Dear Editor:

Dermatofibroma is a common cutaneous nodule of unknown etiology that frequently occurs on the extremities. Although most dermatofibroma are usually asymptomatic, itching and pain are often noted in some patients. Furthermore, it is known to be the most common tumor among all painful skin tumors¹. The pain of deep-seated dermatofibroma may be due to tumoral nerve invasion or mass effect on the nerve fibers². However, there have been no studies investigating pain of typical dermatofibroma in the medical literature. Protein gene product 9.5 (PGP 9.5) is known as a sensitive neural/nerve sheath marker and preferably used for a wide range of cutaneous tumors. We quantitatively assessed the expression PGP 9.5-immunopositive nerve fiber bundles in patients with dermatofibroma with and without pain as previously published³. This study was approved by the institutional review board of Pusan National University Hospital (IRB no.H-1812-011-074), and the requirement for informed consent was waived. We retrospectively investigated the subjects diagnosed with dermatofibroma, all of whom underwent a skin biopsy, and each specimen was stained immunohistochemically with a PGP 9.5 polyclonal antibody (1:1,000; UltraClone, Cambridge, UK). Demographics and other clinical data were collected through our patient record database at PNUH from January 2013 to March 2019. We included patients with dermatofibroma that were smaller than 5.0 cm in diameter, located on leg, and histologically proven to be the common type. We subdivided patients into 2 groups according to the presence of pain or tenderness. The interpretation for intensity of PGP 9.5 expression were performed by experienced pathologist (one of the co-authors). In each specimen, the presence of nerve fiber bundles was comprehensively demonstrated with both hematoxylin-eosin and PGP 9.5 stains. Also, the number of PGP 9.5-immunopositive nerve fiber bundles was counted within the tumor mass and adjacent dermis aside from the main lesion, respectively, and compared quantitatively between the two compartments.

All statistical analyses were performed using IBM SPSS ver. 21 (IBM Corp., Armonk, NY, USA). For comparison of the investigated data between the groups, the chi-square test or Fisher’s exact test were used for categorical variables, and the independent t-test was used for continuous variables. A p-value < 0.05 was considered statistically significant.

Overall, 22 patients with dermatofibroma were included in the study (Table 1). Furthermore, 14 patients (63.6%) complaining of pain or tenderness were assigned to group 1; and 8 patients (36.4%) without pain or tenderness were assigned to group 2. No statistically significant differences were observed in the demographic characteristics between both groups, such as mean age or sex ratio. The average sizes of the lesions were 53.9±25.9 mm² and

36.6 ± 18.8 mm² in groups 1 and 2, respectively, with mean durations of 15.1 ± 10.6 months and 17.8 ± 12.3 months in groups 1 and 2, respectively. There were no significant differences in lesion size or duration between patients with and without pain (p > 0.05).

In an analysis of the association between the immunopositive nerve fiber bundles and pain, nerve bundles were observed within the tumor and the adjacent dermis in 13 patients (92.9%) and 12 patients (85.7%), respectively, in group 1. However, in group 2, nerves were observed within the tumor of 6 (75.0%) and the adjacent dermis of 5 (62.5%). The number of immunopositive nerve fiber bundles within the tumor and adjacent dermis were variable (Fig. 1). Furthermore, 11 (78.6%) and 2 (25.0%) specimens in groups 1 and 2, respectively, showed more nerve fiber bundles within the tumor compared to the adjacent dermis. There were no significant differences in the proportion of cases that showed nerve fiber bundles between both groups (92.9% vs. 75.0%, p = 0.527; 85.7% vs. 62.5%, p = 0.309). However, the predilection of PGP 9.5 expression within tumor mass were more pronounced in group 1 than in group 2, and this demonstrated a statistically significant difference (78.6% vs. 25.0%; p = 0.026).

To our knowledge, this is the first comparative study to assess the pathogenesis of pain in dermatofibroma, especially with a PGP 9.5 stain. We found that dermatofibroma with pain had higher PGP 9.5-stained nerve fiber bundles within the tumor compared to the adjacent dermis. A previous study on benign dermal neoplasm demonstrated that dermatofibroma had only negative to weak staining for PGP 9.5, but these data only focused on a comparison with other tumors and did not correlate it to the clinical manifestation⁴.

In a study for the pathogenesis of pain in angioleiomyomas, a well-known painful tumor, most cases had nerve fibers immunoreactive for neural markers within the tumor stroma besides the capsule⁵. Likewise, although the mechanisms that lead to pain in dermatofibroma are not fully understood, the more abundant innervation within the tumor rather than the adjacent dermis may play a role in mediating pain.

We hypothesized that the mechanism of pain in patients with typical dermatofibroma was caused by nerves that are scattered within lesions and are likely to be mechanically compressed by densely proliferating fibrohistiocytic cells, which is similar to the pathological mechanism of pain in angioleiomyomas⁶.

However, our study has several limitations. First, the number of subjects were rather small for a statistical analysis of the pathological mechanism of pain in dermatofibroma. Second, although the margins of adjacent dermis were de-

### Table 1. Clinical characteristics and distribution of nerve fiber bundles detected by protein gene product 9.5 (PGP 9.5) between different groups according to the presence of pain

| Variable                        | Group 1* | Group 2† | p-value |
|---------------------------------|----------|----------|---------|
| Age (yr)                        | 31.4 ± 6.7 | 38.1 ± 8.9 | 0.057   |
| Sex                             | 1.000    | 1.000    |         |
| Male                            | 4 (28.6) | 3 (37.5) |         |
| Female                          | 10 (71.4)| 5 (62.5) |         |
| Size (mm²)                      | 53.9 ± 25.9 | 36.6 ± 18.8 | 0.114   |
| Duration (mo)                   | 15.1 ± 10.6 | 17.8 ± 12.3 | 0.652   |
| Presence of nerve fiber bundles |          |          |         |
| Within tumor                    | 13 (92.9) | 6 (75.0) | 0.527   |
| Adjacent dermis                 | 12 (85.7) | 5 (62.5) | 0.309   |
| Within tumor > adjacent dermis  | 11 (78.6) | 2 (25.0) | 0.026   |

Values are presented as number (%) or mean ± standard deviation. *Patients with pain or tenderness (n=14), †Asymptomatic patients (n=8). †The number of cases that presented with more nerve fiber bundles within the tumor than the adjacent dermis.

---

**Fig. 1.** Expression of protein gene product 9.5 (PGP 9.5) in representative specimens of dermatofibroma (within tumor mass and adjacent dermis, respectively, 100×). (A) Granular pattern of immunostaining with PGP 9.5 highlighting nerve fiber bundles within the main mass (inlet image showing an enlarged view of the aggregates of nerve fibers, 200×), and (B) those within the adjacent dermis. Black ink marking to distinguish areas away from the main lesion.
fined as the area within a high-power field (40×) from the outline of the tumor based on previous reports, a more strict and clear-cut definition of adjacent dermis is unclear because of a non-capsulated, poorly demarcated tumor. Although our results must be interpreted in the context of the limitations, these provide information on the association between pain and its pathogenesis in dermatofibroma.
