolating between these states. Keep in mind that this is only a way of classifying the homotopy classes and that in fact all the states represented by $(2\pi n, 2\pi m)$ for integers $m$ and $n$ are one in the same vacuum state.

The simplest domain wall is described by a continuous transition from the ground state $(\phi_u, \phi_d) = (0, 0)$ to the state labeled $(\phi_u, \phi_d) = (2\pi, 0)$ as described by the vacuum solution Equation (2.11) with $\theta = 2\pi$ (or, equivalently, $l = -1$ in Equation (2.2)). This wall corresponds to a single winding around the $U(1)$ manifold. It is also possible to wind in the opposite sense. To summarize, the two topologically stable domain walls of minimal energy correspond to one winding in each direction and are classified by the transitions from $(\phi_u, \phi_d) = (0, 0)$ to:

**Soliton** $(\phi_u, \phi_d) = (2\pi, 0)$.

**Antisoliton** $(\phi_u, \phi_d) = (-2\pi, 0)$.

Note, that in the chiral limit $m_u = m_d$ and $\xi = 0$, thus the transitions to $(\phi_u, \phi_d) = (0, \pm 2\pi)$ have the same energy and there is a degeneracy. If $m_u > m_d$, then these transition in $\phi_d$ are the minimal energy solutions and the $\phi_u$ solutions above become unstable. In reality $m_d > m_u$, and the transitions to $(\phi_u, \phi_d) = (\pm 2\pi, 0)$ are the only stable transitions.
The general case of Equations (4.10) cannot be solved analytically and we present the numerical solution of Equation (4.10) in Figure 3. In order to gain an intuitive understanding of this wall, we examine the solution in the limit \( m \ll m' \). In this case, the last term of (4.10) dominates unless \( \phi_S \) is very close to the vacuum states, \( \phi_S \approx 2\pi n \). Thus, the central structure of the \( \phi_S \) field is governed by the differential equation:

\[
\ddot{\phi}_S = \frac{8E}{N_c f_\pi^2} \sin \left( \frac{\phi_S}{N_c} \right).
\] (4.11)

Now, there is the issue of the cusp singularity when \( \phi_S = \pi \) because we change from one branch of the potential to another as expressed in Equation (2.2). By definition, we keep the lowest energy branch, such that the right hand side of Equation (4.11) is understood to be the function \( \sin(\phi_S/N_c) \) for \( 0 \leq \phi_S \leq \pi \) and \( \sin((\phi_S - 2\pi)/N_c) \) for \( \pi \leq \phi_S \leq 2\pi \). However, we notice that the equations of motion are symmetric with respect to the center of the wall (which we take as \( z = z_0 \)), hence \( \phi_S = \pi \) only at the center of the wall and not before, so we can simply look at half of the domain, \( z \in (-\infty, 0] \), with boundary conditions \( \phi_S = 0 \) at \( z = -\infty \) and \( \phi_S = \pi \) at \( z = 0 \). The rest of the solution will be symmetric with \( \phi_S = 2\pi \) at \( z = +\infty \). Equation (4.11) with the boundary conditions above has the solution

\[
\phi_S(z) \equiv \phi_u + \phi_d = \begin{cases} 
4N_c \tan^{-1} \left[ \tan \frac{\pi}{4N_c} e^\mu(z-z_0) \right], & z \leq z_0 \\
2\pi - 4N_c \tan^{-1} \left[ \tan \frac{\pi}{4N_c} e^{-\mu(z-z_0)} \right], & z \geq z_0 
\end{cases}
\] (4.12)

where \( z_0 \) is the position of the center of the domain wall and

\[
\mu \equiv \frac{2\sqrt{2} \sqrt{E}}{N_c f_\pi} \sim N_c^{-1/2}, \quad \lim_{m \to 0} \mu = m'
\] (4.13)

is the inverse width of the wall, which is equal to the \( m' \) mass in the chiral limit (see Equation (1.3)). In any case—even out of the chiral limit—the width of the domain wall scales as \( \mu \sim N_c^{-1/2} \) in the large \( N_c \) limit: in this limit, the wall becomes a true soliton. Thus, we see that the dynamics of the central portion of QCD domain walls is governed by the \( \eta' \) field. We shall also refer to the \( \phi_S \) transition (4.12) which occurs in several places (see for example Section 1.3.2) as the \( \eta' \) domain wall. The first derivative of the solution is continuous at \( z = z_0 \), but the second derivative exhibits a finite jump.

Before we continue our discussions regarding the structure of QCD domain walls, a short remark is in order: The sine-Gordon equation which is similar to Equation (4.11) with a cusp singularity, was first considered in [34] where a solution similar to (4.12) was presented. There is a fundamental difference, however, between domain walls discussed in [34] and the domain walls we consider here. In [34], the domain walls were constructed as auxiliary objects in order to describe a decay of metastable
vacuum states which may exist under the certain circumstances. The walls we discuss here classically stable physical objects where the solutions interpolate between the same vacuum state; their existence is a consequence of the topology of the $U(1)$ singlet $\eta'$ field. This topology, represented by the exact symmetry $\theta \equiv \theta + 2\pi n$ in Equation (2.2) is a very general property of QCD and does not depend on the specific choice of parameters or functional form of the effective potential. Similar equations and solutions with application to the axion physics were also discussed in [39].

The solution described above dominates on scales where $|z| \leq \mu^{-1}$, however, the isotopical triplet pion transition can only have a structure on scales larger than $m_\pi^{-1} \gg \mu^{-1}$ and so the central structure of the $\eta'$ wall can have little effect on the pion field. Indeed, we can see that, for $|z| \gg \mu^{-1}$, $\phi_S$ is approximately constant with the vacuum values. Making this approximation, we see that the isotopical triplet field is governed by the equation

$$\ddot{\phi}_T = 2m_\pi^2 \sin \left( \frac{\phi_T}{2} \right).$$

This has the same form as (4.11) and hence the solution is

$$\phi_T(z) = \phi_u - \phi_d = \begin{cases} 
8 \tan^{-1} \left[ \tan \frac{\pi}{8} e^{m_\pi(z-z_0)} \right], & z \ll z_0 - \mu^{-1}, \\
2\pi - 8 \tan^{-1} \left[ \tan \frac{\pi}{8} e^{-m_\pi(z-z_0)} \right], & z \gg z_0 + \mu^{-1},
\end{cases}$$

which is a reasonable approximation for all $z$. Numerical solutions for the $\phi_S$ and $\phi_T$ fields are shown along with the same solution in terms of the $\phi_u$ and $\phi_d$ in Figure 3. As we can see from the explicit form of the presented solution, the $\eta'$ transition is sandwiched in the pion transition. This is a key feature for some applications of this type of the domain wall as discussed in [9] for example.

The wall surface tension defined by Equation (4.3) can be easily calculated analytically in the chiral limit when the analytical solution is known and is given by Equations (4.12) and (4.15). Simple calculations leads to the following result

$$\sigma = \frac{4N_c}{\sqrt{2}} f_\pi \sqrt{\frac{f_{\alpha_s}}{32\pi} G^2} \left( 1 - \cos \frac{\pi}{2N_c} \right) + O(m_qf_\pi^2).$$

Thus, in the large $N_c$ limit, we find that

$$\sigma \sim \sqrt{N_c} + O(m_qf_\pi^2).$$

In case when $m_q \neq 0$, an analytical solution is not known, but numerically, $\sigma$ is close to the estimate (4.16).

### 4.3 Axion Dominated Domain Walls

In the previous subsection when the QCD domain walls were discussed, the axion was not introduced as a dynamical field. In this subsection we assume that the axions
exist. In this case there are domain walls in which the axion is the dominant player. The introduction of axions, in most cases, makes the domain wall an absolutely stable object. Our case is no exception and the axion model under discussion, (which is the $N = 2$ axion models according to the classification [30, 31, 32]) is an absolutely stable object. At the same time it is well-known [38, 40], that stable domain walls can be a cosmological disaster. We do not address in this paper the problem of avoiding a domain wall dominated universe. Rather, we would like to describe some new elements in the structure of axion domain walls, which were not previously discussed.

The first and most natural type of the axion domain wall was discussed by Huang and Sikivie [41] who neglected the $\eta'$ field in their construction. We shall refer to this wall as the Axion-Pion domain wall ($a_\pi$). As shown in [41], it has a width of the scale $\sim m_{a}^{-1} \gg \Lambda_{QCD}^{-1}$ for both the axion and $\pi$ meson components. As Huang and Sikivie expected, the $\eta'$ plays a very small role in this wall. In what follows we include a discussion of this type of domain wall for the completeness.

Our original result is to description a new type of the axion domain wall in which the $\eta'$ field is a dominant player. We shall call this new solution the Axion-Eta' domain wall ($a_{\eta'}$). This new type of the domain wall was considered for the first time in [9] as a possible source for galactic magnetic fields in early universe. In what follows we give a detail description of the solution for the $a_{\eta'}$ wall. Here we want to mention the fundamental difference between the $a_{\pi}$ wall discussed in [41] and the $a_{\eta'}$ wall introduced in [9]. Unlike the $a_{\pi}$ wall which has structure only on the huge scale of $m_{a}^{-1}$, the $a_{\eta'}$ wall has nontrivial structure at both the axion scale $m_{a}^{-1}$ as well as at the QCD scale $m_{\eta'}^{-1} \sim \Lambda_{QCD}^{-1}$. The reason for this is that, in the

**Figure 3:** Basic form of the QCD domain walls. Notice that the scale for the pion transition is larger than for the eta' transition. Notice that the width of the $\eta'$ wall is set by the scale $m_{\eta'}$.
presence of the non-zero axion field (which is equivalent to a non-zero $\theta$ parameter),
the pion mass is efficiently suppressed due to its Goldstone nature, thus the pion field follows the axion field and has a structure on the same $m_a^{-1}$ scale. The $\eta'$, however, is not very sensitive to $\theta$ and so it remains massive. Again, the $a_{\eta'}$ solution has a sandwich structure with the singlet transition occurring at the center of the wall. One can adopt the viewpoint that the $a_{\eta'}$ domain wall is an axion domain wall with a QCD domain wall sandwiched in the center. This phenomenon is critical for applications involving the interaction of domain walls with strongly interacting particles. Indeed, there is no way for the $a_{\pi}$ wall to trap any strongly interacting particles, like nucleons, because of the huge difference in scales; the $a_{\eta'}$ wall, however, has a QCD structure and can therefore efficiently interact with nucleons on the QCD scale $\Lambda_{\text{QCD}}^{-1}$. Regarding the wall tension (4.3), it is dominated by the axion physics and thus has the same order of magnitude for both types of the axion domain walls which is proportional to $\sigma \sim M/m_a \sim f_a f_\pi m_\pi$ as found in [41].

4.3.1 Axion-Pion Domain Wall

The solution discussed by Huang and Sikivie corresponds to the transition $(a, \phi_u, \phi_d) : (0,0,0) \rightarrow (\pi, \pi, -\pi)$, i.e., by a transition in the axion and pion fields only. This transition describes the $a_{\pi}$ wall. Indeed, in terms of $(a, \phi_S, \phi_T)$ this transition corresponds to a nontrivial behavior of the axion and triplet pion component $\phi_T$ of the $\phi_u, \phi_d$ fields: $(a, \phi_S, \phi_T) : (0,0,0) \rightarrow (\pi, 0, 2\pi)$. The other transition (the $a_{\eta'}$ wall) corresponds to the transition $(a, \phi_u, \phi_d) : (0,0,0) \rightarrow (-\pi, \pi, \pi)$ in which the singlet $\eta'$ field is dominant: $(a, \phi_S, \phi_T) : (0,0,0) \rightarrow (-\pi, 2\pi, 0)$. It will be considered later on.

Huang and Sikivie discussed the solution to this wall in the limit where the $\eta'$ field is extremely massive and hence they neglected its role. It can be integrated out which effectively corresponds to fixing it $\eta'(z) = 0$. Indeed, if we simply fix $\eta'(z) = 0$ in our equations, then we reproduce their solution. When $E$ is large, then $m_\pi \ll m_{\eta'}$ as Huang and Sikivie assumed, the effects of the $\eta'$ particle can be neglected and the solution for the the axion and pion fields presented in [41] is valid for the boundary conditions described above. We plot this numerical solution which includes the eta' effects in Figure 3. As announced above, the $a_{\pi}$ solution has the only scale of $\sim m_a^{-1}$ for both components, axion as well as the pion field $\sim \phi_T$. The $\eta'$ field remains close to the its vacuum value and only slightly corrects the solution.

4.3.2 Axion-Eta' Domain Wall

Having looked at the solution of the $a_{\pi}$ wall, we now investigate the structure of the $a_{\eta'}$ domain wall which is a new solution. This solution corresponds to the transition $(a, \phi_u, \phi_d) : (0,0,0) \rightarrow (\pi, \pi, \pi)$. Now the singlet $\eta'$ field undergoes a transition instead of the triplet pion field: $(a, \phi_S, \phi_T) : (0,0,0) \rightarrow (-\pi, 2\pi, 0)$. As we discussed above, the singlet field never becomes massless, and therefore, a new structure at the
Figure 4: Basic form of the $a_\pi$ domain wall. Notice that all the fields have a structure on the scale of $m_a^{-1}$ and that the isotopical singlet fields plays a very small role.

QCD scale $\sim \Lambda_{\text{QCD}}^{-1}$ emerges in sharp contrast to the well-studied $a_\pi$ domain wall [41] where no such structure appears. We should note that the potential (4.6) has the same vacuum energy at $\phi_S = 0$ as well as at $\phi_S = 2\pi$ due to the change of $\phi_S$ field to the lowest energy branch at $\phi_S = \pi$ as described by Equation (2.2). Therefore, this domain wall interpolates between two degenerate states, and thus, like the $a_\pi$ domain wall [41], the solution under these considerations is absolutely stable.

For $|z| \gg \mu^{-1}$, the last term in (4.9) is negligible and so the solution behaves like the $a_\pi$ wall. What happens is that, away from the wall, the axion field dominates and shapes the wall as it does in with the $a_\pi$ solution. Again, the pion mass is suppressed and $\phi_S \approx 0$. As $z \sim \mu^{-1}$ however, the last term of (4.10) starts to dominate the behaviour. At this point, the $a_{\eta'}$ wall undergoes a sharp transition similar to the QCD domain wall described by (4.12). We plot this solution along with a blowup in Figure (5). Notice also, that the singlet field cancels the effects of the axion near the center of the wall, and so the pion field becomes massive again as it undergoes its transition.

5. Decay of the QCD domain walls

We do not have much new to say regarding the generalities of domain walls, nor do we have a resolution for the general problem of avoiding a domain wall dominated universe. We have nothing new to say regarding the stability or evolution of axion domain walls [42, 43, 44, 45, 46, 47, 48, 49] (which were also discussed in the previous sections), see [50] and references therein for a recent review on the subject. We refer the reader to the nice text book [38] for general discussion about domain walls,
Figure 5: Basic form of the $a_\eta'$ domain walls with a closeup where the axion field $a \approx \pi/2$. Notice that the large scale structure is similar to that of the $a_\pi$ wall, but that there is also a small scale structure on the scale of $m_\eta'$. Near the center of the wall, the pion regains its mass and undergoes a transition on the scale of $m_\pi$.

other topological defects and their role in the early universe. This section is devoted specifically to the QCD domain walls discussed in Section 4.2.

Up to now, we have treated the domain walls as topologically stable objects. In the large $N_c = \infty$ and chiral $m_q = 0$ limits, this is the case, however, to order $1/N_c$, quantum fluctuations provide a way for these walls to decay. Here we argue that QCD domain walls (not the axion walls) are unstable on the quantum level due to a tunneling mode of decay. We estimate the relevant life-time of these walls with respect to this quantum transition: We show that, although the walls don’t live long on a cosmological scale, the exponential suppression of the tunneling decay mode may result in the lifetime of the walls being much larger than the QCD scale $\Lambda_{QCD}$.

Therefore, these walls do not pose a cosmological problem as one might naively suspect.

Having said that the QCD domain walls are unstable, a very natural question occurs: “What sense does it make to study an object which does not presently exist?” The answer is: “It does not make much sense if we study QCD at the present cosmological epoch. However, if we want to understand what happened shortly after the QCD phase transition in the evolution of the early universe, or what may happen at RHIC after the transition from a quark-gluon plasma to the hadronic phase when system cools, then this is perfectly reasonable question to ask.

---

6We should remind the reader once again that the existence of the QCD domain walls described above is a consequence of the well-understood symmetry $\theta \rightarrow \theta + 2\pi n$ and is a consequence of the topological charge quantization: their existence is not based on any model-dependent assumptions we have made to support the specific calculations in the previous sections. The question now is not the existence of these walls, but whether or not they live long enough to affect relevant physics.
and hopefully answer!" Indeed, according to the standard theory of cosmological phase transitions [38, 51], if, below a critical temperature $T_c$, the potential develops a number of degenerate minima, then the choice of minima will depend on random fluctuations in fields. The minima that the fields settle to can be expected to differ in various regions space. If neighboring volumes fall into different minima, then a kink (domain wall) will form as a boundary between them\(^7\).

For the present estimate of the decay rate for the QCD domain wall, the only information we need from the previous sections are: the domain wall tension $\sigma$ and the wall thickness. In the chiral limit for two light flavors $N_f = 2$, the tension $\sigma$ is given by Equation (4.16) which we would like to present in the following form:

$$\sigma = \frac{4N_c f_\pi \sqrt{E}}{\sqrt{2}} \left(1 - \cos \frac{\pi}{2N_c}\right). \tag{5.1}$$

In this formula, the $\sqrt{2}$ in denominator should be replaced by $\sqrt{N_f}$ for an arbitrary $N_f$; however in all numerical estimates we shall use $N_f = 2$ which we believe is very good approximation for our problem in the limit $m_u \simeq m_d \ll m_s$ as Equations (2.10) and (2.11) suggest. Besides that, for $N_c \geq 3$, one can approximate $1 - \cos[\pi/(2N_c)] \simeq \pi^2/(8N_c^2)$ such that Equation (5.1) takes especially simple form which will be used in the numerical estimates which follow,

$$\sigma = \frac{\pi^2 f_\pi \sqrt{E}}{2\sqrt{2N_c}} \sim \sqrt{N_c} \tag{5.2}$$

The question of which wall thickness is relevant is more subtle due to the “sandwich structure” of the QCD domain walls described above. As we discussed in the previous sections, however, the core of the QCD domain wall is determined by the flavour isotopical singlet $\eta'$ field with thickness $\mu^{-1} \simeq m_{\eta'}^{-1}$, while the $\pi$ meson halo has a much larger size $\sim m_\pi^{-1}$. Nevertheless, in what follows we treat the QCD domain wall as the object with wall thickness of order $m_{\eta'}^{-1}$ due to the fact that the most important contribution to $\sigma$ comes from this small region of $\Delta z \sim m_{\eta'}^{-1}$. Indeed, as Equation (1.3) suggests, the contribution to $\sigma$ from the $\eta'$ field is proportional to $E\Delta z \sim E/m_{\eta'}$. At the same time, the contribution to $\sigma$ from the $\pi$ field, which was ignored in (5.1) and (5.2), is proportional to $m_q \langle \bar{\Psi} \Psi \rangle \Delta z \sim m_q \langle \bar{\Psi} \Psi \rangle/m_\pi \sim m_\pi \to 0$ which vanishes in the chiral limit. To represent the qualitative results of the real

\(^7\) Whether or not domain wall actually will form at the QCD transition in the early universe is an unresolved issue. Presently it is believed that the QCD phase transition is actually a smooth crossover (see [52] for a review of the QCD phase diagram). If this is the case, then it is possible that no domain walls form because the universe cools very slowly. To resolve this question, one must estimate the relaxation timescales involved: if the crossover is sharp enough, then domain walls may still form. At the RHIC, however, the system is quenched due to the rapid expansion of the colliding ions and so the formation of domain walls is very likely if an appropriate part of the phase diagram is explored by the reaction.
world, we preserve the chiral limit as we take \( N_c \) to be large, thus, despite of the fact that the \( \pi \) meson cloud is of a much larger in size, its contribution to \( \sigma \) is much smaller in both the large, and the physical \( N_c \) limits. Numerically, the \( \pi \) contribution consists only 10\% of \( \sigma \) and we ignore this contribution in what follows.

We are now prepared to discuss the decay of the QCD domain walls. The decay mechanism is due to a tunneling process which creates a hole in the domain wall. This hole connects the configurations \((\phi_u, \phi_d) = (0, 0)\) to the \((\phi_u, \phi_d) = (2\pi, 0)\) domain (see Equation (2.11)). This decay mechanism is similar to the decay of a metastable wall bounded by strings, and we use a similar technique to estimate the tunneling probability. In this case, the walls can decay by quantum nucleation of holes which are bounded by strings. The idea of the calculation was suggested by Kibble [53], and has been used many times since then (see the textbook [38] for a review). The most well known example of such a calculation is the calculations of the decay rate in the so-called \( N_{PQ} = 1 \) axion model where the axion domain wall become unstable for a similar reason due to the presence of axion strings [45, 46, 47, 48, 49, 50]. However, as was emphasized in [54], the existence of strings as the solutions to the classical equations of motion is not essential for this decay mechanism (see below). Some configurations, not necessarily the solutions of classical equations of motion, which satisfy appropriate boundary conditions, may play the role played by strings in the \( N_{PQ} = 1 \) axion model.

To be more specific, let us consider a closed path starting in the first domain with \((\phi_u, \phi_d) = (0, 0)\), which goes through the hole and finally returns back to the starting point by crossing the wall somewhere far away from the hole. The phase change along the path is clearly equals to \( \phi_u + \phi_d = 2\pi \). Therefore, the absolute value of a field which gives the mass to the \( \eta' \) field (the dominant part of the domain wall) has to vanish at some point inside the region encircled by the path. By moving the path around the hole continuously, one can convince oneself that there is a loop of a string-like configuration (where the absolute value of a relevant field vanishes such that the \( \eta' \) singlet phase is a well defined) enclosing the hole somewhere. In this consideration we did not assume that a hole, or string enclosing the hole, are solutions of the equations of motion\(^8\). They do not have to be solutions.

\(^8\)It is quite obvious that such a configuration cannot be described within our non-linear \( \sigma \) model given by Equation (2.2) where it was assumed that the gluon as well as the chiral condensates are non-zero constants. In this case, the singlet phase is not well defined everywhere. However, in the case of a triplet \( \pi \) meson string, such a configuration can easily be constructed within a linear \( \sigma \) model by allowing the absolute value of the chiral condensate to fluctuate along with the Goldstone phase (\( \pi \) meson field). The \( \sigma \) term in the linear \( \sigma \) model essentially describes the rigidity of the potential. Indeed, the corresponding calculations within a linear \( \sigma \) model were carried out in [55] where it was demonstrated that the solution describing the \( \pi \) meson string exists, albeit unstable as expected from the topological arguments. To carry out a similar calculations in our case for the singlet \( \eta' \) phase, one should allow fluctuations of the gluon fields: the fields that give mass to \( \eta' \) meson and that describe the rigidity of the relevant potential. (See (3.1).)
However, if we want to describe the hole nucleation semi-classically [38, 53], then we should look for a corresponding instanton which is a solution of Euclidean (imaginary time, $t = i\tau$) field equations, approaching the unperturbed wall solution at $\tau \rightarrow \pm \infty$. In this case the probability $P$ of creating a hole with radius $R$ per area $S$ per time $T$ can be estimated as follows\(^9\) [53, 56, 57]:

$$
\frac{P}{ST} \sim \left[ \sqrt{\frac{S_0}{2\pi}} \right]^3 e^{-S_0 \times \text{Det}}, \quad (5.3)
$$

where $S_0$ is the classical instanton action; $\text{Det}$ can be calculated by analyzing small perturbations (non-zero modes contribution) about the instanton, (see [57] for an explanation of the meaning of this term) and will be estimated using dimensional arguments; and $(\sqrt{S_0/(2\pi)})^3$ is the contribution due to three zero modes describing the instanton position.\(^10\)

If the radius (a critical radius $R_c$ to be estimated later) of the nucleating hole is much greater than the wall thickness, we can use the thin-string and thin-wall approximation, in this case, the action for the string and for the wall are proportional to the corresponding worldsheet areas [53],

$$
S_0 = 4\pi R^2 \alpha - \frac{4\pi}{3} R^3 \sigma. \quad (5.4)
$$

Here $\sigma$ is the wall tension (5.2), and $\alpha$ is the string tension, to be estimated. The world sheet of a static wall lying in the $x$–$y$ plane is the three-dimensional hyperplane $z = 0$. In the instanton solution, this hyperplane has a “hole” which is bounded by the closed worldsheet of the string. Minimizing (5.4) with respect to $R$ we find that

$$
R_c = \frac{2\alpha}{\sigma}, \quad S_0 = \frac{16\pi \alpha^3}{3\sigma^2}. \quad (5.5)
$$

The Lorentzian evolution of the hole after nucleation can be found by making the inverse replacement $\tau \rightarrow -it$ from Euclidean to Minkowski space-time. The hole expands with time as $x^2 + y^2 = R^2 + t^2$, rapidly approaching the speed of light.

### 5.1 String Tension

Now we want to estimate the string tension $\alpha$. As discussed in Section [3.2], we cannot make this estimate with Equation (2.2) where the gluon degrees of freedom are integrated out and replaced by their vacuum expectation values: such a theory discussion.)

\(^9\)The estimate given below is designed for illustrative purposes only, and should be considered as a very rough estimation of the effect to an accuracy not better than the order of magnitude.

\(^10\)The three zero modes in our case should be compared with the four zero modes from the calculations of [57]. This difference is due to the fact that in [57] the decay of three dimensional metastable vacuum state was discussed. In our case, we discuss a decay of a two-dimensional object.
does not support strings. Instead, we have to take one step back and describe the dynamics of the gluon condensate by considering the original Lagrangian \[12, 13\] which includes the complex gluon degrees of freedom \(h\). In this effective theory, the complex gluonic field will sit in a Mexican-hat potential with \(|\langle h \rangle| = \text{const}\). The phase of \(\langle h \rangle\) will be the light degree of freedom associated with the \(\eta'\) field. The string represents a localized region about which \(h = 0\). In the effective theory (2.2) this represents a singularity, but here the singularity is allowed, although it is energetically costly. The string tension is associated with the energy cost required to form the string and this is directly related to the height of the peak of the Mexican-hat potential.

For the purposes of this paper, we will be unable to calculate the string tension exactly, but can estimate it dimensionally by considering the effective potential including the \(h\) degrees of freedom as we shall do in the next section where we will show that

\[ \alpha \sim \sqrt{2E} \sim N_c. \] (5.6)

### 5.2 Heavy Degrees of Freedom

The effective potential of the original Lagrangian \[12, 13\] which includes the complex gluonic degrees of freedom \(h\) is given by:

\[
V(\theta, h, U) = \left( \frac{h}{4N_c} \log \left[ \left( \frac{h}{2eE} \right)^{N_c} \frac{\text{Det} U}{e^{-i\theta}} \right] - \frac{1}{2} \text{Tr} MU \right) + \text{H.c.} \tag{5.7}
\]

This satisfies all the conformal and chiral anomalous Ward identities, has the correct large \(N_c\) behaviour etc. (see \[12, 13, 34\] for details). Integrating out the heavy \(h\) field will bring us back to Equation (2.2). (It is interesting to note that the structure of Equation (5.7) is quite similar in structure to the effective potential for SQCD \[11\] and gluodynamics \[58\].)

Let us stop for a moment to consider the form of this potential. When we integrate out the heavy gluon degrees of freedom, we replace \(h\) with its vacuum expectation value \(\langle h \rangle\). The vacuum expectation value\(^\text{11}\) of the \(h\) is given by

\[
\langle h \rangle = 2E \exp\left(-i \sum \frac{\phi_i}{N_c}\right) \tag{5.8}
\]

such that (5.7) becomes

\[
V(U) \Big|_{\theta=0 \atop h=\langle h \rangle} = -E \cos \frac{\sum \phi_i}{N_c} - \sum M_i \cos \phi_i, \tag{5.9}
\]

\(^\text{11}\)For more accurate treatment of the minimization procedure which carefully accounts for the different branches, see the original paper \[34\].
in agreement with (2.8). With $h$ fixed at its vacuum expectation value, the singlet combination $\phi_S = \sum \phi_i$ exhibits the $U(1)$ topology described above and our domain walls are stable. Now, however, we allow the gluon condensate to fluctuate, which can be parameterized as $h = \rho(h)$ where $\rho$ is a real physical field related to glueballs. In this case, the potential $V$ is given by

$$V(\rho, \phi_S) = +E\rho (\log \rho - 1) \cos \frac{\phi_S}{N_c}$$

(5.10)

where we have neglected the terms proportional to $M$ as they are negligible since they only contribute a constant offset due to the $\phi_T$ field. For an early phenomenological discussion of the potential (5.10) without the $\phi_S$ fields, see [59].

Now the combined degrees of freedom $\rho$ and $\phi_S$ are no longer restricted to the circle $\rho = 1$ as they were in the effective theory (2.2). The $U(1)$ topology is no longer a constraint of the fields and thus, the walls are not topologically stable. Instead, the restriction of $\rho \approx 1$ is dynamical, and made by a barrier at $h = 0$. Thus, with these degrees of freedom, the fields parameterize the plane, however, the potential is that of a tilted Mexican-hat with a barrier at $h = 0$. The barrier is high enough that a domain wall interpolating around the trough of the hat is classically stable. If the barrier were infinitely high as we assumed when we fixed $\rho = 1$ as we did in (2.2), then the $\phi_S$ field could wind around the barrier and would be topologically stable. With a finite barrier, however, the field can tunnel through the barrier as described above. This situation is analogous to the case of the string and peg shown in Figure 2. We show a more accurate picture of the barrier (5.10) in Figure 3.\footnote{We are indebted to Misha Stephanov for suggesting this nice intuitive picture for explaining the domain wall decay mechanism.} The relative heights of the the peak and troughs are given below:

$$\Delta V_{\text{peak}} = \Delta V_1 + \Delta V_2 = E \sim N_c^2,$$

(5.11)

$$\Delta V_1 = E \cos \frac{\pi}{N_c} \sim N_c^2,$$

(5.12)

$$\Delta V_2 = E \left(1 - \cos \frac{\pi}{N_c}\right) \sim 1.$$

(5.13)

The most important property of the potential is the following: The absolute minimum of the potential in the chiral limit corresponds to the value $V_{\text{min}} = -E$ which is the ground state of our world with $\rho = 1$ and $\phi_s = 0$. At the same time, the maximum of the potential (2.2), where one branch changes to another one is $V = -E\cos(\pi/N_c)$ where $\phi_S = \pi$ (we are still taking $\theta = 0$). This corresponds to the point $\rho = 1$ and $\phi_S = \pi$ in the potential (5.10). Thus, the trough of the Mexican-hat is given where $h = \langle h \rangle$, i.e. at radius $\rho = 1$ and the maximum $V = -E\cos(\pi/N_c)$ of the potential (2.2) is exactly the barrier through which the $\eta'$ field interpolates to form the QCD domain wall. It is important to note that the height of the barrier
Figure 6: Profile of the “Mexican-hat” potential (5.10). The slice is made along the axis through $\phi_S = \pi$ to the left and $\phi_S = 0$ to the right. The trough of the potential lowers from the cusp at $\rho = 1$, $\phi = \pi$ where $V = -E \cos(\pi/N_c)$ down to the vacuum state $V_{\text{min}} = -E$. The hump where $V = 0$ is at the origin is where $h = \rho \exp(i\phi_S/N_c) = 0$ and hence the singlet field $\phi_S$ can have any value at this point. It is by passing across this point that a QCD domain wall can tunnel and a hole can form. The important qualitative features of this potential are the height of the central peak $\Delta V_{\text{Peak}}$ (5.11), the relative heights of the cusp to the peak $\Delta V_1$ (5.12) and the trough to the cusp $\Delta V_2$ (5.13).

for the potential (2.2) is numerically is quite high $\sim E(1 - \cos \frac{\pi}{N_c})$, but vanishes in large $N_c$ limit. Indeed, in this limit, the peak of the barrier is degenerate with the absolute minimum $V_{\text{min}} = -E$ of the potential as it should be\textsuperscript{13}. The height of this barrier describes how much the Mexican-hat is tilted.

The other important property of the potential (5.10) is its value where the singlet phase $\sum \phi_i$ is not well defined at the peak of the Mexican-hat. From (5.10) it is clear that this occurs for $h = 0$. It is this peak of the Mexican-hat in Figure 6 (or the peg in Figure 2) that classically prevents $\rho \rightarrow 0$ and that makes the QCD domain wall classically stable. When a hole tunnels through the wall, it must be surrounded by

\textsuperscript{13}Remember, the $\eta'$ direction becomes flat in the large $N_c$ limit as $m_{\eta'} \rightarrow 0$. 

a “string” where the field passes through the region $h = 0$. The height of the peak thus determines the energetic cost to create such a string (and hence the hole). The potential (5.10) vanishes at the center of the string $V(h = 0) = 0$, which implies that the barrier at $h = 0$ is quite high: $\Delta V_{\text{peak}} = E$. As expected, the barrier at $h = 0$ should be order of $E \sim N_c^2$ in contrast with the barrier to the $\eta'$ domain wall where one expects a suppression by some power of $N_c$. We also note that the total number of distinct classically stable solutions can be estimated from the condition that $\cos(\pi k/N_c) > 0$ where the barrier for the $\eta'$ field is still lower than the peak $h = 0$. Thus, $-N_c/2 < k < N_c/2$ where $k$ labels the winding number of the solution. Thus we see that for $N_c \leq 2$ there is no admissible classically stable solution, but for $N_c \geq 3$ classically stable solutions are allowed. In our model with potential (5.10) we see explicitly that, for $N_c = 3$, there is one classically stable domain wall while for $N_c = 2$ there are no classically stable solutions.

Thus, the height of the peak above the vacuum energy state $V_{\text{min}} = -E$ is $E$: this is the only relevant parameter related to the string tension, and thus relation (5.3) should hold to an order of magnitude

5.3 Cusps

The presence of cusps in the potentials (5.10) and (2.2) should be addressed. These potentials are low energy effective theories and the cusps represent unknown physics in the heavier degrees of freedom. Properly including the physics of the higher degrees of freedom would surely smooth these cusps and alter the exact form of the potentials, but the qualitative features responsible for the formation and decay of the domain walls would remain. Consider (5.10) in Figure 6: the peak would be smoothed, but as long as $\Delta V_1 > 0$, the classical solutions remain stable and the qualitative picture remains the same.

The quantitative estimates to be presented below, however, are definitely sensitive to the higher degrees of freedom. Indeed, the domain wall and the string are localized about the cusp regions of the potential and are thus very sensitive to the heavy degrees of freedom. As a result, our estimates of the string tension $\alpha$ and wall tension $\sigma$ may not be numerically valid. It is even possible for the $N_c$ dependence to change as has been discussed for supersymmetric domain walls [60].

It may seem surprising that the $N_c$ behaviour could be modified, but we have explicitly neglected order $O(1)$ terms in (4.14), for example, by taking the chiral limit $m_q \to 0$ before the large $N_c$ limit. While this is qualitatively justified—the form of the potential responsible for generating the domain walls is qualitatively the same—

\[ \alpha \sim \sqrt{2E} \sim (0.28 \text{GeV})^2 \]

should not be considered as a strong overestimation; rather it should be considered as a lower bound. Indeed, if one considers the $\pi$ meson string [55] which should be much softer (and therefore, would possess much smaller $\alpha_\pi$) one finds, nevertheless, that $\alpha_\pi \simeq \pi f^2_\pi$ is very close numerically to our estimation for the $\eta'$ string tension.
it is not quantitatively justified. Nevertheless, in the real world, the chiral limit is a
good approximation and we expect the qualitative limit discussed to remain valid.

5.4 \( N_c = 3 \)

We have shown that, in the large \( N_c \) limit while preserving approximate chiral sym-
metry, QCD domain walls are stable to leading order and that, to leading order, they
can decay through a tunneling mechanism. The decay rate is related to the string
tension (5.6) and domain wall tension (4.16). We now extrapolate back to \( N_c = 3 \)
to show that, it is at least possible that the lifetime of the domain walls remains
macroscopic even though the only scale involved is \( \Lambda_{\text{QCD}} \). For \( N_c = 3 \) and \( N_f = 2 \)
we have:

\[
\begin{align*}
\alpha & \simeq \sqrt{2E} \sim (0.29 \text{ GeV})^2, \\
\sigma & \sim \frac{\pi^2 f_\pi \sqrt{E}}{2\sqrt{2}N_c} \sim f_\pi (0.26 \text{ GeV})^2 \sim (0.21 \text{ GeV})^3 \\
R_c & = \frac{2\alpha}{\sigma} \sim \frac{2.4}{f_\pi}, \\
S_0 & = \frac{16\pi\alpha^3}{3\sigma^2} \sim \frac{256N_c^2 \sqrt{2E}}{3\pi^3 f_\pi^2} \sim (110 - 140),
\end{align*}
\]

where the uncertainty in \( S_0 \) reflects a 10\% variation in \( \alpha \) from the central value
given in (5.14d). This is not an estimate of the uncertainty in \( S_0 \): realistic errors
in the estimate (5.14d) would be much higher as we have neglected many effects: It
is nevertheless quite remarkable that, in spite of the fact that all parameters in our
problem are of order \( \Lambda_{\text{QCD}} \), the classical action \( S_0 \) may still be numerically large, and
thus the corresponding tunneling probability (5.3) may be quite small. We do not
see any simple explanation for this phenomenon except for the fact that expressions
(5.4) and (5.14d) for \( S_0 \) contains a huge numerical factor \( 16\pi/3 \) of purely geometrical
origin. In addition, since \( S_0 \sim N_c^2 \), one expects an additional enhancement in \( S_0 \),
even for \( N_c = 3 \).

At this point we must address the validity of the large \( N_c \) approximation to
the physical region of \( N_c = 3 \). Qualitatively we expect the physics to be the same.
The potential (5.7) displayed in Figure 6 has the same qualitative form for \( N_c > 2 \):
namely, the central peak is much higher than the troughs and classically stable
solutions are admitted. Including heavier gluonic degrees of freedom, while certainly
affecting the numerical results, will not modify this qualitative picture.

Perhaps we should have included the effects of other light degrees of freedom
such as the other pions, kaons etc. In the \( N_c = 3 \) case, these degrees of freedom
are certainly relevant, but they are not related to the physics which governs the
QCD domain walls. We emphasize: QCD domain walls are predominantly related
to gluonic structures, and these degrees of freedom are appropriately treated in the
effective theories (2.2) and (5.7). The case is similar to that of the mass of the $\eta'$ particle (2.15): while there are contributions from the same processes that govern the other mesons, these terms are proportional to $m_q$. The $\eta'$ is different because it couples to the anomaly and picks up an abnormally large mass proportional to the vacuum energy $E$. These effects dominate over the others because the chiral limit $m_q \sim 0$ is well preserved with respect to the gluonic scale. In the same way that the mass of the $\eta'$ is insensitive to the effects of the mesons and other light degrees of freedom, the qualitative behaviour of QCD domain walls—which results from the same physics as the $\eta'$ mass—should be insensitive to these light particles. Numerically one should account for scattering etc. off the domain walls, but for the qualitative estimates presented here, the light mesons are inconsequential. For the same reason, we do not expect the other mesons ($\rho$, $\Omega$ etc.) to change the qualitative physical behaviour. The key point is the Mexican-hat shape of the potential (5.7) and that the potential of the central peak—where $\rho = 0$ and the phase of the $\eta'$ phase is not well-defined—is much higher than any point in the trough defining the low-energy theory (2.2). Low-energy fluctuations will not affect the height of the peak which makes the $\eta'$ domain walls classically stable.

The $\eta'$ mass serves to emphasize the validity of the large $N_c$ limit in another way: The approximation of the chiral limit (2.16) remains valid up until $N_c \sim 10$. Thus, the physical case of $N_c = 3$ should be related to the chiral large $N_c$ limit that we have explored in this paper.

One other interesting note: As we mentioned earlier, in QCD there is only one dimensional parameter, $\Lambda_{\text{QCD}}$, and it is thus generally believed that the semi-classical approximation in QCD cannot be parametrically justified. Nevertheless, $R_c$ is numerically quite large—much larger than the width $\mu^{-1}$ of the domain wall (4.13) which is set by $m_{\eta'}^{-1}$. Therefore, the semi-classical approximation (5.3) is somewhat justified a posteriori.

### 5.5 Lifetime

Now, we are prepared to make our last step and estimate the probability of creating a hole with radius $R_c \sim 8N_c/(\pi^2f_\pi)$:

$$\frac{P}{T} \pi R_c^3 e^{-S_0} \times \text{Det} \sim \pi R_c^3 E^{\frac{3}{4}} \left[ \frac{S_0}{2\pi} \right]^3 e^{-S_0}. \quad (5.15)$$

We have estimated $\text{Det} \sim E^{\frac{3}{4}}$ dimensionally. Using the numerical values for $R_c$ and $S_0 \simeq 130$ given in (5.14) we arrive to the following final result:

$$\frac{P}{T} \sim 10^3 e^{-130}\text{GeV} \sim 10^{-30}\text{s}^{-1}. \quad (5.16)$$

The most amazing result of the estimate (5.16) is the astonishingly small probability for the decay $P \sim 10^{-50} \text{ GeV}$ which one might naively expect to be on the GeV
level. This small number leads to a very large life time for the domain walls, and consequently, makes them relevant to cosmology at the QCD scale. Of course, our estimation of \( S_0 \) is not robust, and even small variation of parameters may drastically change our estimate (5.16), making it much larger or much smaller. The point we wish to emphasize here is that it is at least possible for QCD domain walls to live long enough to have non-trivial physical effects.

First of all, let us estimate an average size \( l \) of a domain wall before it collapses with an average lifetime of \( \tau_l \sim \frac{l}{c} \). This corresponds the situation when the probability of the decay is close to one. If \( L \) is the Hubble size scale, \( L \sim 30 \text{ km} \), then

\[
P \simeq \frac{P}{\pi \pi \pi} \cdot \tau_l \sim \frac{P}{\pi \pi \pi} \cdot \frac{L}{c} \cdot \left( \frac{l}{L} \right)^3 \sim 10^{-30} \text{s}^{-1} \cdot 10^{36} \cdot 10^{-4} \cdot \left( \frac{l}{L} \right)^3 \sim 10^2 \left( \frac{l}{L} \right)^3 \sim 1.
\]

(5.17)

Formula (5.17) implies that the average size \( l \) of the domain wall before it collapses could be as large as the Hubble size \( l \sim 10^{-2/3} \cdot L \sim 0.2L \). It also implies that on a Hubble scale domain wall \( L \), the average number of holes which will be formed is approximately \( \langle n \rangle \sim (L/l)^2 \sim 25 \). Finally, the lifetime of a Hubble size domain wall is expected to be on the scale of

\[
\tau_l \sim \frac{L}{\sqrt{\langle n \rangle} c} \sim 2 \cdot 10^{-5} \text{s},
\]

(5.18)

which is macroscopically large!

It is clear that all these phenomena are due to the astonishingly small number (5.16) which makes the link between QCD and cosmology feasible. This small number is due to the tunneling process rather than some special fine-tuning arrangements. As we mentioned above, we have not made any adjustments to the phenomenological parameters used in the estimates. Rather, we have used the standard set of parameters introduced in Equation (2.2). To conclude the discussion of (5.16) we would like to remind the reader that similar miracles related to tunneling processes happens in physics quite often. For example, the difference in life time for \( U^{238} \) and \( Po^{212} \) under \( \alpha \) decay is on the order of \( 10^{20} \) in spite of the fact that the “internal” physics of these nuclei, and all internal scales are very similar.

We should be careful to qualify this result. First, it assumes that the effective Lagrangian (2.2) is a good description of the low energy physics of QCD including the physics of the \( \eta' \) field. This assumption is well justified in the large \( N_c \) limit. The theory is not quantitatively justified as \( N_c \to 3 \) as we discussed in Section 5.4. Nevertheless, the qualitative features of the potential responsible for producing the domain walls persist for all \( N_c \geq 3 \) as shown in Figure 6 so we expect the qualitative features to remain. Second, it assumes that the semi-classical calculation leading to (5.13) is justified. This is certainly not justified a-priori, but is somewhat justified.
a-posteriori. Third, we have assumed $T = 0$ for this analysis. Thermal fluctuations may considerably reduce the lifetime of these walls. While this is a concern for cosmological domain walls, it should not be a concern at RHIC where the quenched approximation should be valid (see also Footnote 7). Finally, the interaction of the domain wall with nucleons can drastically change the numerical properties of the domain wall due to the strong interaction of all relevant fields. In particular, the domain walls may become much more stable in the presence of nucleons, and even account for the strong self-interacting dark matter discussed in [61, 62]. We hope to return to these considerations in a separate publication.

6. Conclusion and Future Directions

The main results of this paper is expressed by the formulae (4.12) and (5.16) where a new type of a quasi-stable QCD matter—the QCD domain wall (which could have a macroscopically large size!)—is described. The qualitative picture for the QCD domain walls is exact in the chiral large $N_c$ limit where the QCD domain walls are stable. To leading order, the walls decay as discussed, though the lifetime (5.16) of the QCD domain walls is potentially very large. If this is the case, such objects might play an important role on the evolution of the early universe soon after the QCD phase transition. As a by-product, we also found a new type of axion domain wall ($a_{\eta'}$) with QCD structure. This may also have further cosmological applications if the axions exist. See [9] for a first attempt in these directions.

Unfortunately, we do not yet have a good microscopic picture of QCD in the low temperature, low density regime with small $N_c = 3$, thus we cannot further justify the effective theory (2.2). This analysis, however, show that there is at least the hope of forming macroscopically large domain walls with QCD scale. Additional support for these objects comes from the high density regime we have better control of the physics. In this case, QCD domain walls nearly certainly exist [63]. Furthermore, if one accepts a conjecture on quark-hadron continuity at low temperature with respect to variations in the chemical potential $\mu$ [64], then one can make the following argument: If for large $\mu$ domain walls exist, but for low $\mu$ they do not, then there should be some sort of phase transition as one lowers $\mu$. Thus, the continuity conjecture supports the existence of quasi-stable QCD domain walls at lower densities, at least down to the densities of hypernuclear matter. Coupled with the fact that gluon and quark condensates do not vary much as one moves to the low density limit, we suspects that the qualitative picture holds even for zero density.

It would be very exciting if QCD domain walls can be studied at RHIC (Relativistic Heavy Ion Collider) [65]. Such a research would be the first experimental attempt to directly study the fundamental properties of the QCD vacuum structure. In this case the temperature would fall rapidly due to the rapid expansion and we expect that we can neglect thermal fluctuations as we have here.
In any case, QCD domain walls are a very interesting feature of QCD and may live long enough to affect many areas of particle physics and astrophysics. We look forward to further study of these creatures!

7. Acknowledgments

This work is supported in part by the National Science and Engineering Research Council of Canada. AZ wishes to thank Misha Stephanov and Edward Shuryak for valuable comments and very useful discussions regarding the possibility of studying QCD domain walls at RHIC. He is also grateful to Paul Stenhardt for explaining his works [61, 62] and for discussions of possibility of QCD domain walls as a strongly interacting dark matter candidate and thanks G. Dvali, G. Gabadadze and M. Shifman for useful discussions.
