ON NEED FOR TOPOLOGY- AWARE GENERATIVE MODELS FOR MANIFOLD-BASED DEFENSES

Anonymous authors
Paper under double-blind review

ABSTRACT

ML algorithms or models, especially deep neural networks (DNNs), have shown significant promise in several areas. However, recently researchers have demonstrated that ML algorithms, especially DNNs, are vulnerable to adversarial examples (slightly perturbed samples that cause mis-classification). Existence of adversarial examples has hindered deployment of ML algorithms in safety-critical sectors, such as security. Several defenses for adversarial examples exist in the literature. One of the important classes of defenses are manifold-based defenses, where a sample is "pulled back" into the data manifold before classifying. These defenses rely on the manifold assumption (data lie in a manifold of lower dimension than the input space). These defenses use a generative model to approximate the input distribution. This paper asks the following question: do the generative models used in manifold-based defenses need to be topology-aware? Our paper suggests the answer is yes. We provide theoretical and empirical evidence to support our claim.

1 INTRODUCTION

Machine learning (ML) algorithms, especially deep-neural networks (DNNs), have had resounding success in several domains. However, adversarial examples have hindered their deployment in safety-critical domains, such as autonomous driving and malware detection. Adversarial examples are constructed by an adversary adding a small perturbation to a data-point so that it is misclassified. Several algorithms for constructing adversarial examples exist in the literature (Biggio et al., 2013; Szegedy et al., 2013; Goodfellow et al., 2014b; Kurakin et al., 2016a; Carlini & Wagner, 2017; Madry et al., 2017; Papernot et al., 2017). Numerous defenses for adversarial examples also have been explored (Kurakin et al., 2016b; Guo et al., 2017; Sinha et al., 2017; Song et al., 2017; Tramèr et al., 2017; Xie et al., 2017; Dhillon et al., 2018; Raghunathan et al., 2018; Cohen et al., 2019; Dubey et al., 2019).

In this paper we focus on "manifold-based" defenses (Ilyas et al., 2017; Samangouei et al., 2018). The general idea in these defenses is to "pull back" the data point into the data manifold before classification. These defenses leverage the fact that in several domains, natural data lies in a low-dimensional manifold (henceforth referred to as the manifold assumptions) (Zhu & Goldberg, 2009). The data distribution and hence actual manifold that the natural data lies in is usually unknown, so these defenses use a generative model to "approximate" the data distribution. Generative models attempt to learn to generate data according to the underlying data distribution (the input to a generative model is usually random noise from a known distribution, such as Gaussian or uniform). There are various types of generative models in the literature, such as VAE (Kingma & Welling, 2013), GAN (Goodfellow et al., 2014a) and reversible generative models, e.g. Real NVP (Dinh et al., 2016).

This paper addresses the following question:

Do manifold-based defenses need to be aware of the topology of the underlying data manifold?

This paper suggests that the answer to this question is yes. We demonstrate that if the generative model does not capture the topology of the underlying manifold, it can adversely affect these defenses. In these cases, the underlying generative model is being used as an approximation of the underlying manifold. We believe that this opens a rich avenue for future work on using topology-aware generative models for defense to adversarial examples.
Contributions and Roadmap. We begin with a brief description of related work in Section 2. Section 3 provides the requisite mathematical background. Our main theoretical results are provided in Section 4. Informally our result says that if the generative model is not topology-aware, it can lead to "topological mismatch" between the distribution induced by the generative model and the actual distribution. Section 5 experimentally verifies our theoretical results, and investigates their ramifications on a manifold-based defenses called Invert-and-Classify (INC) [Ilyas et al., 2017; Samangouei et al., 2018].

2 RELATED WORK

2.1 Generative models

As a method for sampling high dimensional data, generative models find applications in various fields in applied math and engineering, e.g. image processing, reinforcement learning, etc. Learning data-generating distribution with neural networks includes well-known examples of Variational Autoencoder (VAE) [Kingma & Welling, 2013] and variations of Generative Adversarial Network (GAN) [Goodfellow et al., 2014a; Radford et al., 2015; Zhao et al., 2016].

These generative models learn how to map latent variables into generated samples. VAE is a variational Bayesian approach, so it approximates posterior distribution over latent vectors (given training samples) by a simpler variational distribution. As other variational Bayesian methods do, VAE tries to minimize the KL divergence between the posterior distribution and the variational distribution by minimizing the reconstruction error of the auto-encoder. GAN is another type of approach to learning how to transform latent vectors into samples. Unlike other approaches, GAN learns the target distribution by training two networks – generator and discriminator – simultaneously.

In addition to generating plausible samples, some generative models construct bijective relation between latent vector and generated samples, so that the probability density of the generated sample can be estimated. Due to its bijective nature, such generative models are reversible. Some examples are normalizing flow [Rezende & Mohamed, 2015], Masked Autoregressive Flow (MAF) [Papamakarios et al., 2017], Real NVP [Dinh et al., 2016], and Glow [Kingma & Dhariwal, 2018].

2.2 APPLICATIONS OF GENERATIVE MODELS IN ADVERSARIAL MACHINE LEARNING

The DNN based classifier has been shown to be vulnerable to adversarial attacks [Szegedy et al., 2013; Goodfellow et al., 2014b; Moosavi-Dezfooli et al., 2016; Papernot et al., 2016; Madry et al., 2017]. Several hypothesis try explaining such vulnerability [Szegedy et al., 2013; Goodfellow et al., 2014b; Tanay & Griffin, 2016; Feinman et al., 2017], and one explanation is that the adversarial examples lie far away from the data manifold. This idea leads to defense approaches making use of the geometry learned from the dataset – by projecting the given input to the nearest point in the data manifold.

To learn a manifold from a given dataset, generative models can be exploited. The main idea is to approximate the data-generating distribution with a generative model, to facilitate searching over data manifold by searching over the space of latent vectors. The term invert and classify (INC) was coined to describe this type of defense [Ilyas et al., 2017], and different types of generative models were tried to detect adversarial examples [Ilyas et al., 2017; Song et al., 2017; Samangouei et al., 2018]. Usually, the projection is done by searching the latent vector that minimizes the geometric distance [Ilyas et al., 2017; Samangouei et al., 2018]. However, despite the promising theoretical background, it turned out that all of those methods are still vulnerable [Athalye et al., 2018; Ilyas et al., 2017].

3 BACKGROUND

We formally describe data generation, based on the well-known manifold assumption: data tend to be distributed along a manifold whose dimension is lower than the underlying space. In our model of data generation, we provide a formal definition of data-generating manifold $M$ on which the data-generating distribution lies so that $M$ conforms to the manifold assumption.

3.1 Requirements

Real-world data tends to be noisy, so they do not easily correspond to an underlying manifold. We first focus on an ideal case where data is generated solely from the manifold $M$ without noise.
When we call such a generative model a data-generating manifold \( M \). The data-generating manifold \( M \) contains class-wise disjoint manifolds, there is a classifier \( f \) on \( \mathbb{R}^n \) separating these manifolds. If \( f \) separates the manifolds of \( M \), any misclassified point should lie out of \( M \). Therefore, to change a correct classification near manifold, any adversary would pull a sample further out of the manifold. By projecting misclassified points to the nearest manifold, we may

In the setting of classification with \( l \) labels, we consider manifolds \( M_1, \ldots, M_l \subset \mathbb{R}^n \) that correspond to the generation of data in each class \( i \in \{1, \ldots, l\} \), respectively. We assume that those manifolds are pairwise disjoint, i.e. \( M_i \cap M_j = \emptyset \) for any \( i \neq j \), but the resulting data distribution may contain ambiguities that can be classified into any of \( i \) and \( j \). We set the data-generating manifold \( M \) as the union of those manifolds, \( M = M_1 \cup \ldots \cup M_l \). We assume \( M \) to be a compact Riemannian manifold with a volume measure \( dM \) induced by its Riemannian metric. When a density function \( p \) defined on \( M \) satisfies some requirements, it is possible to compute probabilities over \( M \) via \( \int_{x \in M} p(x)dM(x) \). We call such \( M \) equipped with \( p \) an \textit{extension is further discussed in Appendix D.2.}

In practice, data generation is affected by noise, so not all data lie on the data-generating manifold. Therefore, we incorporate the noise as an artifact of data-generation and extend the density \( p \) on \( M \) to the density \( p_M \) on the entire \( \mathbb{R}^n \) by assigning local noise densities on \( M \). We consider a procedure that (1) samples a point \( x_0 \) from \( M \) first, (2) adds a noise vector \( n \) to get an observed point \( \hat{x} = x_0 + n \). Here, the noise \( n \) is a random vector sampled from a probability distribution, centered at \( x_0 \), whose \textit{noise density function} is \( \nu_n \).

**(R0)** The translated noise density function, \( \nu_x(\hat{x} - x) \), is the density of noise \( x = \hat{x} - x \) being chosen for a given \( x \). Given \( x_0 = x \), since adding noise \( n \) is the only way to generate \( \hat{x} \) by perturbing \( x_0 \), \( p_M(\hat{x} | x_0 = x) \) is equal to \( \nu_x(n) \).

### 3.2 Extending density

When \( M \) is equipped with a density function \( p \) and measure \( dM \) that we can integrate over \( M \), we can compute the density after random noise is added. For a fixed point \( \hat{x} \in \mathbb{R}^n \), there is a family of density functions indexed by \( x \in M - \) the conditional density function \( p_M(\hat{x} | x_0 = x) \). The idea is to compute the density for compound distribution as follows:

\[
p_M(\hat{x}) = \int_{x \in M} p_M(\hat{x} | x_0 = x) p(\hat{x})dM(\hat{x})
\]

where \( p \) is the probability density function defined on \( M \).

Due to the requirement **(R0)**, the conditional density is equal to the translated noise density \( \nu_x(\hat{x} - x) \).

\[
p_M(\hat{x}) = \int_{x \in M} \nu_x(\hat{x} - x) p(\hat{x})dM(\hat{x})
\]

Since \( \nu_x(\hat{x} - x) \) is a function on \( x \) when \( \hat{x} \) is fixed, computing this integration can be viewed as computing expectation of a real-valued function defined on \( M \). Computing such expectation has been explored in [Pennec 1999]. A demonstrative example is provided in Appendix B and this extension is further discussed in Appendix D.2.

### 3.3 Generative models

A generative model tries to find a statistical model for joint density \( p(x, y) \) [Ng & Jordan 2002]. We mainly discuss a specific type that learns a transform from one distribution \( D_X \) to another target distribution \( D_Z \). Commonly, a latent vector \( z \sim D_Z \) is sampled from a relatively simpler distribution, e.g. Gaussian, then a pre-trained deterministic function \( G \) maps to a sample \( x = G(z) \).

Specifically, we focus on \textit{reversible generative models} to facilitate the comparison between the density of generated samples and the target density. In this approach, the dimensions of latent vectors is set to be the same as that of the samples to be generated. Also, for a given \( x \), the density of its inverse image \( z = G^{-1}(x) \) is computed by the \textit{change of variable formula},

\[
p_X(x) = p_Z(z) \left| \det \left( \frac{\partial G(z)}{\partial z^i} \right) \right|^{-1}
\]

where \( p_X \), \( p_Z \) are the probability densities (of \( D_X \), \( D_Z \), respectively), and \( \frac{\partial G(z)}{\partial z^i} \) is the Jacobian of \( G \) as a function from \( \mathbb{R}^n \) to itself.

### 3.4 Invert and Classify (INC) approach for robust classification

As the data-generating manifold \( M \) contains class-wise disjoint manifolds, there is a classifier \( f \) on \( \mathbb{R}^n \) separating these manifolds. If \( f \) separates the manifolds of \( M \), any misclassified point should lie out of \( M \). Therefore, to change a correct classification near manifold, any adversary would pull a sample further out of the manifold. By projecting misclassified points to the nearest manifold, we may
expect the classification to be corrected by the projection. Invert and Classify (INC) method [Ilyas et al., 2017; Samangouei et al., 2018] implements this using a generative model.

The main idea of INC is to invert the perturbed sample by projecting to the nearest point on data-generating manifold. Ideally, the data-generating manifold $M$ is accessible. For any point $(\hat{x}, y)$ with $f(\hat{x}) \neq y$, out-of-manifold perturbation is reduced by projecting $\hat{x}$ to $x^*$ on $M$.

$$x^* = \arg \min_{x \in M} d(x, \hat{x})$$  \hspace{1cm} (3)

where $d$ is a metric defined on the domain $X$. If perfect classification on $M$ is assumed (model is well-trained on $M$) and $\hat{x}$ is close enough to the manifold of correct label, classification $f(x^*)$ is likely to be correct, since $x^*$ is likely to lie on the correct manifold.

The manifold $M$ is unknown in practice. However, as $M$ is the data-generating manifold of $D_X$, a generative model $G$ for $D_X$ is trained to approximate $M$. Then, searching over $M$ is replaced by searching over latent vectors of $G$. The optimization with this approximation is used by the INC approach.

$$x^* = G(z^*) \text{ where } z^* = \arg \min_{z \in \mathcal{Z}} d(G(z), \hat{x})$$  \hspace{1cm} (4)

4 Topological Properties of Data from Generative Models

In this paper, we study the significance of differences in the topological properties of the latent vector distribution and the target distribution, in learning generative models. Initial information about the topology of target distribution$^1$ is crucial to the generative model performance. Specifically, if there are fundamental topological differences between the target distribution and the distribution of the latent vector, then any continuous generative model $G$ cannot approximate the target distribution properly (irrespective of the use training method). Due to the space limit, all proofs are presented in Appendix C.

4.1 Topology of Distributions Based on Level Sets

The data-generating manifold is a geometric shape that corresponds to the distribution. However, this manifold is not accessible in most cases and we only have indirect access via the distribution extended from it. Therefore, we consider finding a shape from the extended density, so that this “shape” successfully approximates the data-generating manifold.

$\lambda$-density level set. We use the concept of $\lambda$-density level set to capture geometric features of the density function. Simply put, for a density function $p$ and a threshold $\lambda > 0$, $\lambda$-density level set $L_{p, \lambda}$ is the inverse image $p^{-1}[\lambda, \infty)$. Our theoretical contribution is the conditional existence of a $\lambda$-density level set reflecting the topology of the data-generating manifold, under proper conditions on the noise density.

Assumptions on noise density. For a family of densities $\{\nu_x\}_{x \in M}$, we expect the noise $\nu_x$ to have the following radii.

**Definition 1.** Let $\nu_x$ be a family of noise densities.

- $\lambda$ is small-enough if $L_{\nu_x, \lambda}$ is nonempty for all $x \in M$.
- $\lambda$-bounding radius $\delta_{x, \lambda} := \min \{ \delta \mid L_{\nu_x, \lambda} \subseteq B_\delta(0) \}$

  If $\max_{x \in M} \delta_{x, \lambda}$ exists for some $\lambda$, we denote the maximum value as $\delta_\lambda$.

- $\lambda$-guaranteeing radius $\epsilon_{x, \lambda} := \max \{ \epsilon \mid B_\epsilon(0) \subseteq L_{\nu_x, \lambda} \}$

  If $\min_{x \in M} \epsilon_{x, \lambda}$ exists for some $\lambda$, we simply the minimum value as $\epsilon_\lambda$.

Sufficient conditions for the existence of these radii are discussed in Appendix D.3. The properties of these radii are summarized in Lemma 1. (The proof follows from Definition 1).

**Lemma 1.** Let $\nu_x$ be a family of noise densities and let $\lambda$ be small-enough. Then,

$$\|\hat{x} - x\| > \delta_\lambda \implies \nu_x(\hat{x} - x) < \lambda$$

$$\|\hat{x} - x\| \leq \epsilon_\lambda \implies \nu_x(\hat{x} - x) \geq \lambda$$

whenever $\delta_\lambda$ and $\epsilon_\lambda$ exist.

$^1$The term topology of distributions, refers to the topology of shapes that correspond to the distributions.
We can use this theorem to deduce the need for proper information about the target distribution when noise densities have continuously varying radii, with the compactness of $M$.

With the definitions above, we proved the following main theorem.

**Definition 2** (Continuously varying radii). Noise densities $\nu_x$ have continuously varying radii if, for a fixed small-enough $\lambda$, both $\delta_{x,\lambda}$ and $\epsilon_{x,\lambda}$ are continuous functions of $x \in M$.

When noise densities have continuously varying radii, with the compactness of $M$, we can apply the extreme value theorem to guarantee the existence of both $\delta_{\lambda} = \max_{x \in \mathcal{M}} \delta_{x,\lambda}$ and $\epsilon_{\lambda} = \min_{x \in \mathcal{M}} \epsilon_{x,\lambda}$.

### 4.2 Main Theorem

Our main theorem establishes, under the assumptions on noise densities from Section 4.1, the existence of a $\lambda$ such that,

- **(Inclusion)** The $\lambda$-density level set $L_{PM,\lambda}$ includes the data-generating manifold $M$.
- **(Separation)** The $\lambda$-density level set $L_{PM,\lambda}$ consists of connected components such that each component contains at most one manifold $M_i$.

**Definition 3.** Consider a data-generating manifold $M$ with density function $p$. For a radius $\epsilon > 0$, we define $\omega_{\epsilon}$ to be the minimum (over $x \in M$) probability of sampling $x' \in M$ in an $\epsilon$-ball $B_\epsilon(x)$.

$$\omega_{\epsilon} := \min_{x \in M} \Pr[x' \in B_\epsilon(x)]$$

**Definition 4** (Class-wise distance). Let $(X, d)$ be a metric space and let $M = \bigcup_{i=1}^I M_i$ be a data-generating manifold in $X$. The class-wise distance $d_{cw}$ of $M$ is defined as,

$$d_{cw} = \min_{i,j \in [I]} \min_{x \in M_i, x' \in M_j} d(x, x')$$

With the definitions above, we proved the following main theorem.

**Theorem 1.** Pick any small-enough threshold $\lambda$. Fix a value $\lambda^* \leq \omega_{\epsilon,\lambda}$ and let $\delta^* = \delta_{\lambda^*}$ be the $\lambda^*$-bounding radius. If $d_{cw}$ of $M$ is larger than $2\delta^*$, then the level set $L_{PM,\lambda^*}$ satisfies the followings.

- $L_{PM,\lambda^*}$ contains the data-generating manifold $M$.
- Each connected component of $L_{PM,\lambda^*}$ contains at most one manifold $M_i$ of class $i$.

### 4.3 Application to the Generative Model

We show an application of Theorem 1. We denote the target distribution by $D_X$, the latent distribution by $D_Z$, and the distribution of $G(z)$ where $z \sim D_Z$ by $D_{G(Z)}$. Similarly, we denote the corresponding $\lambda$-density level sets of densities by $L^X_\lambda$, $L^Z_\lambda$, and $L_{G(Z)}^G$. We assume the generative model $G$ to be continuous. Then, we get the following theorem regarding the difference between $L^X_\lambda$ and $L_{G(Z)}^G$.

**Theorem 2.** Let $D_Z$ be a mixture of $n_Z$ multivariate Gaussian distributions, and let the data-generating manifold of $D_X$ contain $n_X$ components. Let $G$ be a continuous generative model for $D_X$ using latent vectors from $D_Z$. Let $\lambda^*$ be the threshold value from the Theorem 1 If $n_Z < n_X$, $L^X_{\lambda^*}$ and $L_{G(Z)}^G$ do not agree on the number of connected component.

We can use this theorem to deduce the need for proper information about the target distribution when training a generative model, especially if it is used for a security-critical application, e.g. INC.

**Corollary 1.** If Theorem 2 is satisfied, there is a point $\hat{x} \in \mathbb{R}^n$ such that $\hat{x} \notin L^X_{\lambda^*}$, but $\hat{x} \in L_{G(Z)}^G$.

---

2 In Appendix D.4, Theorem 2 is generalized for more topological properties.
As a result, with density at least $\lambda^*$, $G$ generates a point $\hat{x}$ which is unlikely to be generated by the target distribution. Since INC is based on generations of $G$, INC method can output an out-of-manifold point as a solution of optimization $\frac{d}{dt} (\lambda^* G (x^t) ) = 0$.

5 Experimental result

In this section, we empirically demonstrate the consequence of the two theorems and explore their implication for the INC defense. Our main goals are to check (1) the correctness of Theorem 2 and Corollary 1 for toy datasets, and (2) the improvement in INC performance using a topology-aware generative model. Our three main questions and the corresponding answers are,

**Q1** Can we experimentally verify the results of section 4.3? Specifically, can we find cases that the level sets of $D_X$ and $\lambda G (Z)$ have different numbers of connected components?

**Q2** How does INC fail when the generative model is ignorant of topology information?

**Q3** Does the topology-aware generative model improve the INC performance?

(A1) Theorem 2 and Corollary 1 can be verified by plotting $\lambda$-density level set. Especially, we visualize the $\lambda$-density level set of $\lambda G (Z)$ reflecting Theorem 2 and Corollary 1.

(A2) When generative model is not trained with topology information, naive INC may fail. We found out two possible reasons regarding INC failure: (1) choice of a bad initial point and (2) out-of-manifold search due to non-separation of density level set.

(A3) The performance of INC is improved by training generative models with topology information on the target distribution. We improved the average INC performance by decreasing the error induced by projection to 30% compared to the topology-ignorant counterpart.

In the rest of this section, we provide a more detailed description of our experiments. First, we briefly describe the experimental setup in section 5.1: datasets and latent vector distributions. Then, section 5.2 and 5.3 describe the experimental results regarding the findings summarized above. Additional details are in Appendix E that includes model architecture, INC implementation, and more results about INC improvement.

5.1 Experimental setup

Datasets. For all experiments, we use three toy datasets in $\mathbb{R}^2$: two-moons, spirals, and circles. Table 1 summarizes the parameterizations of each data-generating manifold and Figure 2 are the plots of the corresponding data-generating manifolds. To construct the training set, we first sampled

| two-moons | spirals | circles |
|-----------|---------|---------|
| $M_0 : \{(x_1, x_2) \mid x_1 = \cos \theta, x_2 = \sin \theta \}$ | $M_0 : \{(x_1, x_2) \mid x_1 = 4e^{t} \cos(t), x_2 = 4e^{t} \sin(t) \}$ | $M_0 : \{(x_1, x_2) \mid x_1 = \cos \theta, x_2 = \sin \theta \}$ |
| $M_1 : \{(x_1, x_2) \mid x_1 = 1 - \cos \theta, x_2 = 1 - \sin \theta + \frac{1}{2} \}$ | $M_1 : \{(x_1, x_2) \mid x_1 = 4e^{t} \cos(t + \frac{\pi}{2}), x_2 = 4e^{t} \sin(t + \frac{\pi}{2}) \}$ | $M_1 : \{(x_1, x_2) \mid x_1 = \frac{1}{2} \cos \theta, x_2 = \frac{1}{2} \sin \theta \}$ |
| for $\theta \in [0, \pi]$ | for $t \in [0, T]$ where $T = \ln \left( \frac{15}{2^{2}} + 1 \right)$ | for $\theta \in [0, 2\pi]$ |

Table 1: Parameterizations of dataset used in the experiments.

1000 points uniformly from each manifold $M_i$, then each point was perturbed by isotropic Gaussian noise $\mathcal{N}(0, \sigma^2 I_2)$ with $\sigma = 0.05$. Before the training, each training set was standardized by a preprocessing of Scikit-learn package.

Latent vector distributions. For latent vector distributions $D_Z$, we prepared three mixtures of $n_Z$ Gaussian distributions with $n_Z \in \{1, 2, 3\}$. For the target distribution with $l = n_X$ classes, to choose of $n_Z$, we use $(n_X - 1)$ for topology-ignorant training and $n_X$ for topology-aware training.

5.2 Visual verification of theorems

The goal of this section is to verify the Theorem 2 and the Corollary 1 by visualizing the level set reflecting the statements. Figure 3 shows the $\lambda$-density level sets of densities of $\lambda G (Z)$ using the same

\[ t = \ln \left( \frac{s}{\sqrt{2}} + 1 \right) \quad \text{for } s \in [0, 15] \]
threshold $\lambda = 0.01$. The first row and the second row show the results from the topology-ignorant version and those from the topology-aware version, respectively. Each column corresponds to each dataset. All distributions are scaled for the standardization preprocessing before the training.

In general, level set components are separated when the generative model is topology-aware. On the contrary, the topology-ignorant generative models introduce connections between level set components, as anticipated by the Corollary 1. Due to this connection, the topology-ignorant generative models achieve less number of connected components in its level set, and this verifies the Theorem 2 for our choice of $\lambda^* = 0.01$.

5.3 INC FAILURE DUE TO THE LACK OF INFORMATION ON THE DISTRIBUTION TOPOLOGY

We present how the non-separation of level set components influences the performance of the INC. We provide two possible explanations of why INC fails. First is the bad initialization causing a suboptimal solution on a manifold not-the-nearest to the input. The second is due to an artifact, induced by the topological difference producing an out-of-manifold solution.

Figure 4 presents three visualized examples of INC with a topology-ignorant generative model for two-moons. In each plot, the black dot is the given point $\hat{x}$, and cyan dot is the initial point from choosing $z$ randomly from the latent vector distribution $\mathcal{N}(0, I_2)$, and magenta dot is the final point outputted by INC. All intermediate points of the optimization are plotted with dots, changing colors gradually from cyan to magenta. The training set for two-moon used in the training procedure is plotted in gray.
Figure 4: Successful and failed cases of INC using topology-ignorant generative model of two-moon.

- (a) INC with an ideal initialization: The initial point was chosen in the same manifold as the manifold closest to \( \hat{x} \). Then, the INC optimization searches along the manifold, converging to a point close to \( \hat{x} \).
- (b) INC with a bad initialization: The initial point was chosen on the other manifold than the manifold containing the desired solution, so INC converged to a local optimum on the wrong manifold. Our topology-aware INC performs manifold-wise initialization to circumvent this issue.
- (c) INC searching out of manifold: Not only did INC converge in a wrong manifold, but a nontrivial amount of intermediate points also lie out of manifold, resulting in an out-of-manifold solution (see Figure 3a-c).

5.4 INC Improvement via Topology-Aware Generative Model

We demonstrate that INC performance is improved by using topology-aware generative models. To measure the performance of INC, 100 points are chosen uniformly from each manifold \( M_i \). Then, each point \( x \) is perturbed by \( n_x \) normal to the manifold at \( x \), generating 200 adversarial points \( \hat{x} = x + r n_x \). For all datasets, \( r = 0.2 \) is used for perturbation size. We expect two types of INC to map \( \hat{x} \) back to the original point \( x \), as \( x \) is the optimal solution to (3). We define the projection error of INC as \( \| \text{INC}(\hat{x}) - x \|_2 \), and collect the statistics of projection errors over all \( \hat{x} \).

Table 2: Comparison of the projection errors of INC based on the topology-awareness of the model.

| Two-moons | Spirals | Circles |
|-----------|---------|---------|
| topology-ignorant | topology-aware | topology-ignorant | topology-aware | topology-ignorant | topology-aware |
| 0.647 (0.666) | 0.148 (0.208) | 1.523 (1.338) | 0.443 (0.440) | 0.699 (0.491) | 0.180 (0.259) |

Table 2 shows the projection error statistics for two types of generative model. Each pair of columns is the results on the indicated dataset. For each pair, one column shows the performance of the topology-ignorant INC and the other column shows that of the topology-aware counterpart. Numbers in each cell are average and standard deviation (in parenthesis) of the projection error. For any dataset, topology-aware INC achieves significantly lower projection errors. Histograms of the projection errors and more experiment with INC applications are provided in Appendix F.

6 Conclusion

We theoretically and experimentally discussed the necessity of topology-awareness in the training of generative models, especially in security-critical applications. A continuous generative model is sensitive to the topological mismatch between the latent vector distribution and the target distribution. Such mismatch leads to potential problems with manifold-based adversarial defenses utilizing generative models such as INC. We described two cases when INC fails: the bad initialization and the artifacts from the topological difference. We experimentally verified that topology-aware training effectively prevents these problems, thereby improving the effectiveness of generative models in manifold-based defense. After topology-aware training of generative models, the INC projection errors fell down to 30% of the errors of the topology-ignorant INC.

A Mathematical Background

A.1 General Topology

We introduce definitions and theorems related to general topology appeared in the paper. For more details, all the definitions and theorems can be found in Munkres [Munkres, 2000].

Definitions in general topology. We first provide the precise definitions of the terms we brought from the general topology.

Definition 5 (Topological space). A topology on a set $X$ is a collection $T$ of subsets of $X$ having the following properties.

1. $\emptyset$ and $X$ are in $T$.
2. The union of the elements of any subcollection of $T$ is in $T$.
3. The intersection of the elements of any finite subcollection of $T$ is in $T$.

A set $X$ for which a topology $T$ has been specified is called a topological space.

For example, a collection of all open sets in $\mathbb{R}^n$ is a topology, thus $\mathbb{R}^n$ is a topological space. If a topology can be constructed by taking arbitrary union and a finite number of intersections of a smaller collection $B$ of subsets of $X$, we call $B$ is a basis of the topology.

Pick a metric $d$ in $\mathbb{R}^n$ and consider $B$ a set of all open balls in $\mathbb{R}^n$ using the metric $d$. The topology of $\mathbb{R}^n$ can be constructed by taking $B$ as a basis. When this construction is possible, metric $d$ is said to induce the topology.

Definition 6 (Metrizable space). If $X$ is a topological space, $X$ is said to be metrizable if there exists a metric $d$ on the set $X$ that induces the topology of $X$. A metric space is a metrizable space $X$ together with a specific metric $d$ that gives the topology of $X$.

Since $\mathbb{R}^n$ is equipped with Euclidean metric that induces its topology, $\mathbb{R}^n$ is metrizable.

Continuity and the extreme value theorem. Let $X$ and $Y$ be topological spaces In the field of general topology, a function $f : X \rightarrow Y$ is said to be continuous, if for any subset $V$ open in $Y$, its inverse image $f^{-1}(V)$ is open in $X$. Moreover, if $f$ is a continuous bijection whose inverse is also continuous, $f$ is called a homeomorphism. The notion of homeomorphism is important as it always preserves topological property, e.g. connectedness, compactness, etc., and this will be used in the further generalization of Theorem 2.

Here, we only introduce the generalized statement of extreme value theorem.

Theorem 3 (Extreme value theorem). Let $f : X \rightarrow Y$ be continuous, where $Y$ is an ordered set. If $X$ is compact, then there exist points $\underline{x}$ and $\overline{x}$ in $X$ such that $f(\underline{x}) \leq f(x) \leq f(\overline{x})$ for every $x \in X$.

Specifically, if a manifold $M$ is a compact subset in $\mathbb{R}^n$, we may use $X = M$ and $Y = \mathbb{R}$.

Normal space and Urysohn lemma. The Urysohn lemma was used to prove the Corollary 1. We first introduce the notion of normal space.

Definition 7 (Normal space). Let $X$ be a topological space that one-point sets in $X$ are closed. Then, $X$ is normal if for each pair $A$, $B$ of disjoint closed sets of $X$, there exist disjoint open sets containing $A$ and $B$, respectively.

Urysohn’s lemma is another equivalent condition for a space to be normal.

Theorem 4 (Urysohn lemma). Let $X$ be a normal topological space; let $A$ and $B$ be disjoint closed subsets in $X$. Let $[a, b]$ be a closed interval in the real line. Then there exists a continuous map $f : X \rightarrow [a, b]$ such that $f(x) = a$ for every $x$ in $A$, and $f(x) = b$ for every $x$ in $B$.

To apply this lemma to $\mathbb{R}^n$, we only need the following theorem.

Theorem 5. Every metrizable space is normal.

Since $\mathbb{R}^n$ is metrizable, it is a normal space by Theorem 5. Therefore, we can apply Urysohn lemma to any pair of disjoint subsets in $\mathbb{R}^n$, to show the existence of a continuous map $f : X \rightarrow [0, 1]$. 

Under review as a conference paper at ICLR 2020
A.2 DIFFERENTIAL GEOMETRY

We provide the definitions from differential geometry (Lee, 2003) used in the paper.

Manifold and tangent space.

Definition 8 (Manifold). Suppose $M$ is a topological space. We say $M$ is a topological manifold of dimension $k$ if it has the following properties.

1. For any pair of distinct points $x_1, x_2 \in M$, there are disjoint open subsets $U_1, U_2 \subset M$ such that $x_1 \in U$ and $x_2 \in V$.
2. There exists a countable basis for the topology of $M$.
3. Every point has a neighborhood $U$ that is homeomorphic to an open subset $\hat{U}$ of $\mathbb{R}^k$.

There are different ways to define tangent space of $k$-dimensional manifold $M$. Informally, it can be understood as geometric tangent space to $M \subset \mathbb{R}^n$ at a point $x \in M$, which is a collection of pairs $(X, v)$ where $v$ is a vector tangentially passing through $x$. Here we put a more formal definition of tangent space. Consider a vector space $C^\infty(M)$, a set of smooth functions on $M$.

Definition 9 (Tangent space). Let $x$ be a point of a smooth manifold $M$. A linear map $X : C^\infty(M) \to \mathbb{R}$ is called a derivation at $x$ if it satisfies

$$X(fg) = f(x)Xg + g(x)Xf$$

for all $f, g \in C^\infty(M)$.

The set of all derivations of $C^\infty(M)$ at $x$ forms a vector space called the tangent space to $M$ at $x$, and is denoted by $T_x(M)$.

Riemannian metric. As tangent space $T_x(M)$ is a vector space for each $x \in M$, we can consider an inner product $g_{xf}$ defined on $T_x(M)$.

Definition 10 (Riemannian metric). A Riemannian metric $g$ on a smooth manifold $M$ is a smooth collection of inner products $g_x$ defined for each $T_x(M)$. The condition for smoothness of $g$ is that, for any smooth vector fields $X, Y$ on $M$, the mapping $x \mapsto g_x(X|_x, Y|_x)$.

A manifold $M$ equipped with a Riemannian metric $g$ is called a Riemannian manifold.

B EXAMPLES

Computing density $p$ over a Riemannian manifold $M$. This section presents example computations of the probability computations from the Section D.1 and 3.2. As a concrete example of computing density over a manifold, we use the following simple manifolds, so-called two-moons in $\mathbb{R}^2$.

$$M_0 = \{(x_1, x_2) \mid x_1 = \cos \theta, x_2 = \sin \theta \text{ for } \theta \in [0, \pi]\}$$

$$M_1 = \{(x_1, x_2) \mid x_1 = 1 - \cos \theta, x_2 = 1 - \sin \theta + \frac{1}{4} \text{ for } \theta \in [0, \pi]\}$$

We take $M = M_0 \cup M_1$ as our example manifold. Figure 5(a) shows the manifold of two-moons dataset plotted in different colors: $M_0$ in red and $M_1$ in blue.

First recall the following equation (equation 8) from the Section D.1.

$$\int_{x \in M} p(x) dM(x) = \int_{u \in D} p(X(u)) \sqrt{\det[g_{X(u)}]} |d\mathbf{u}|$$

where $[g_{X(u)}]$ is the $k \times k$ matrix representation of the inner product $g_{X(u)}$ at $X(u) \in M$.

Especially, when a manifold in $\mathbb{R}^n$ is of dimension 1, i.e. parameterized curve $\gamma : [a, b] \to \mathbb{R}^n$, the integration (8) can be written in simpler way.

$$\int_{x \in M} p(x) dM(x) = \int_{t=a}^{b} p(\gamma(t)) \|\gamma'(t)\| dt$$

(5)

where $\gamma'(t)$ is the $n$-dimensional velocity vector at $t \in [a, b]$. 
Let $p$ be a probability density function defined on $M$. As $M$ is composed of two disjoint manifolds $M_0$ and $M_1$, we consider conditional densities $p_0, p_1$ as follows.

\[
p_0(x) = p(x \mid x \in M_0) = \frac{p|_{M_0}(x)}{Pr[x \in M_0]}
\]

\[
p_1(x) = p(x \mid x \in M_1) = \frac{p|_{M_1}(x)}{Pr[x \in M_1]}
\]

(6)

Here, $p|_{M_0}$ and $p|_{M_1}$ are the density function $p$ with its domain restricted to $M_0$ and $M_1$, respectively. By our definition of data-generating manifolds, $Pr[x \in M_i]$ corresponds to the probability of data generation for class $i$, i.e. $Pr[y = i]$. For a concrete example of such density, uniform density for each manifold $M_i$ can be defined as $p_i(x) = \frac{1}{\pi}$ for all $x \in M_i$.

Note that each of manifolds are parameterized curves in $\mathbb{R}^2$,

\[
\begin{align*}
\gamma_0 : \theta &\mapsto (\cos \theta, \sin \theta) \\
\gamma_1 : \theta &\mapsto (1 - \cos \theta, 1 - \sin \theta + 0.5)
\end{align*}
\]

with constant speed $\|\gamma_0'(\theta)\| = \|\gamma_1'(\theta)\| = 1$ at all $\theta \in [0, \pi]$. Therefore, from equation (5),

\[
\begin{align*}
\int_{x \in M_0} p|_{M_0}(x) dM_0(x) &= \int_{\theta=0}^{\pi} p(\gamma_0(\theta)) d\theta \\
\int_{x \in M_0} p|_{M_1}(x) dM_1(x) &= \int_{\theta=0}^{\pi} p(\gamma_1(\theta)) d\theta
\end{align*}
\]

(7)

For any measurable subset $A \subseteq M$, the probability for an event that $x$ is in $A$ can be computed as follows.

\[
Pr[x \in A] = \int_{x \in A \subseteq M} p(x) dM(x) = \int_{x \in A \cap M_0} p|_{M_0}(x) dM_0(x) + \int_{x \in A \cap M_1} p|_{M_1}(x) dM_1(x)
\]

\[
= \int_{\theta \in [0, \pi]} p(\gamma_0(\theta)) d\theta + \int_{\theta \in [0, \pi]} p(\gamma_1(\theta)) d\theta \quad \therefore (7)
\]

\[
= Pr[x \in M_0] \int_{\theta \in [0, \pi]} p_0(\gamma_0(\theta)) d\theta + Pr[x \in M_1] \int_{\theta \in [0, \pi]} p_1(\gamma_1(\theta)) d\theta \quad \therefore (6)
\]

\[
= \frac{1}{\pi} \left( Pr[x \in M_0] \int_{\theta \in [0, \pi]} \int_{\gamma_0(\theta) \in A} 1 d\theta + Pr[x \in M_1] \int_{\theta \in [0, \pi]} \int_{\gamma_1(\theta) \in A} 1 d\theta \right)
\]
We can briefly check all the requirements [R1], [R2], and [R3]. The computation of \( \Pr[x \in A] \) is based on [R1], so [R1] is satisfied trivially. Also, \( p \) is a function defined only on \( M \), thus [R2] is clear, i.e. \( \text{supp}(p) = \{ x \in \mathbb{R}^n \mid p(x) > 0 \} \subseteq M \). To check [R3] when \( A = M_i \), computing this integration will result in the exact probability \( \Pr[x \in M_i] = \Pr[y = i] \), so when \( A = M \), computing the integration will result in \( \Pr[y = 0] + \Pr[y = 1] = 1 \), as desired in the requirements.

**Extending density to \( \mathbb{R}^n \).** We extend the domain to \( \mathbb{R}^n \) for the example of two-moon. We show an example that under a proper noise density function, we can construct the density extended from \( M \) satisfying the requirement [R0]. For simplicity, we choose isotropic Gaussian distribution, \( N(0, \sigma^2 I) \) with standard deviation \( \sigma \) for each dimension, as the noise density function \( \nu_x \) for all \( x \in \mathbb{M} \). Such noise density \( \nu_x \) defined in \( \mathbb{R}^n \) can be written as follows.

\[
\nu_x(n_x) = \frac{1}{\sqrt{2\pi} \sigma^2} \exp \left( -\frac{\| n_x \|^2}{2\sigma^2} \right)
\]

By putting \( n_x = x - \hat{x} \) to density equation above,

\[
p_M(\hat{x}) = \int_{\mathbb{R}^n} \frac{1}{\sqrt{2\pi} \sigma^2} \exp \left( -\frac{\| x - \hat{x} \|^2}{2\sigma^2} \right) p(x) dM(x)
\]

Specifically, we assume an isotropic Gaussian distribution with \( \sigma = 0.05 \) as the noise density \( \nu_x \) for all \( x \in M \).

By the equation (1), we have the following computation of density on \( \hat{x} \).

\[
p_M(\hat{x}) = \int_{\mathbb{R}^n} \nu_x(\hat{x} - x)p(x) dM(x)
\]

\[
= \int_{\mathbb{R}^n} \nu_x(\hat{x} - x)p_{M_0}(x) dM(x) + \int_{\mathbb{R}^n} \nu_x(\hat{x} - x)p_{M_1}(x) dM(x)
\]

\[
= \int_{\theta = 0}^\pi \nu_x(\hat{x} - x)p_{M_0}(\gamma_0(\theta)) d\theta + \int_{\theta = 0}^\pi \nu_x(\hat{x} - x)p_{M_1}(\gamma_1(\theta)) d\theta \quad (\because [5])
\]

\[
= \Pr[x \in M_0] \int_{\theta = 0}^\pi \nu_x(\hat{x} - x)p_{0}(\gamma_0(\theta)) d\theta
\]

\[
+ \Pr[x \in M_1] \int_{\theta = 0}^\pi \nu_x(\hat{x} - x)p_{1}(\gamma_1(\theta)) d\theta \quad (\because [6])
\]

\[
= \frac{1}{\sqrt{2\pi} \sigma^2} \left[ \Pr[x \in M_0] \int_{\theta = 0}^\pi \exp \left( -\frac{\| x - \hat{x} \|^2}{2\sigma^2} \right) d\theta
\]

\[
+ \Pr[x \in M_1] \int_{\theta = 0}^\pi \exp \left( -\frac{\| x - \hat{x} \|^2}{2\sigma^2} \right) d\theta \right]
\]

We can also check that the requirement [R0] is satisfied by the construction; our construction (equation (1)) is based on [R0]. The computed density is shown in Figure 5b.

C. **Proofs**

In this Section, we provide the proofs for statements that appeared in Section 4.

C.1 **Proof of Theorem 1**

To begin with, pick a value \( \lambda \) such that the \( \lambda \)-density level set \( L_{\lambda} \) is nonempty for all \( x \in M \). As we use noise densities \( \nu_x \) described in Section 4.1, it is safe to assume that both \( \lambda \)-bounding radius \( \delta_x = \max_{x \in M} \delta_{x, \lambda} \) and \( \lambda \)-guaranteeing radius \( \epsilon_x = \min_{x \in M} \epsilon_{x, \lambda} \) exist.

Then, we can prove that, with a proper choice of threshold \( \lambda \), \( \lambda \)-density level set includes the data-generating manifold.

**Lemma 2.** Assume that noise densities have radii in Definition 1 for all \( x \in M \) and a small enough \( \lambda > 0 \). Then, for any \( x \in M \), the density \( p_M(x) \) is at least \( \omega_x \lambda \), i.e. \( p_M(x) \geq \omega_x \lambda \), where \( \epsilon = \epsilon_{x, \lambda} \).

**Proof.** By Lemma 1

\[
x \in B_\epsilon(x) \iff x \in B_{\epsilon}(x) = B_{\epsilon_{x}}(x) \quad (\because \epsilon = \epsilon_{x, \lambda})
\]

\[
\implies \nu_{x \epsilon}(x - x) \geq \lambda
\]
Then, we can lower bound the density \( p_M(x) \) as follows.
\[
p_M(x) = \int_{x' \in M} \nu(x - x') p(x') dM(x') \\
\geq \int_{x' \in M \cap B_\delta(x)} \nu(x - x') p(x') dM(x') \\
\geq \lambda \int_{x' \in M \cap B_\delta(x)} p(x') dM(x') \\
= \lambda \Pr_{x' \in M}[x' \in B_\delta(x)] \\
\geq \omega_\lambda \lambda
\]

This lemma shows that the thresholding the extended density \( p_M \) with threshold \( \lambda^* \leq \omega_\lambda \lambda \) guarantees the level set to include the entire manifold \( M \).

**Corollary 1.** For any threshold \( \lambda^* \leq \omega_\lambda \lambda \), the corresponding \( \lambda^* \)-density level set \( L_{p_M, \lambda^*} \) of the extended density \( p_M \) includes the data-generating manifold \( M \).

Similarly, we show that, with a proper choice of threshold \( \lambda \), each connected component of \( \lambda \)-density level set contains at most one manifold.

**Lemma 3.** Assume a family of noise densities satisfies the assumptions of Section 4.1. Let \( \lambda > 0 \) be a value such that the \( \lambda \)-density level set \( L_{\nu_\lambda} \) is nonempty for any \( x \in M \). Also, let \( \delta = \delta_\lambda \) be the maximum \( \lambda \)-bounding radius over \( M \). Then, for any \( x \notin N_\delta(M) \), the extended density value is smaller than \( \lambda \), i.e. \( p_M(x) < \lambda \).

**Proof.** By Lemma 1,
\[
x \notin N_\delta(M) \iff x \notin B_\delta(x) = B_{\delta_\lambda}(x) \text{ for any } x \in M \quad (\because \delta = \delta_\lambda)
\]
\[
x \notin B_{\delta_\lambda}(x) \text{ for any } x \in M
\]
Then, we can upper bound the density \( p_M(x) \) as follows.
\[
p_M(x) = \int_{x \in M} \nu(x - x) p(x) dM(x)
\]
\[
< \lambda \int_{x \in M} p(x) dM(x) \quad (\because x \notin N_{\delta_\lambda}(M))
\]
\[
= \lambda
\]

This lemma says that, the \( \lambda \)-density level set is included by the \( \delta \)-neighborhood \( N_\delta(M) \) of the data-generating manifold \( M \).

Now, we can deduce the following main result.

**Theorem 1.** Pick any \( \lambda^* \leq \omega_\lambda \lambda \) threshold value satisfying the Corollary 1. If the class-wise distance of data-generating manifold is larger than \( 2\delta^* \) where \( \delta^* = \delta_{\lambda^*} \) (the \( \lambda^* \)-bounding radius), then the level set \( L_{p_M, \lambda^*} \) satisfies the followings.

- \( L_{p_M, \lambda^*} \) contains the data-generating manifold \( M \).
- Each connected component of \( L_{p_M, \lambda^*} \) contains at most one manifold \( M_i \) of class \( i \).

**Proof.** The first property is a direct application of Corollary 1 for \( \lambda^* = \omega_\lambda \lambda \).

For the Second property, since the class-wise distance of \( M \) is larger than \( 2\delta^* \), the \( \delta^*- \)neighborhood of manifolds are pairwise disjoint, i.e. \( N_{\delta^*}(M_i) \cap N_{\delta^*}(M_j) = \emptyset \) for each \( i \neq j \). Therefore, \( N_{\delta^*}(M) \) has exactly \( k \) connected components \( N_i = N_{\delta^*}(M_i) \)'s.

By Lemma 3 \( \delta^*- \)neighborhood \( N_{\delta^*}(M) \) contains the level set \( L_{p_M, \lambda^*} \), thus each connected component of \( L_{p_M, \lambda^*} \) is in exactly one of \( N_i \)'s. Since \( M \) is contained in \( L_{p_M, \lambda^*} \), each \( M_i \) is contained in some connected component \( C \) of \( L_{p_M, \lambda^*} \) which is in \( N_i \). Then, for any \( j \neq i, M_j \not\subset C \subset N_i \), since \( M_j \) is in \( N_j \) which is disjoint to \( N_i \). Therefore, if a connected component \( C \) contains a manifold \( M_i \), then it cannot contain any other manifold. 

\[\square\]
C.2 Proofs for Section 4.3

Theorem 2. Let \( D_Z \) be a mixture of \( n_Z \) multivariate Gaussian distributions, and let \( D_X \) be the target distribution from a data-generating manifold with \( n_X \) manifolds. Let \( G \) be a continuous generative model for \( D_X \) using latent vectors from \( D_Z \). Assume the Theorem 1 is satisfied, and let \( \lambda^* \) be the threshold value from the Theorem 1. If \( n_Z < n_X \), \( L_X^{C} \) and \( L_X^{G(Z)} \) do not agree on the number of connected component.

Proof. Since \( L_X^{C} \) is the results of Theorem 1, the number of connected component of \( L_X^{C} \) is at least \( n_X \).

However, since \( D_Z \) is a mixture of Gaussians, for any value of \( \lambda \) (including the special case \( \lambda = \lambda^* \)), \( L_X^{C} \) can never have more than \( n_Z \) connected components. Since \( G \) is continuous, it preserves the number of connected components, \( L_X^{G(Z)} = G(L_X^{C}) \) has at most \( n_Z \) connected components. As \( n_Z < n_X \), \( L_X^{C} \) and \( L_X^{G(Z)} \) can never agree on the number of connected components.

Corollary 2. If Theorem 2 is satisfied, there is a point \( \hat{x} \in \mathbb{R}^n \) such that \( \hat{x} \notin L_X^{C} \) but \( \hat{x} \in L_X^{G(Z)} \).

Proof. Since \( n_Z < n_X \), there exists a connected components \( C \) of \( L_X^{G(Z)} \), containing at least two connected components of \( S_X^C \). Without loss of generality, assume \( C \) contains exactly two connected components \( C \) and \( C' \). By definition, \( \lambda \)-level set is a closed set, so \( C \) and \( C' \) are disjoint closed sets. In Euclidean space \( \mathbb{R}^n \), the Urysohn lemma tells us that for any disjoint pair of closed sets \( A, A' \) in \( \mathbb{R}^n \), there is a continuous function \( f \) such that \( f|_A(x) = 0 \) and \( f|_{A'}(x) = 1 \) for any \( x \in \mathbb{R}^n \).

Especially, when \( A = C \) and \( A' = C' \), there exists a continuous function \( f \) such that,

- \( f(x) = 0 \) for all \( x \) in \( C \)
- \( f(x) = 1 \) for all \( x \) in \( C' \)

Consider \( S = f^{-1}(\frac{1}{2}) \) which is a separating plane separating \( C \) and \( C' \). If \( \tilde{C} \cap S = \emptyset \), then \( \tilde{C} \cap S = f^{-1}[0, \frac{1}{2}) \) and \( \tilde{C} \cap S = f^{-1}(\frac{1}{2}, 1] \) will be two open set in subspace \( \tilde{C} \), whose union is \( \tilde{C} \).

This implies that \( \tilde{C} \) is disconnected, which is a contradiction. Therefore, \( \tilde{C} \cap S \) should be nonempty, and any point \( x \) in \( \tilde{C} \cap S \) is not in \( L_X^{C} \).

D Further Discussion

D.1 Computing density over a data-generating manifold

When \( M \) is a Riemannian manifold equipped with a Riemannian metric \( g \), we can compute probabilities over \( M \). There are two essential components of probability computation: (a) a density function \( p \) and (b) a measure \( dM \) over \( M \). We assume \( p \) and \( dM \) to satisfy the followings.

- (R1) For any measurable subset \( A \subseteq M \), i.e. \( \text{Pr}[x \in A] = \int_{x \in A} p(x) dM(x) \).
- (R2) \( p \) is zero everywhere out of \( M \), i.e. \( \text{supp}(p) = \{ x \in \mathbb{R}^n \mid p(x) > 0 \} \subseteq M \)
- (R3) For any \( (x, y) \), \( x \) is sampled from \( M_i \) if and only if \( y = i \), i.e. \( \text{Pr}[x \in M_i] = \text{Pr}[y = i] \)

When equipped with such \( p \) and \( dM \), we call \( M \) as a data-generating manifold.

Probability over a Riemannian manifold. We show how to compute a probability of \( x \) being generated from a Riemannian manifold \( M \). We assume a \( k \)-dimensional manifold \( M \) equipped with a Riemannian metric \( g \), a family of inner products \( g_x \) on tangent spaces \( T_x M \). In this case, \( g \) induces the volume measure \( dM \) for integration over \( M \). If \( M \) is parameterized by \( x = X(u) \) for \( u \in D \subseteq \mathbb{R}^k \), the integration of a density function \( p \) on \( M \) is as follows.

\[
\int_{x \in M} p(x) dM(x) = \int_{u \in D} p(X(u)) \sqrt{\det[g_{X(u)}]} du
\]

where \( [g_{X(u)}] \) is the \( k \times k \) matrix representation of the inner product \( g_{X(u)} \) at \( X(u) \in M \).

In section B a concrete example of this computation will be provided.
D.2 Density extension of the Section 3.2

This section introduces some remaining discussions regarding our data-generating process from a data-generating manifold.

Relation to kernel density estimation. While this extension is computing the density of compound distribution, it can be interpreted as computing expectation over a family of locally defined densities. Such expected value can be observed in previous approaches of density estimation. For example, if \( \nu_x \) is isotropic Gaussian for each \( x \), the above integration is equivalent to the kernel density estimation, with Gaussian kernel, over infinitely many points on \( M \).

Observed property of the extended density. In Figure 5b in Section B, we can observe that the extended density achieved higher values near the data-generating manifold. We formalize this observation to discuss its implication to the INC approach.

Let \( d(\hat{x}, M) \) to be the minimum distance from \( \hat{x} \) to the manifold \( M \).

\((C1)\) For any given \( \hat{x} \), let \( y^* \) be the class label whose conditional density \( p_M(\hat{x}|y = y^*) \) dominates \( p_M(\hat{x}|y = i) \) for \( i \neq y^* \).

\[
y^* \in \arg\max_{i \in [1]} p_M(\hat{x}|y = i)
\]  

and let \( M_{y^*} \) be the manifold corresponding to \( y^* \).

\((C2)\) For \( y^* \) satisfying \((C1)\) we choose \( y^* \) such that the distance of \( \hat{x} \) from the manifold \( d(\hat{x}, M_{y^*}) \) is the smallest.

If there are multiple \( y^* \) satisfying both of \((C1)\) and \((C2)\) we expect the following property to be true for all of those \( y^* \).

\((P1)\) Consider the shortest line from \( \hat{x} \) to the manifold \( M_{y^*} \). As \( \hat{x} \) goes closer to \( M_{y^*} \) along this line, \( \hat{x} \) should be more likely to be generated as the influence of noise decreases when moving away from the manifold. Therefore, we expect our density \( p_M \) to have the following property.

\[
x^* \in \arg\min_{x \in M_{y^*}} d(\hat{x}, x)\implies p_M(x) \leq p_M((1 - \lambda)\hat{x} + \lambda x^*) \text{ for all } \lambda \in [0, 1]
\]  

Actually, this provides another justification of INC. In reality, the density conditioned by the label is not available even after running a generative model, so finding \( y^* \) with \((C1)\) is relatively hard. If we only consider \((C2)\) without filtering \( y^* \) via \((C1)\) we are finding a point \( x \in M \) achieving the minimum distance to \( \hat{x} \), which is the optimization above. Then projecting \( \hat{x} \) to the \( x^* \), i.e. the solution of the optimization can be explained by \([10]\) when \( \lambda = 1 \), \( p_M \) is the highest along the shortest line between \( \hat{x} \) and \( x^* \).

D.3 Sufficient conditions for the existence of radii

We discuss the sufficient conditions guaranteeing the existence of radii introduced in Definition 11.

Those sufficient conditions are derived from natural intuition about the properties of distributions in most machine learning context.

The first intuition is that the influence of noise should diminish as observed sample \( \hat{x} \) moves away from a source point \( x_o \). Therefore, we formalize the noise whose density decreases as the noise \( n = \hat{x} - x_o \) gets bigger. We formalize boundedness of noise densities via the boundedness of their \( \lambda \)-density level sets and continuity of noise density via the continuity of individual \( \nu_x \).

**Definition 11** (Center-peaked noise density). Noise density functions \( \nu_x \) are center-peaked, if for any source point \( x \in M \) and any noise vector \( n \in \mathbb{R}^n \) with \( \|n\| > 0 \), \( \nu_x(n) < \nu_x(\lambda n) \) for all \( \lambda \in (0, 1) \).

**Definition 12** (Bounded noise density). Noise density functions \( \nu_x \) are bounded, if a \( \lambda \)-density level set is nonempty, there is a radius \( \delta \) by which the \( \lambda \)-density level set is bounded, i.e. \( L_{\nu_x, \lambda} \subseteq B_\delta(0) \) where \( B_\delta(0) \) is the closed ball of radius \( \delta \) centered at \( 0 \).

**Definition 13** (Continuous noise density). Noise density functions \( \nu_x \) are continuous, if \( \nu_x \) is continuous in \( \mathbb{R}^n \), for any \( x \in M \).
We try generalizing the Theorem 2 to handle more concepts in topology. The Theorem 2 mainly uses the conditions of the Theorem 1, and let \( G \) be the target manifold. Consider a generative model \( M \) using the latent vectors sampled from \( D \). Assume that \( G \) is a homeomorphism from \( \mathbb{R}^n \) to itself. Assume that data-generating manifold satisfies the conditions of the Theorem 2 and let \( \lambda^* \) be the threshold value that \( L_{\lambda^*} \) corresponds to that level.

Under the conditions above, the radii in Definition 1 always exist.

**Proposition 1.** If noise densities \( \nu_k \) are center-peaked, bounded, and continuous. Then, any nonempty \( \lambda \)-density level set \( L_{\nu_k, \lambda} \) has both \( \lambda \)-bounding radius \( \delta_{\nu, \lambda} \) and \( \lambda \)-guaranteeing radius \( \epsilon_{\nu, \lambda} \).

**Proof.** Let \( \nu_k \) be a center peaked, level set bounded family of continuous noise densities. Since \( \nu_k \) is continuous, level set \( L_{\nu_k, \lambda} = \nu_k^{-1}[\lambda, \infty) \) is closed as an inverse image of \( \nu_k \). Therefore, it’s boundary \( \partial L_{\nu_k, \lambda} \) is contained in \( L_{\nu_k, \lambda} \).

Because \( \nu_k \) is level set bounded, level set \( L_{\nu_k, \lambda} \) is bounded by a closed ball \( \overline{B_\delta(0)} \) with radius \( \delta \geq 0 \). Since \( \nu_k \) is center peaked, a nonempty level set \( L_{\nu_k, \lambda} \) always contains \( 0 \) as the maximum is achieved at \( 0 \). Moreover, there exists a closed neighborhood ball \( B_\epsilon(0) \) with radius \( \epsilon \geq 0 \) contained in the level set \( L_{\nu_k, \lambda} \). Now it is enough to show that the minimum of \( \delta \) and the maximum of \( \epsilon \) exist.

Since \( L_{\nu_k, \lambda} \) is bounded, its boundary \( \partial L_{\nu_k, \lambda} \) is also bounded. \( \partial L_{\nu_k, \lambda} \) is closed and bounded, thus it is a compact set. Therefore, the \( L \)-Euclidean norm, as a continuous function, should achieve the maximum \( \overline{\tau} \) and the minimum \( \underline{\tau} \) on \( \partial L_{\nu_k, \lambda} \) by the extreme value theorem. From the choice of \( \delta \) and \( \epsilon \), we can get,

\[
\epsilon \leq \underline{\tau} \leq \overline{\tau} \leq \delta
\]

Therefore, we can find the minimum \( \delta_{\nu, \lambda} = \tau \) and the maximum \( \epsilon_{\nu, \lambda} = \overline{\tau} \).

**D.4 Generalization of the Theorem**

We try generalizing the Theorem 2 to handle more concepts in topology. Theorem 2 mainly uses a fact that the number of connected components of \( \lambda \)-density level set is preserved by a continuous generative model \( G \).

In algebraic topology, each connected component corresponds to a generator of 0-th homology group \( H_0 \), and continuity of a function is enough to preserve each component. In general, generators of \( i \)-th homology group \( H_i \) for \( i > 0 \) are not preserved by a continuous map, so we need to restrict \( G \) further. By requiring \( G \) to be a homeomorphism, we can safely guarantee that all topological properties are preserved by \( G \), therefore we can generalize the Theorem 2 with a homeomorphic generative model \( G \).

To generalize the proof of the Theorem 2 we first provide the sketch of the proof.

1. \( \lambda^* \)-density level set \( L_{\lambda^*} \) of mixture of Gaussian has at most \( n_Z \) connected component.
2. Since \( G \) is continuous, the number of connected components of \( L_{\lambda^*}^X(Z) = G(L_{\lambda^*}^X) \) is same to the number of connected components of \( L_{\lambda^*}^X \), so it is also at most \( n_Z \).
3. We chose \( \lambda^* \) so that \( L_{\lambda^*}^X \) is included in \( \delta^* \)-neighborhood of \( M \).
4. By assumption on the class-wise distance of \( M \), \( \delta^* \)-neighborhood of \( M \) has exactly same number of connected components to \( M \), i.e. \( n_X \). Therefore \( L_{\lambda^*}^X \) has at least \( n_X \) connected components.
5. By (2) and (4) we conclude that \( L_{\lambda^*}^X(Z) \) and \( L_{\lambda^*}^X \) do not agree on the number of connected components as long as \( n_Z < n_X \).

In this proof, \( n_Z \) corresponds to the maximal 0-th Betti number of \( L_{\lambda^*}^X \), i.e. the number of generators of \( H_0(L_{\lambda^*}^X) \). If we keep using a mixture of Gaussians as latent vector distribution, all components of \( L_{\lambda^*}^X \) are contractible, so we may use 0 as the maximal \( i \)-th Betti number.

Also, \( n_X \) corresponds to the 0-th Betti number of \( M \) and it worked as the minimal 0-th Betti number of \( L_{\lambda^*}^X \). The condition on the class-wise distance of \( M \) is used to ensure \( n_Y \) to be a lower bound. Combining these observations, we can get the following generalized statement.

**Theorem 3.** Let \( D_Z \) be a mixture of multivariate Gaussian distributions, and let \( D_X \) be the target distribution from data-generating manifold \( M \). Let \( n_i \) be the \( i \)-th Betti number of \( M \).

Consider a generative model \( G \) is used to approximate \( D_X \) using the latent vectors sampled from \( D_Z \). Assume that \( G \) is a homeomorphism from \( \mathbb{R}^n \) to itself. Assume that data-generating manifold satisfies the conditions of the Theorem 1 and let \( \lambda^* \) be the threshold value that \( L_{\lambda^*}^X \) corresponds to that level.
set. Assume that for some \( j > 0 \), the homomorphism \( \iota^* \) induced by the inclusion \( \iota : M \to N_{\delta^*}(M) \) is injective. \(^4\)

If \( 0 < n_j \), \( L^X_{N_j} \) and \( L^{G(Z)}_{L^X_{N_j}} \) do not agree on the number of connected component.

**Proof.** Since \( L^X_{N_j} \) is the results of Theorem \(^1\) it includes \( M \) and is included by \( \delta^*\)-neighborhood \( N_{\delta^*}(M) \) of \( M \). Define inclusions \( \iota_1, \iota_2 \) as,

\[
\iota_1 : M \to L^X_{N_j}, \quad \iota_2 : L^X_{N_j} \to N_{\delta^*}(M)
\]

Clearly, \( \iota = \iota_2 \circ \iota_1 \).

Let \( \iota_1^* \) and \( \iota_2^* \) be induced homomorphisms of \( \iota_1 \) and \( \iota_2 \), resp.

By the assumption, any generator \([a]\) in \( H_j(M) \) is injectively mapped to a nonzero generator \( \iota^*([a]) \) in \( H_j(N_{\delta^*}(M)) \). Therefore, the \( j \)-th Betti number of \( N_{\delta^*}(M) \) is equal to that of \( M \), i.e. \( n_j \). Note that \( j \)-th Betti number is the rank of \( j \)-th homology group \( \text{rank}(H_j(N_{\delta^*}(M))) \). Because \( \iota_2^* \) is a homomorphism from \( H_j(L^X_{N_j}) \) to \( H_j(N_{\delta^*}(M)) \), \( \text{rank}(L^X_{N_j}) \geq \text{rank}(H_j(N_{\delta^*}(M))) \). Therefore the \( j \)-th Betti number of \( L^X_{N_j} \) is at least \( n_j \).

However, since \( D_Z \) is a mixture of Gaussians, for any value of \( \lambda \) (including the special case \( \lambda = \lambda^* \)), \( L^X_{N_j} \) does not have any generator of \( j \)-th homology group, so it has \( j \)-th Betti number 0 for all \( j > 0 \). Since \( G \) is homeomorphic, it preserves all the Betti numbers, thus \( L^{G(Z)}_{L^X_{N_j}} = G(L^X_{N_j}) \) has the same \( j \)-th Betti number. As \( 0 < n_j \), \( L^X_{N_j} \) and \( L^{G(Z)}_{L^X_{N_j}} \) can never agree on the number of connected components.

Later in Section \(^5.2\) we will see the Figure \(^3\) from the circles dataset, which is a remarkable example that \( L^{G(Z)}_{L^X_{N_j}} \) has the same number of connected components, but does not have any loop (non-contractible circle). This is empirical evidence of the Theorem \(^4\) so it is explained by mismatches in the topology of distributions. Each concentric circle has \( Z \) as its first homology group as circle contains exactly one generator. However, latent vector distribution always has a trivial first homology group, as any level set of a mixture of Gaussians is a set of contractible connected components.

### E DETAILS OF EXPERIMENTS IN THE SECTION \(^5\)

**Latent vector distributions.** For latent vector distributions \( D_Z \), we prepared three different mixtures of \( n_Z \) Gaussian distributions along \( \{1, 2, 3\} \). When \( n_Z = 1 \), we simply use \( N(0, I_2) \). When \( n_Z = 2, 3 \), we arranged \( n_Z \) Gaussian distributions along a circle of radius \( R = 2.5 \), so that \( i \)-th Gaussian has mean at \( \mu_i = (R \sin(\pi \frac{i}{n}), R \cos(\pi \frac{i}{n})) \) with \( \sigma = 0.5 \) for \( n = 2 \) and \( \sigma = 0.3 \) for \( n = 3 \). Then, the uniform mixture of the arranged Gaussian were used as \( D_Z \).

**Training generative models.** Our experiments mostly use the Tensorflow Probability (Dillon et al., 2017) library which contains the implementation of reversible generative models. Especially, the Tensorflow Probability library contains an implementation of the Real NVP coupling layer that we used as the building blocks of our models. The default template provided by Tensorflow Probability library was used to construct each Real NVP coupling layer with two hidden layers of 128 units. Each model uses eight coupling layers that are followed by permutation exchanging two dimensions of \( \mathbb{R}^2 \) except for the last coupling layer.

We describe the details of the training procedure of the generative models used in Section \(^5\). In Section \(^5\) we prepared two different types of generative models: topology-ignorant and topology-aware.

The **topology-ignorant** type is the usual Real NVP model. This model uses the empirical estimation of log-likelihood as over a training batch \( \{x_1, \ldots, x_m\} \) as its training loss.

\[
\ell_o = \frac{1}{m} \sum_{i=1}^{m} \log(p_X(x_i))
\]

\(^4\)Any generator of the \( j \)-th homology group \( H_j(M) \) of \( M \) is mapped to a nonzero generators of the \( j \)-th homology group \( H_j(N_{\delta^*}(M)) \) of \( \delta^*\)-neighborhood of \( M \).
where \( p_X \) is estimated by applying the change of variables formula – equation (2) in Section 3.3.

The topology-aware type is the Real NVP model trained with information about the number of connected components, i.e. the number of class labels \( l \). Using the number of labels, the densities \( p_X \) and \( p_Z \) can be decomposed as follows.

\[
p_X(x) = \sum_{i \in \{1,...,l\}} \Pr[y = i] p_{X,i}(x)
\]
\[
p_Z(z) = \sum_{i \in \{1,...,l\}} \Pr[y = i] p_{Z,i}(z)
\]

(11)

where \( p_{X,i}(x) = p_X(x | y = i) \) and each \( p_{Z,i} \) is the \( i \)-th Gaussian component described in Section 5.1. Since \( \Pr[y = i] \) is not generally known, the uniform distribution \( \Pr[y = i] = \frac{1}{l} \) is used, where \( l \) is the number of classification labels.

The main idea is class-wise training, i.e. training each \( p_{X,i} \) from each \( p_{Z,i} \). Applying the change of variable formula for each class \( i \),

\[
p_{X,i}(x) = p_{Z,i}(z) \left| \det \left( \frac{\partial G(z)}{\partial z^T} \right) \right|^{-1}
\]

(12)

Combining equations (11) and (12), we get the change of variable formula (2), so this approach works as a reversible generative model allowing the density computation.

We define the class-wise loss function \( \ell_i \) for class-wise training as follows.

\[
\ell_i = \frac{1}{m_i} \sum_{t=1}^{m_i} \mathbb{I}[y_t = i] \log(p_{X,i}(x_t))
\]

where \( m_i \) is the number of training samples in class \( i \). Then, we train a generative model using the weighted sum of \( \ell_i \) as the training loss function.

\[
\ell_{\text{ex}} = \sum_{i \in \{1,...,l\}} \Pr[y = i] \ell_i
\]

Each model was trained for 30000 epoch. For each epoch, a batch of 200 random samples was chosen from two-moons and circles dataset, and a batch of 300 random samples was chosen from the spirals dataset. For the choices of latent vector distribution, we chose the mixture of \( l - 1 \) Gaussians for topology-ignorant type, whereas we chose the mixture of \( l \) Gaussians for topology-aware type.

**INC implementation.** When INC is implemented with a reversible generative model \( G \), for any given \( \hat{x} \in \mathbb{R}^n \) there exist a trivial solution \( z^* = G^{-1}(\hat{x}) \) to the optimization (4), achieving \( d(G(z^*), x) = 0 \). This is even true for \( \hat{x} \) out of the manifold, resulting in the situation that the output \( x^* = G(z^*) = \hat{x} \) is still out of the data-generating manifold.

To manage this problem, we add another term penalizing a low density of latent vector to the objective function. Thus, in our INC implementation, we solve the following optimization problem.

\[
x^* = G(z^*) \text{ where } z^* = \arg \min_{z \sim p_z} [d(G(z), \hat{x}) + \alpha(M - p_Z(z))]
\]

(13)

where \( \alpha \) is the regularization factor and \( M \) is the maximum possible value of the density \( p_Z \) of the latent vector distribution. For the choice of regularization factor, we used the same value \( \alpha = 1 \) during the entire experiments.

To solve each optimization problem, we used the built-in adam optimizer (Kingma & Ba 2014) in Tensorflow package, 100 iteration using learning rate 0.01 with random sampling of \( z \).

When implementing INC using a topology-aware generative model, we used the following strategy to improve its robustness.

- As topology-aware generative model generates each manifold from each Gaussian component, we first sample initial points from each manifold by randomly choosing latent vectors \( z_1, \ldots, z_t \) from each Gaussian component.
We run INC for \( i \)-th manifold by solving the following optimization.

\[
x^*_i = G(z^*_i) \text{ where } z^*_i = \arg\min_{z \sim D_Z} [d(G(z), \hat{x}) + \alpha(M_i - p_{Z,i}(z))]
\]

where \( M_i \) is the maximum value of \( i \)-th Gaussian component. The regularization term is designed to penalize \( z \) that is unlikely to be generated by \( i \)-th Gaussian component, so we only search in the range of \( i \)-th Gaussian component, i.e. \( i \)-th manifold.

Choose the final solution \( x^*_i \) achieving the minimum \( d(x^*_i, \hat{x}) \), breaking ties randomly.

Since each search is performed only on each submanifold, the artifact observed in 5.3 never appears during the optimization process. Also, choosing initial points from each manifold prevents the bad initialization problem mentioned in 5.3.

### F MORE EXPERIMENTAL RESULTS

We present more experimental results about the INC performance comparing topology-aware generative model to its topology-ignorant counterpart.

**Histogram for projection error distributions in 5.4.** Figure 6 presents the histogram of the projection errors distributed from 0 to the diameter of the distribution. Each row corresponds to each dataset, whereas the first column and the second column represent the results from the topology-ignorant model and the topology-aware model, respectively. All histograms are normalized so that the sum of values adds up to 1. To explain, the \( y \)-axis of each histogram is the estimated probability that INC achieves the projection error on the \( x \)-axis. Not only that we can observe the improved mean of projection errors in the histograms, but we can also check the reduced standard deviation, i.e. we get more consistent projection errors near the mean.

**Additional experiments for the INC performance.** Finally, we present experiments to demonstrate the effect of the level set discrepancy on the INC performance. First, we begin with training support vector machines (SVMs) performing classification tasks for our target distributions. For training data, we randomly sampled 1000 training points from each data-generating manifold. The baseline SVMs were intentionally ill-trained, by using high kernel coefficient \( \gamma = 100 \).

After training SVMs, we form other classifiers by applying INC to ill-trained SVMs. To explain, for each dataset, we have four types of classifiers as follows.

1. Ill-trained SVM: Baseline classifier
2. Ideal INC: Classifier with INC with direct access to the data-generating manifolds
3. topology-ignorant INC: Classifier with INC with data distribution approximated by a topology-ignorant generative model
4. topology-aware INC: Classifier with INC with data distribution approximated by a topology-aware generative model

We want to emphasize that direct access to the data-generating manifold is not possible in general. However, applying INC based on such direct access gives us an INC purely based on the geometry, so it is an ideal form of INC that should be approximated. Also, since topology-ignorant is affected by a bad choice of an initial point, we reduce the effect of bad initialization by sampling more initial points and taking the best solution among the projection results. For this number of initial choices, we chose initial points as many as the number of manifolds, which is exactly the same as the number of initial points for the topology-aware INC model.

To demonstrate the improvement in the robustness of the model, we visualize the effect by depicting the decision boundary of each classifier. To be specific, we form a \( 300 \times 300 \) grid on the domain of \([-3, 3] \times [-3, 3]\), then compute the result of classification. The depicted decision boundaries are presented in Figure 7. Each row corresponds to each dataset: two moons, spirals, and circles, respectively. Each column corresponds to classifier 1-4 described above, from the first column to the fourth column, respectively. From Figure 7, it is visually evident that topology-aware INC models provide more proper approximations to the ideal INC model.

In general, choosing unnecessarily high kernel coefficient \( \gamma \) causes overfitting (Chaudhuri et al., 2017), inducing decision boundary close to the training data.
Figure 6: Histograms of the projection errors of INC. Each $y$-axis represents the estimated probability that INC incurs the projection error on the corresponding $x$-axis.
Figure 7: Changes in the decision boundaries of ill-trained SVM after INC applications.
