A two-component model
for $\gamma^*$-p scattering
at small Bjorken $x$

Abstract

We extend the Golec-Biernat-Wüsthoff model for virtual photon -
proton scattering to include the resolved photon component explicitly.
The parameters of the resolved photon component are taken from the
literature, while the parameters of the dipole-nucleon interaction are
fitted to the HERA data in a selected limited range of $x$ and $Q^2$. A
good agreement with experimental data is obtained far beyond the
region of the fit.

1 Introduction

The recent decade of investigating deep inelastic scattering at very small
Bjorken $x$ at HERA has provided precise data for the $F_2$ structure function
or equivalently for $\sigma^\gamma_{tot}$ at large center-of-mass energies. Many phenomeno-
logical analyses have been performed in order to fit the data. The theoretical
analyses can be divided into two general classes. One group of models tries
to fit the data using the so-called dipole representation. In this approach,
initiated by Nikolaev and Zakharov $^1$, one fits parameters of the dipole-
nucleon interaction $^2$ $^3$ $^4$ as a function of the transverse quark-antiquark
distance. Another group of models uses rather the momentum representa-
tion $^5$ $^6$ $^7$. Still another approach $^8$ tries to fit the so-called unintegrated
gluon distributions to the HERA data (see also $^9$).

The fits in the dipole representation take into account only a simple quark-
antiquark Fock component of the photon. However, the higher Fock com-
ponents seem to be important to understand the diffraction $^{10}$ in detail. The
importance of the higher Fock states is at present not fully understood.
The first theoretical step in going beyond the $q\bar{q}$ component has been un-
dertaken only recently $^{11}$. However, no quantitative estimates exist up to
now. Only a very schematic QCD-inspired model was considered in Ref. [14]. On the phenomenological side, the jet production in virtual-photon-proton scattering, especially at small photon virtuality, shows clearly the presence of the resolved photon component (see e.g. [15]) which seems impossible to be explained with the quark-antiquark component only. The ratio of the dijet cross section with $x_{\gamma}^{OBS} < 0.75$ (resolved component) to that with $x_{\gamma}^{OBS} > 0.75$ (direct component) has been found to increase as $Q^2$ decreases. The variable $x_{\gamma}^{OBS}$ is to be interpreted as the fractional momentum of the photon taking part in the dijet production. At large photon virtuality the resolved photon component disappears. The observed $Q^2$ dependence of the resolved photon component is roughly consistent with the naive VDM form factor [11]. The present NLO calculations of jet and dijet production include these phenomenological form factors when going from real to virtual photons (see e.g. [16]). Such a phenomenological factor is then prescribed to the structure of virtual photon, and more precisely to the parton distributions in the virtual photon. The resolved photon component seems also crucial for understanding the world data for the $F_2^p(x, Q^2) - F_2^n(x, Q^2)$ [9]. All these arguments put into question the simple fits to the total photon-nucleon cross section with the colour dipole component alone, and call for a multi-component parametrization.

In the light of the extremely successful phenomenological description in Ref. [2] it is interesting to see if any phenomenological two-component model can do a better job. It is the aim of this note to analyze phenomenologically if such a two-component model can satisfactorily describe the HERA data for the photon-proton total cross section. In our exploratory analysis, the higher Fock components are parametrized by the standard vector dominance cross section, i.e. our model is similar in spirit to the Badelek-Kwiecinski model [18].

2 Formulation of the model

It is known that the LO total $\gamma^*N$ cross section in the so-called dipole or mixed representation can be written in the form

$$\sigma_{\gamma^*N}^{\text{tot}} = \sum_q \int dz \int d^2 \rho \sigma_{T,L} |\Psi^{T,L}_{\gamma^*\rightarrow q\bar{q}}(Q,z,\rho)|^2 \cdot \sigma_{(q\bar{q})N}(x,\rho).$$

(1)

In this paper we take the so-called quark-antiquark photon wave function of perturbative form [11]. As usual, in order to correct the photon wave function for large dipole sizes (nonperturbative region) we introduce an effective quark/antiquark mass ($m_{\text{eff}} = m_0$).
The dipole representation \(^{(1)}\) has been used in recent years to fit the virtual photon - nucleon total cross section \(^{(2, 3)}\). The best fit has been achieved in the saturation model of Golec-Biernat-Wüsthoff \(^{(2)}\). In their approach the dipole-nucleon cross section was parametrized as

\[
\sigma(x, \rho) = \sigma_0 \left[ 1 - \exp \left( -\frac{\rho^2}{4R_0^2(x)} \right) \right],
\]

(2)

where the Bjorken \(x\) dependent radius \(R_0\) is given by

\[
R_0(x) = \frac{1}{1\text{GeV}} \left( \frac{x}{x_0} \right)^{\lambda/2}.
\]

(3)

Model parameters (normalization constant \(\sigma_0\) and parameters \(x_0\) and \(\lambda\)) have been determined by the fit to the inclusive data on \(F_2\) for \(x < 0.01\) \(^{(2)}\).

In the GBW approach, the dipole-nucleon cross section is parametrized as a function of Bjorken \(x\). As discussed in \(^{(19)}\), it would be useful to have rather a parametrization in the gluon longitudinal momentum fraction \(x_g \neq x\) instead of the Bjorken \(x\). Then one could use the unintegrated gluon distribution which is related to the dipole-nucleon cross section as

\[
\sigma(q\bar{q})_N(x_g, \rho) = \sigma(W, Q^2, z, \rho),
\]

(4)

Therefore, we find it more appropriate to parametrize the dipole-nucleon cross section as \(x_g\) instead of the Bjorken \(x\). This involves the following replacement in Eq.(2)

\[
\sigma(x, \rho) \rightarrow \sigma(x_g, \rho),
\]

(5)

which means also a replacement of \(x\) by \(x_g\) in Eq.(3). As discussed in \(^{(19)}\), an exact calculation of \(x_g\) in the dipole representation is, however, not possible, and we approximate \(x_g \rightarrow (M^2_{qq} + Q^2)/(W^2 + Q^2)\), where \(M^2_{qq} = m^2_q/(z(1-z))\) with \(m_q\) being effective quark mass \(m_q = m_0\) for \(u/\bar{u}\) and \(d/\bar{d}\) (anti)quarks and \(m_q = m_0 + 0.15\) GeV for \(s/\bar{s}\) (anti)quarks. This means that in our approach the dipole-nucleon cross section \(\sigma_{(q\bar{q})_N} = \sigma(W, Q^2, z, \rho)\). This must be contrasted to the approach of Ref.\(^{(2)}\), where there is no \(z\) dependence of \(\sigma_{(q\bar{q})_N}\).

Including higher Fock components of the (virtual) photon, one could write
somewhat schematically:

\[ \sigma_{\gamma^*N}^{tot} = \sum_q \int d\Omega_2 |\Psi_{\gamma^* \rightarrow q\bar{q}}(\omega_2)|^2 \cdot \sigma_{(q\bar{q})N}(\omega_2) \]

\[ + \sum_q \int d\Omega_3 |\Psi_{\gamma^* \rightarrow q\bar{q}g}(\omega_3)|^2 \cdot \sigma_{(q\bar{q}g)N}(\omega_3) \]

\[ + \ldots \ldots . \]  

(6)

The differentials above \( d\Omega_2 \) and \( d\Omega_3 \) represent phase space volumes for the \( q\bar{q} \) and \( q\bar{q}g \) components, respectively, and \( \omega_2, \omega_3 \) represent the corresponding sets of kinematical variables necessary to describe the relevant process. The second and all subsequent terms are of the type of a resolved photon. A rigorous approach to the problem is rather difficult \[13\] and has not been pursued numerically.

We shall not try to follow the theoretical path sketched above. Our aim here is somewhat different. We intend to construct a simple two-component model. One component of our phenomenological model is the dipole \( q\bar{q} \) component, while the other one is meant to represent the resolved photon explicitly. Trying to keep our model as simple as possible and inspired by the phenomenological results mentioned in the introduction, we wish to check if the standard vector dominance model (VDM) contribution can be a reasonable representation of the resolved photon. Our approach should not be understood as a replacement of the missing terms in Eq.(6). In our opinion, the VDM contribution under consideration contains nonperturbative terms which cannot be easily generated by the formal expansion \[6\]. However, as already mentioned in the introduction, in many exclusive processes the VDM contribution represents phenomenologically the resolved photon fairly well.

The cross section for the VDM component, equivalently called here the resolved photon component, is calculated in the standard way

\[ \sigma_{\gamma^*N}^{VDM} (W, Q^2) = \sum_V \frac{4\pi M_V^4 \sigma_{Vtot}^{VN}(W)}{\gamma_V^2 (Q^2 + M_V^2)^2} \cdot (1 - x) . \]

(7)

We take the simplest diagonal version of VDM with \( \rho, \omega \) and \( \phi \) mesons included. As discussed recently in \[20\], the contributions of higher vector states are expected to be damped. Above the meson-nucleon resonances it is reasonable to approximate

\[ \sigma_{tot}^{\rho N} = \sigma_{tot}^{\omega N} = \frac{1}{2} \left[ \sigma_{tot}^{\pi^+p} + \sigma_{tot}^{\pi^-p} \right] , \]

(8)

with a similar expression for \( \sigma_{tot}^{\phi p} \[22\]. A simple Regge parametrization of the experimental pion-nucleon cross section by Donnachie and Landshoff is
used \[21\]. As in \[22\], we take $\gamma$’s calculated from the leptonic decays of vector mesons, including finite-width corrections. The factor $(1-x)$ is meant to extend the VDM contribution towards larger Bjorken $x$.

\section{Fit to the HERA data}

In the previous section we presented formulae for the virtual photon - nucleon cross section. The relation between $\sigma_{tot}^{\gamma\gamma^*N}$ and $F_2$ is a matter of convention. In the so-called Hand convention one obtains

$$\sigma_{tot}^{\gamma\gamma^*N}(W,Q^2) = \frac{4\pi^2\alpha_{em}}{Q^2(1-x)} \left( 1 + \frac{4M_N^2x^2}{Q^2} \right) \cdot F_2(x,Q^2). \quad (9)$$

If the Gilman convention is used instead, then

$$\sigma_{tot}^{\gamma\gamma^*N}(W,Q^2) = \frac{4\pi^2\alpha_{em}}{Q^2} \sqrt{1 + \frac{4M_N^2x^2}{Q^2}} \cdot F_2(x,Q^2). \quad (10)$$

We transform the structure function data from \[26\] in the standard but approximate way \footnote{Both prescription (9) and (10) converge to the standard formula below in the limit of small $x$.}

$$\sigma_{tot}^{\gamma\gamma^*N}(W,Q^2) = \frac{4\pi^2\alpha_{em}}{Q^2} \cdot F_2(x,Q^2). \quad (11)$$

Then we perform two independent fits to the HERA data. In fit 1, only dipole nucleon interaction is included (see Eq.(11))

$$FIT1: \quad \sigma_{tot}^{\gamma\gamma^*N} = \sigma_{dip}^{\gamma\gamma^*N}. \quad (12)$$

In fit 2 in addition we include the resolved photon component in the spirit of the vector meson dominance model (see Eq.(7))

$$FIT2: \quad \sigma_{tot}^{\gamma\gamma^*N} = \sigma_{dip}^{\gamma\gamma^*N} + \sigma_{VDM}^{\gamma\gamma^*N}. \quad (13)$$

In these fits we limit to $0.15 \text{ GeV}^2 < Q^2 < 10 \text{ GeV}^2$. The upper limit is dictated by the simplicity of our model. It is known that at large photon virtualities one has to include QCD evolution \[24\], which is ignored in the present analysis for simplicity. The maximal Bjorken $x$ in the data sample included in our fit is 0.021, and minimal $W = 17.4$ GeV. With the selection criterion specified, we select 159 experimental data points.
Table 1: Compilation of fit parameters.

| fit        | $m_0$ (GeV) | $\sigma_0$ (mb) | $x_0$    | $\lambda$ | $\chi^2$ |
|------------|-------------|-----------------|----------|------------|----------|
| FIT1       |             |                 |          |            |          |
| dipole only| 0.10        | 17.0            | 9.50e-4  | 0.302      | 8.125    |

|            | 0.15       | 8.0             | 0.0194   | 0.3107     | 1.553    |
|            | 0.20       | 8.0             | 0.0198   | 0.3213     | 1.812    |
|            | 0.30       | 15.0            | 1.67e-3  | 0.250      | 1.412    |
|            | 0.40       | 24.0            | 2.20e-4  | 0.230      | 1.505    |
|            | 0.60       | 55.0            | 1.10e-5  | 0.230      | 4.632    |

In Table 1 we present the model parameters obtained from the fit. The region of small $Q^2$ is sensitive to the value of the effective quark mass. This nonperturbative parameter is related e.g. to the confinement and cannot be obtained from the first principles. Therefore, in the table we show results with different values of this parameter. From the fit we find $\sigma_0^{fit1} \gg \sigma_0^{fit2}$ for the same value of the effective quark mass. We have extended the range of effective quark masses in fit 2 (dipole+VDM). A good quality fit can be obtained in the broad range of $m_0$. The $\chi^2$ criterion by itself does not allow one to answer the question which set of parameters is better. The value of the $\chi^2$ per degree of freedom is shown in the last column. The value of $\chi^2$ in fit 2 (dipole+VDM) is much smaller than that in fit 1 (dipole only), which is not acceptable statistically. This can be taken as the evidence for resolved photon component.

In order to illustrate how well the model parameters can be determined from the fit to experimental data, in Fig 1 we show two-dimensional maps of $\chi^2$ in both cases. Here $m_0 = 0.15$ GeV and 0.20 GeV was taken for fit1 and fit2, respectively. Well defined minima are clearly seen. It can be seen from Table 1 and Fig 1 that the parameter $x_0$ changes dramatically when the VDM component is included, while $\lambda$ stays almost the same.

The quality of the fit can be judged by inspecting Figs 2 - 5. Since there is a rather weak dependence of the cross section on $W$, therefore in the figures showing $Q^2$ dependence both theoretical curves and experimental points are rescaled by an extra factor $2^n$, where $n$ counts the subsequent subsets of data of a given $W$ shown in Fig 3 and 5. Only the cross sections for the lowest energy chosen ($W = 18$ GeV) are left unchanged. By careful inspection of the figures one can see the superiority of the fit 2. In presenting the
results we have made an arbitrary choice of $m_0$. The results for other sets of parameters (different $m_0$) are almost indistinguishable in the range of the fit. They differ somewhat, however, outside the range of the fit where no experimental data are available. The theoretical curves with dipole component only underestimate somewhat the low $Q^2$ data. We wish to stress that the quality of our fit 1 is worse than that of the original saturation model of Golec-Biernat-Wüsthoff [2]. We conclude, therefore, that parameterizing the dipole-nucleon cross section as a function of the Bjorken $x$, instead of $x_g$, is essential for the good quality of the fit in Ref.[2].

Having shown that a good-quality two-component fit to the HERA data with very small number of parameters is possible, we wish to show a decomposition of the cross section into the two model components. In Fig.6 and Fig.7 we show separate contributions of both components as a function of $W$- and $Q^2$, respectively. While at low energy the VDM contribution dominates due to the subleading reggeon exchange, at higher energies they are of comparable size. The VDM contribution, being a higher twist effect, dominates at small values of photon virtualities. At larger $Q^2$ the dipole component becomes dominant. This effect is almost independent of energy.

Up to now we have concentrated on very low-$x$ region relevant for DIS at HERA. It is interesting to check what happens if we go to somewhat larger Bjorken $x$ or smaller energies $W$. In this region one cannot neglect the valence quark contribution to the cross section. Then the cross section is a sum of three components:

$$
\sigma_{\gamma^*N}(W, Q^2) = \sigma_{\gamma^*N}^{\text{dip}}(W, Q^2) + \sigma_{\gamma^*N}^{\text{VDM}}(W, Q^2) + \sigma_{\gamma^*N}^{\text{val}}(W, Q^2),
$$

where the last component is calculated according to Eq.(11) with

$$
F_2(x, Q^2) \to \tilde{F}_2(x, Q^2) = \frac{Q^2}{Q^2 + Q_0^2} \left( \frac{4}{9} x u_{\text{val}}(x, Q^2) + \frac{1}{9} x d_{\text{val}}(x, Q^2) \right).
$$

We freeze $Q^2$ below $Q^2_{\text{min}} = 0.25$ GeV. In the present calculation we take the leading order valence quark distributions from Ref.[25]. The $Q^2$-dependent factor in front of the r.h.s. of Eq.15 is necessary when extrapolating the quark contribution to the non-DIS, low-$Q^2$ region (see e.g. [22]). The parameter $Q_0^2 (=0.8$ GeV$^2$) is taken from a global analysis of the experimental data in [22]. In Fig. 8 we compare predictions of our two models (fits) also with fixed target data [27, 28]. The fixed target data are represented by solid symbols, while the HERA data by open circles. Formula (14) is used to calculate both experimental and theoretical $\sigma_{\gamma^*p}^{\text{tot}}$ cross sections. A better agreement is obtained with model 2 (dipole+VDM), especially at $Q^2 \sim 3 - 5$ GeV$^2$, i.e. for the NMC data. An overestimation of model 2 at small energies and small
photon virtualities may be caused by neglecting a form factor responsible for correcting the VDM contribution for finite times of hadronic fluctuations [22]. Summarizing, there is a phenomenological evidence for the presence of the resolved photon component from the analysis of experimental data for $F_2$ in consistency with exclusive reactions.

4 Conclusions

Recent fits to the total $\gamma^*p$ cross section in the literature include only the quark-antiquark component in the Fock decomposition of the photon wave function. The contribution of the higher Fock components, neglected so far, is not known and difficult to calculate consistently within quantum chromodynamics. The first trials to include the $q\bar{q}g$ Fock component within perturbative QCD have not be quantified in the literature. Nonperturbative effects, not easy to implement within the framework mentioned, can be also expected. It is known from the phenomenology of the exclusive reactions that the traditional vector dominance model in many cases gives a good estimate of the effects characteristic for resolved photon. In this note we have analyzed if a two-component model, which includes the $q\bar{q}$ component and the more complicated components replaced by the standard VDM, can provide a good description of the HERA data for $\gamma^*p$ scattering.

In order to quantify the effect of the resolved photon we have performed two different fits to the HERA data. In fit No.1 we include only the dipole component. Here we have used the flexible and successful parametrization of Golec-Biernat and Wüsthoff. In comparison to their fit, in our fit we parametrize the dipole-nucleon cross section in terms of a variable which is closer to the gluon longitudinal momentum fraction $x_g$ than to the Bjorken $x$. Such a fit is useful on its own, as the corresponding unintegrated gluon distribution can be used to estimate cross sections for many exclusive processes. In fit No.2, in addition we include the VDM component while keeping the same functional form of parametrization for the dipole-nucleon interaction. A better fit is obtained if the resolved photon component of the type of VDM is included. When going to slightly larger Bjorken $x$, the model must be supplemented for valence quark contribution. If this is done, the model describes also the fixed target data quite well. The two models give different predictions in the regions of the phase space where no experimental data are available.

Our phenomenological analysis is only a first step towards a better understanding of the role which the higher Fock components of the photon play in both inclusive and exclusive processes. The relation of the phenomenological
VDM contribution to the formal expansion discussed in the paper requires further study. A numerical calculation of higher-order pQCD effects is called for to start addressing this question quantitatively.

Acknowledgments We are indebted to Jan Kwieciński for a useful discussion, and Krzysztof Golec-Biernat for a discussion and files with experimental data.
