The $d$-wave pairing correlations along with spin correlation are calculated with quantum Monte Carlo method for the two-dimensional Hubbard model on lattice structures representing organic superconductors $\kappa$-(BEDT-TTF)$_2$X and (TMTSF)$_2$X. In both cases the pairing correlations for superconducting order parameters with nodes are found to be enhanced. The symmetry and the enhancement of the pairing is systematically correlated with the spin structure factor, suggesting a spin-fluctuation mediated pairing. We have further found that, as we deform the Fermi surface to make the system approach the half-filled square lattice, the coherence of the pairing saturates while the local pairing amplitude continues to increase.

PACS numbers: 74.20.Mn, 74.70.Kn

It is a great theoretical challenge to explore whether the superconductivity in ‘exotic materials’ such as the cuprates, heavy fermion systems, and (at least some) organic conductors can be encompassed into a single class, i.e., superconductivity mediated by spin-fluctuations. For more than a decade, the possibility of spin-fluctuation-mediated pairings has in fact been investigated intensively both theoretically and experimentally for heavy fermion systems [1] and high $T_C$ cuprates. [2] There, one important sign of spin-fluctuation-mediated pairing has been the superconducting gap with nodes.

There is now a body of accumulating experimental evidence that organic superconductors $\kappa$-(BEDT-TTF)$_2$X [3] and (TMTSF)$_2$X [4] also have non-$s$-wave gap like in heavy fermion or cuprate systems. The unconventional pairing, along with the proximity of superconductivity to antiferromagnetic or spin density wave state, suggest that pairing may be mediated by spin-fluctuation. The pseudogap-like behavior of $1/(T_1T)$ above $T_C$ in $\kappa$-(BEDT-TTF)$_2$X [3,11,12] is also reminiscent of a similar behavior in the underdoped high $T_C$ cuprates, which would suggest that electron correlation may play an important role there. [11]

Theoretically, a simplest many-body Hamiltonian to incorporate the electron correlation is the Hubbard model. Some analytical calculations have supported spin-fluctuation mediated pairing in the Hubbard model on lattices representing $\kappa$-(BEDT-TTF)$_2$X [12–16] or (TMTSF)$_2$X [17]. However, numerical evidences supporting such a possibility have yet to come.

Thus the purpose of the present paper is to explore numerically the pairing correlation in the Hubbard model for lattices representing $\kappa$-(BEDT-TTF)$_2$X and (TMTSF)$_2$X, with a special attention payed to whether the pairing is linked with the behavior of the spin correlation. Comparing the results for the two cases, we find that the symmetry of the pairing is indeed determined by the the peak position of the spin structure factor, which supports spin-fluctuation mediated pairing. We further deform the Fermi surface from the case corresponding to $\kappa$-(BEDT-TTF)$_2$X to find that the coherence of pairs saturates as the system approaches the half-filled square lattice (i.e., where, at least for large enough $U$, the system becomes a Mott insulator with antiferromagnetic order). Here we adopt the ground-state, canonical-ensemble quantum Monte Carlo (QMC) method.

We start from the Hubbard model on a two-dimensional lattice (Fig.1),

$$
\mathcal{H} = - \sum_{x,y,\sigma} \left[ t_x (c_{x,y,\sigma}^\dagger c_{x+1,y,\sigma}) + t_y (c_{x,y,\sigma}^\dagger c_{x,y+1,\sigma}) + t'_x (c_{x,y,\sigma}^\dagger c_{x+1,y+1,\sigma}) + t'_y (c_{x,y,\sigma}^\dagger c_{x-1,y+1,\sigma}) + \text{h.c.} \right]
+ U \sum_{x,y} n_{x,y,\uparrow} n_{x,y,\downarrow}.
$$

Here, $(x, y)$ is the coordinate of a site with the lattice constant taken to be unity, and periodic boundary condition is assumed.

While QMC method has been widely used to investigate the Hubbard model on the 2D square lattice, enhanced pairing correlation had eluded detection. Recently, however, the present authors identified this as...
coming form the fact that the pair-scattering processes that produce superconductivity has a very small energy scale of $O(0.01t)$ or less \cite{18,19}: if one takes a closed shell condition (a parameter set with no ground state degeneracy for $U = 0$), the energy gap between the highest occupied levels (HOLs) and the lowest unoccupied levels (LULs) for $U = 0$ is as large as $\sim O(0.1t)$ for tractable system sizes, so that the effect of the low energy pair scatterings would be smeared out. On the other hand, QMC calculations with an open-shell condition, in which the effect of low-energy pair scatterings is expected to be incorporated, suffer from numerical difficulties such as the negative-sign problem. An open-shell configuration is ill-conditioned also in the sense that there are a finite number of levels within an infinitesimal distance from the Fermi energy, so that one can suspect an enhancement of pairing correlations, if any, may be due to such an effect.

We have circumvented the problem by taking slightly different values of $t_x$ and $t_y$ to lift the degeneracy between wave numbers ($k_1, k_2$) and ($k_2, k_1$), and put the Fermi level in between those levels. This way we can prevent the low-energy pair scattering processes from being masked and at the same time take a closed shell configuration. If we take typically $t_y/t_x = 0.999$, which gives HOL-LUL gap $\Delta$ of $< 0.01t$, and $U/t = 1$, we can achieve convergence with respect to the projection imaginary time $\tau$ in the QMC without running into serious sign problem. \cite{20}

We calculate the pairing correlation functions,

$$P(r) = \sum_{|\Delta x|+|\Delta y|=r} \langle O^\dagger(x + \Delta x, y + \Delta y)O(x, y) + O(x + \Delta x, y + \Delta y)O^\dagger(x, y) \rangle$$

with

$$O(x, y) = \sum_{\delta_x, \delta_y, \sigma} \sigma(c_{x,y,\sigma}c_{x+\delta_x,y-\sigma} - c_{x,y,\sigma}c_{x+\delta_y,y-\sigma}),$$

which includes the conventional $d_{x^2-y^2}$ symmetry (with $\delta_x = \delta_y = 1$, corresponding to the order parameter proportional to $f(k) \equiv \cos(k_x) - \cos(k_y)$ in $k$-space), but written here in a general form. Hereafter we define $r \equiv |\Delta x| + |\Delta y|$ as the real space distance. To give an above-mentioned insight, we also calculate the spin structure factor,

$$S(q) = \frac{1}{N} \sum_{i,j} e^{iq \cdot (r_i-r_j)} \langle S_i \cdot S_j \rangle.$$  

We first look into the case where the Fermi surface, represented by HOLs and LULs, resembles those of $\kappa$-(BEDT-TTF)$_2$X materials. It has been proposed that $\kappa$-(BEDT-TTF)$_2$X can be modeled by a single band Hamiltonian on an anisotropic triangular lattice with $t_x = t_y > t'_x \gg t'_y$ and $n = 1$ (half-filled). \cite{21,22} This is because (i) the dimerization of the BEDT-TTF molecules is so strong that we can consider a dimer as a single site as far as the low-energy excitations are concerned, and (ii) the hopping parameter in the $c$ direction alternates between two slightly different values, but the difference is small enough to be neglected as a first approximation.

First we take 134 electrons in a $12 \times 12$ (band filling $n = 0.93$) lattice with $t_x = 1$, $t_y = 0.999$, $t'_x = 0.70$, $t'_y = -0.11$. We have taken $t_y = 0.999$ for the slight lift of degeneracy mentioned above. The reason for taking small but negative $t'_y$ and the slight deviation from $n = 1$
local amplitude of pairing, $p$ fixed around unity. Due to technical reasons. Namely, we are going from the noninteracting case) summed over large distances ($Q \approx (0,0)$) for various values of the band filling $n$. In Fig. 3, a broad peak around $(\pi, \pi)$ is seen. Such an antiferromagnetic spin-fluctuation enhances repulsive (in momentum-space) pair scattering processes with momentum transfer $(\pi, \pi)$. Repulsive pair scattering processes from $\sim \pm (0, \pi)$ to $\sim \pm (\pi, 0)$ (and vice versa) favor a superconducting order parameter that takes the maximum of its absolute value with different signs around these two areas. Thus, the enhancement of the $d_{x^2-y^2}$ pairing correlation along with the peak of $S(Q)$ at $(\pi, \pi)$ are consistent with the spin-fluctuation mediated pairing.

We have further investigated the link between $d_{x^2-y^2}$ pairing correlation and the spin correlation systematically by deforming the Fermi surface. In Fig. 4, the enhancement of the pairing correlation is plotted against $S(Q)$ with $Q = (\pi, \pi)$ for three cases I, II, and III. The main difference among the three cases is in the value of $t_0$ as given in the caption, while other slight differences are due to technical reasons. Namely, we are going from the isotropic triangular lattice (I) to a case close the square lattice (II) via case (II) (corresponding to Fig. 3) for $n$ fixed around unity. $S(Q)$ increases as we approach the half-filled square lattice. In Fig. 5, the pairing is probed from two quantities: the pairing correlation (measured from the noninteracting case) summed over large distances, $p_{LR} \equiv \sum_{r \geq 4} \{[P_d(r)]_{U=1} - [P_d(r)]_{U=0}\}$, and the local amplitude of pairing, $p_0 \equiv [P_d(0)]_{U=1} - [P_d(0)]_{U=0}$.

Fig. 3 shows that $p_0$ grows hand in hand with $S(Q)$, endorsing the spin-fluctuation-mediated formation of $d_{x^2-y^2}$ pairs. On the other hand, $p_{LR}$, the enhancement of the long-range part of $P_d(r)$, which measures the coherence of the pairs, also grows with $S(Q)$ as we go from (I) to (II), but it saturates between (II) and (III), suggesting that the coherence does not necessarily grow with the local pair amplitude.

To show that such a correlation between the $d$-wave pairing and the spin correlations is not accidental for the cases studied above, we move on to the square lattice ($t_y = t_x = 0$) for various values of the band filling $n$. In Fig. 4, we show a plot similar to Fig. 3 for the square lattice, along with the plot against $n$ in the inset. For intermediate densities, $p_{LR}$, $p_0$, and $S(Q)$ all grow as $n$ approaches the half-filling ($n = 1$). If we come too close to half-filling, however, $p_{LR}$ becomes saturated, while $S(Q)$ and $p_0$ keeps growing. This is even more clearly seen at exactly half-filling, where $p_{LR}$ is strongly suppressed (inset of Fig. 3), while $p_0$ continues to grow. The result that, when $S(Q)$ becomes too large, the pairs are formed but their coherence ($p_{LR}$) stops to grow unlikely their local amplitude $p_0$ might have some relevance to the normal-state pseudogap behavior observed close to the superconducting-antiferromagnetic boundary in $ \kappa$-(BEDT-TTF)$_2$X as well as in the underdoped high $T_C$ cuprates.
In order to confirm spin-fluctuation mediated pairing to a wider extent, we next explore the case where the spin structure factor is not peaked around \((\pi, \pi)\), by studying the case with a Fermi surface representing \((\text{TMTSF})_2X\). If we neglect the weak dimerization along the stacking direction, these materials may be modeled by a single band Hamiltonian on a strongly anisotropic two-dimensional lattice with \(t_x/t_y \sim O(0.1)\) \((t_x' = t_y' = 0)\) and \(n = 0.5\) (quarter-filled). \[17\] Here we take 72 particles in \(12 \times 12\) \((n = 0.5)\), \(t_x = 1\), and \(t_y = 0.212\), for which the Fermi surface is as depicted in the lower inset of Fig.6(a).

For this Fermi surface consisting of warped parallel lines around \(k_x \pm \pi/4\), the nesting vector is \((\pi/2, \pi)\), so that the spin structure factor (lower inset of Fig.6(b)) has a peak there. \[23\] Then, pair scattering processes from \(\sim \pm (0, \pi)\) to \(\sim \pm (\pi/2, 0)\) (and vice versa) would be enhanced, which favors a superconducting order parameter proportional to \(f(k) = \cos(2k_x) - \cos(k_y)\) \((\delta_x = 2, \delta_y = 1\) in Eq.\[2\]) rather than the ordinary \(d_{x^2-y^2}\) pairing with \(f(k) = \cos(k_x) - \cos(k_y)\). In fact, the possibility of such a pairing was pointed out in an RPA calculation. \[17\]

In Fig.6 we can see that the pairing correlation for \(f(k) = \cos(2k_x) - \cos(k_y)\) is indeed enhanced, while \(d_{x^2-y^2}\) pairing correlation is not. The result provides another indication that the pairing symmetry is dictated by the dominant spin-fluctuation.

In order to confirm spin-fluctuation mediated pairing to a wider extent, we next explore the case where the spin structure factor is not peaked around \((\pi, \pi)\), by studying the case with a Fermi surface representing \((\text{TMTSF})_2X\). If we neglect the weak dimerization along the stacking direction, these materials may be modeled by a single band Hamiltonian on a strongly anisotropic two-dimensional lattice with \(t_x/t_y \sim O(0.1)\) \((t_x' = t_y' = 0)\) and \(n = 0.5\) (quarter-filled). \[17\] Here we take 72 particles in \(12 \times 12\) \((n = 0.5)\), \(t_x = 1\), and \(t_y = 0.212\), for which the Fermi surface is as depicted in the lower inset of Fig.6(a).

For this Fermi surface consisting of warped parallel lines around \(k_x \pm \pi/4\), the nesting vector is \((\pi/2, \pi)\), so that the spin structure factor (lower inset of Fig.6(b)) has a peak there. \[23\] Then, pair scattering processes from \(\sim \pm (0, \pi)\) to \(\sim \pm (\pi/2, 0)\) (and vice versa) would be enhanced, which favors a superconducting order parameter proportional to \(f(k) = \cos(2k_x) - \cos(k_y)\) \((\delta_x = 2, \delta_y = 1\) in Eq.\[2\]) rather than the ordinary \(d_{x^2-y^2}\) pairing with \(f(k) = \cos(k_x) - \cos(k_y)\). In fact, the possibility of such a pairing was pointed out in an RPA calculation. \[17\]

In Fig.6 we can see that the pairing correlation for \(f(k) = \cos(2k_x) - \cos(k_y)\) is indeed enhanced, while \(d_{x^2-y^2}\) pairing correlation is not. The result provides another indication that the pairing symmetry is dictated by the dominant spin-fluctuation.

To summarize, the present result supports the spin-fluctuation mediated anisotropic pairing scenario in organic superconductors, by the same token as in the high \(T_C\) cuprates discussed in \[18\]-\[19\]. The enhancement of the local pair amplitude grows with \(S(Q)\), while the off-diagonal long-range order \((\mu_{LR})\) stops to do so as the system approaches half-filled square lattice. It is an interesting future problem whether this is caused by the magnetic ordering or the metal-insulator transition, which is difficult to discern at present, since both of them occur at half-filled square lattice (at least for sufficiently large \(U\)). The possibility of the triplet pairing proposed in ref. \[14\] also poses an intriguing issue.

Numerical calculations were performed at the Supercomputer Center, Institute for Solid State Physics, University of Tokyo, and at the Computer Center of the University of Tokyo. K.K. acknowledges support by the Grant-in-Aid for Scientific Research from the Ministry of Education of Japan.

[25] Experimentally the spin density wave in (TMTSF)$_2$X is shown to be incommensurate in the $y$-direction (T. Takahashi et al, J. Phys. Soc. Jpn. 55, 1364 (1986)). In the present context, this is related to the fact that the peak of $S(q)$ around $(\pi/2, \pi)$ is broader in the $y$-direction (see the inset of Fig.6(b)), so that a small perturbation may change the spin structure in that direction. Even so, the conclusion that the electrons in a pair is separated by two lattice spacings in the $x$-direction should not be affected.
