We explore a scheme for guiding cold atoms through a hollow Bessel beam generated by a single axicon and a lens from a 2D magneto-optical trap toward a science chamber. We compare the Bessel beam profiles measured along the optical axis to a numerical propagation of the beam’s wavefront, and we show how it is affected by diffraction during the passage through a long narrow funnel serving as a differential pumping tube between the chambers. We derive an approximate analytic expression for the intensity distribution of the Bessel beam and the dipolar optical force acting on the atoms. By a Monte-Carlo simulation based on a stochastic Runge-Kutta algorithm of the motion of atoms initially prepared at a given temperature we show that a considerable enhancement of the transfer efficiency can be expected in the presence of a sufficiently intense Bessel beam.

1 Introduction

Experiments with ultracold atoms are conditioned to the availability of an extreme ultra-high vacuum (XUHV) environment. This entailed the development of a variety of techniques allowing for a physical separation of a science chamber, maintained at pressures as low as $10^{-11}$ mbar or below, and a preparation chamber. In the preparation chamber the atomic gas is provided by heating a solid chunk of a specific element (in many cases alkaline or alkaline-earth metals) to temperatures sufficiently high to reach noticeable partial pressures of typically above $10^{-9}$ mbar. A long narrow pipe connects both chambers and maintains a differential vacuum. The most common techniques for transferring the atoms between the chambers are the Zeeman slower [3, 31, 37], the double magneto-optical trap (MOT) [31, 36], the 2D-MOT [13], and different types of conveyor belt techniques [7, 16, 21].

The transfer of atoms is always subject to atomic losses due to atoms escaping from the beam. Some experiments resort to funneling the atoms through quadrupolar or hexapolar magnetic waveguides [31, 36, 39, 40, 42, 43], which however only works for atoms that are paramagnetic in their ground state. In this paper, we study the idea of guiding atoms through a hollow Bessel beam (BB) over a distance of 23 cm, from a 2D-MOT created in a preparation chamber, through a 20 mm long and 2 mm wide differential vacuum tube, to a distant 3D-MOT operated in a science chamber. If the frequency of the BB is tuned to the blue of an atomic resonance, the repulsive force exerted on the atoms by the dipolar optical potential will keep the atoms away from the walls of the tube.

Hollow beams in free space, such as Laguerre-Gaussian beams or BBs have been proposed for guiding or trapping atoms [1, 14, 15, 17, 24, 26, 29, 33, 39, 40, 42, 43]. In some cases atoms were guided through the hollow core of a light-carrying optical fiber [9, 33, 35]. For instance, Song et al. [40] prepared a cloud of 100 μK cold cesium atoms from a MOT directly inside the hollow beam tuned 0.25–1.5 GHz to the blue of the Cs cooling transition. They observed acceleration and heating of the atoms due to residual Rayleigh scattering. Xinye Xu et al. [43] demonstrated a 20-fold increase of the transport efficiency of atomic rubidium over a 10 cm long distance through the hollow beam produced by a hollow-core optical fiber in good agreement with Fokker-Planck simulations. And Carrat et al. [11] meticulously characterized the channeling of cold rubidium atoms prepared in a 2D-MOT through a Laguerre-Gauss beam generated by a spatial light modulator. Most experiments rely on Laguerre-Gaussian laser beams, which are easy to produce and stay hollow over very long distances. In this paper we propose and analyze a scheme for guiding a precooled cloud of strontium-88 atoms from a preparation chamber through a narrow funnel into a science chamber via a hollow BB.

Bessel beams are characterized by extremely localized tube-like intensity distribution walls, giving rise to very deep dipolar potentials for atoms. On the other hand, they maintain their shape only over limited distances.

The paper is organized in two main parts: First, we propose a geometry of optical components for creating a hollow BB using a single axicon and a lens. Numerically simulating the evolution of the intensity distribution along the optical axis and mapping it out experimentally, we find that the hollow BB stays diffraction-free over a distance of more than 20 cm. Second we present an analytical approximation of the intensity distribution, which will turn out to be useful for the Monte-Carlo simulations of atomic trajectories presented in the second part of the paper.

2 Bessel beams

Ideally, a BB is a non-diffracting monochromatic solution to the scalar wave equation in cylindrical coordinates carrying an infinite amount of energy [14, 27]. In its simplest form, the electric field of an arbitrary $\nu$-th order BB with wavelength $\lambda$ can be written as,

$$E(\rho, \phi, z) = A_0 \exp(ik_0 z) J_\nu(k_0 \rho) \exp(i\nu \phi),$$

(1)
fying the dispersion relation \( k \) order Bessel function of the first kind. In Eq. (1), \( \alpha \) is the longitudinal and transverse wave numbers satisfying the dispersion relation \( k^2 = k_z^2 + k_\rho^2 = (2\pi/\lambda)^2 \), such that \( k_z = k \cos \theta \) and \( k_\rho = k \sin \theta \), being \( \theta \) the axicon angle associated to the tilted plane of waves propagating along the surface of a cone of half-angle \( \theta \) in the angular spectrum decomposition. Cylindrical coordinates \((\rho, \phi, z)\) have been adopted, and a time harmonic factor \( \exp(-i\omega t) \) has been omitted for brevity. For our purposes, the Rayleigh range is an essential parameter to be considered since the non-diffracting beam must propagate through a 20 cm long differential vacuum tube to minimize losses of atoms during their guidance to the science chamber. The maximum propagation distance up to which a BB can overcome diffraction is given by \( z_{\text{max}} = 2\pi R \bar{r}/\lambda \), where \( R \) is the aperture radius and \( \bar{r} \) is the beam radius [14]. It should be noticed that, in general, \( z_{\text{max}} \) is much greater than the Rayleigh range of a Gaussian beam with an equivalent beam waist radius \( w_g = \bar{r} \).

2.1 Numerical propagation of the phase front

In practice, various techniques have been developed for generating BBs, the simplest one being based on axicons [10] [12] [28] [41]. In this section we numerically simulate the evolution of the phase front of a Gaussian laser beam passing through an axicon and then a focusing lens.

To propagate an optical phase front located at the position \( z_0 \) of the optical axis, we conveniently start from a Gaussian laser beam of waist radius \( w_g \) and electric field strength \( B_0 \),

\[
E_{\text{Gauss}}(x, y, z_0) = B_0 \exp(-\rho^2/w_g^2) ,
\]

where \( \rho = \sqrt{x^2 + y^2} \) is the distance from the optical axis. The electric field is normalized to the total power \( P \) of the light beam, that is, \( I_{0,g} = (c\varepsilon_0/2)|B_0|^2 = 2P/(\pi w_g^2) \).

An axicon is a conical lens of base angle \( \alpha \) made of material with a refractive index \( n_{\text{ref}} \). It transforms an incident phase front \( E_{\text{in}}(\rho) \) according to,

\[
E_{\text{axicon}}(\rho) = E_{\text{in}}(\rho) \exp(-ik_\rho \rho) ,
\]

where

\[
k_\rho \equiv k \sin[(n_{\text{ref}} - 1) \tan \alpha] . \tag{4}
\]

The product \( -k_\rho \rho \) in (3) is then the phase shift suffered by a paraxial beam ray passing through the axicon at a distance \( \rho \) from the optical axis. In contrast, a thin lens with focal distance \( f \) transforms a phase front according to,

\[
E_{\text{lens}}(\rho) = E_{\text{in}}(\rho) \exp(-ik_\rho^2/2f) . \tag{5}
\]

The transformation of a beam due to propagation in free space from position \( z_0 \) to position \( z \) is obtained via [2] [10],

\[
E_{\text{prop}}(x, y, z) = H \ast G = F^{-1} H(z) \ast F[E_{\text{in}}(x, y, z_0)] ,
\]

where \( H(z) = \exp\left(i k z \sqrt{1 - (\lambda k_\rho^2 - \lambda k_\rho^2)^2}\right) \) and \( F \) denotes the two-dimensional Fourier transform in \( x \) and \( y \). The concatenation of the operations [2] to [6] allows to determine the radial distribution of the electric field amplitude at any location \( z \) of the optical axis.

We now apply this formalism to the optical system shown in Fig. 1. An axicon with base angle \( \alpha = 0.5^\circ \) and refractive index \( n_{\text{ref}} = 1.51 \) is placed at \( z = -440 \) mm on the optical axis and a converging lens with focal distance \( f = 200 \) mm at \( z = -200 \) mm. The origin of the system, \( z = 0 \), is chosen to be located in the plane, where the hollow beam intensity is maximum, that is, in the geometrical focal plane of the lens. At the same time, we place the geometric center of the funnel in this plane. A collimated Gaussian laser beam with waist radius of \( w_g = 0.5 \) mm and wavelength \( \lambda = 461 \) nm is injected and propagated along the optical axis using the transfer functions (2-6). The simulation, exhibited in Fig. 2(a), reveals the formation of a more than 20 cm long hollow beam near the origin, when the light is tuned to the blue of an atomic resonance, may serve to guide cold atoms. Fig. 2(b) shows the same simulation, but in the presence of a 20 cm long and 2 mm wide funnel near the origin, through which the BB is threaded. The funnel is introduced into the simulations by simply removing all radial components of the intensity distribution exceeding the funnel diameter over its whole length. A comparison between both simulations reveals the presence of diffraction caused by the funnel: even though the bulk part of the BB clearly passed through the tube, –we note a negligible loss of total light power due to the passage through the funnel of about 4% for the chosen geometry–, peripheral partial waves blocked by the funnel lead to interference filling the interior of the tube with non-negligible light intensity.

In practice, imperfections of the axicon will spoil to some extent the quality of the intensity profile of the BB. To obtain a feeling of that, we mapped the radial intensity distribution at various positions on the optical axis using a CCD camera. The results, shown in Fig. 2(c), demonstrate a good agreement.

2.2 Higher-order Bessel-Gauss description

The dipolar optical force exerted by a BB is obtained as the gradient of its intensity distribution. This presupposes that
the intensity distribution had been numerically calculated on a sufficiently dense grid, and that the force be interpolated between grid points. This makes the Monte-Carlo simulation, to be presented in the following, heavy and slow. The calculation becomes simpler if an approximate but otherwise reliable analytical solution can be found. In this section we investigate whether the analytical description of a paraxial higher-order Bessel-Gauss (HOBG) beam can be used to model the intensity distribution generated by an axicon with a sufficient level of accuracy by comparing it with the numerical propagation of the phase front through the optical system, described in Sec. II.A.

We again consider the optical system of Fig. 1 which is composed by an axicon followed by a focusing lens. Assuming a cylindrical coordinate system centered at the geometrical focus of the lens, a paraxial HOBG of order \( \nu \), transverse wavenumber \( k_\rho \) and electric field strength \( E_0 \) is given by [20, 25, 45]:

\[
E_{bs}(\rho, \phi, z) = E_0 \frac{-i}{2kzq(z)} \exp \left[ i \left( kz + \nu \phi + \frac{k\rho^2}{2z} \right) \right] \times \\
\times \exp \left[ -\frac{1}{4q(z)} \left( \frac{k^2}{k^2 + \rho^2/z^2} \right) \right] J_\nu \left( \frac{ik_\rho \rho}{2kzq(z)} \right),
\]

where in [7] we have defined \( q(z) \equiv \frac{1}{k w^2} - \frac{i}{2kz} \), in which \( w_0 \) is the waist radius of the HOBG. Introducing the abbreviation \( u(z, \rho) = ik_\rho \rho/[2kzq(z)] \), the intensity can be written as,

\[
I_{bs}(\rho, z) = \frac{c_0}{2} |E(\rho, \phi, z)|^2 = I_0 \left| \frac{1}{2kzq} \exp \left( -\frac{k^2}{4k^2q} + \frac{k^2w_0^2 q}{k^2} \right) J_\nu(u) \right|^2 \\
= I_0 k^2 w_0^4 \exp \left( -\frac{k^2 z^2}{2w_0^2 + k^2 w_0^2/2} \right) |J_\nu(u)|^2.
\]

with \( I_0 = (c_0/2)|E_0|^2 \). The intensity is normalized as,

\[
P_{bs} = \int_{\mathbb{R}^2} I_{bs}(\rho, 0) \rho d\rho d\phi = I_0 2 \pi \int_0^\infty \rho \exp \left( -2 \rho^2 / w_0^2 \right) J_\nu(k_\rho \rho)^2 d\rho = \frac{\pi w_0^2}{2} I_0 \exp \left( -k_\rho^2 w_0^2 / 4 \right) I_\nu \left( \frac{1}{\sqrt{2}} k_\rho w_0^2 \right),
\]

where \( I_\nu \) is the modified Bessel function of the first kind. This allows us to fix \( I_0 \) for a given set of parameters \( P_{bs}, w_0, \nu \), and \( k_\rho \).

By using Gaussian beam optics through a lens, the beam waist \( w_0 \) of the HOBG can be related with the radius of the central lobe \( r_{bb} \) of the 0th order BB formed after the axicon and with the distance \( d \) between the 0th order BB focal spot and the lens (distances indicated in Fig. 2(a)). The Bessel zone length formed after the axicon is \( z_{bb} = w_g / \tan \beta = 112 \) mm [14], with \( \beta = (\nu + f - 1) \tan \alpha \). Thus, the distance \( d \) is calculated as \( d = z_{ax}-z_{bb}/2 = 184 \) mm, where \( z_{ax}-z_{bb} = 240 \) mm is the axicon-lens distance. The central lobe radius \( r_{bb} \) is given by \( r_{bb} = 2.405/k_{bb} = 39.6 \) mm [27], with \( k_{bb} = k \sin \beta \) being the transverse wavenumber of the 0th order BB (2.405 is approximately the first non-null root of \( J_0(\cdot) \)). Finally, the beam waist of the HOBG is evaluated by [22]:

\[
w_0 = \left[ \frac{1}{r_{bb}^2} \left( 1 - \frac{d}{f} \right)^2 + \frac{1}{f^2} \right]^{-1/2},
\]

which yields \( w_0 = 0.41 \) mm for our optical system.

Geometric optics predicts the radius of the ring pattern and its width at \( z = 0 \) mm as \( \rho_{max} = \beta f \) and \( \Delta \rho = 3.3(\lambda f)/[\pi w_g] \), respectively [8], whose values for our optical system are \( \rho_{max} = 0.890 \) mm and \( \Delta \rho = 0.194 \) mm. This is in good agreement with the values found in the numerical method of Sec. II.A.

The transverse wavenumber \( k_\rho \) and the order \( \nu \) of the HOBG can be determined from \( \rho_{max} \) and \( \Delta \rho \) values by using the following approach. The field must assume its maximum value at \( \rho = \rho_{max}, \phi = 0, z = 0 \):

\[
E(\rho_{max}, 0, 0) = E_0 \exp \left( -\frac{(\rho_{max}/w_0)^2}{2} \right) J_\nu(k_\rho \rho_{max}),
\]
hence, the maximum value of the function \( J_\nu(s) \) must be at \( s = k_\rho \rho_{\text{max}} \). Since the ring intensity decays at \( \rho = \rho_{\text{max}} + \Delta \rho/2 \), the first root of \( J_\nu(.) \) must be equal to \( k_\rho \cdot (\rho_{\text{max}} + \Delta \rho/2) \). Therefore, \( \nu \) and \( k_\rho \) are evaluated from the following two expressions:

\[
\begin{align*}
\max[J_\nu(s)] & \quad \text{at} \quad s = k_\rho \rho_{\text{max}}, \\
\text{first root of } J_\nu(.) &= k_\rho \cdot (\rho_{\text{max}} + \Delta \rho/2),
\end{align*}
\]

which can be solved numerically. We find for our optical system \( \nu = 30 \) and \( k_\rho = 2.68 \times 10^{-3} k \).

The intensity of the hollow beam calculated by the numerical propagation of the phase front is shown in Fig. 3(a) whereas the intensity of the HOBG beam, calculated from Eq. (7) with order \( \nu = 30 \), waist radius \( w_0 = 0.41 \) mm and \( k_\rho = 2.68 \times 10^{-3} k \), is presented in Fig. 3(b) in the \( xy \)-plane. Apparently, the absolute error is significantly larger for \( z \gg 0 \).

**Figure 3:** (color online) (a) Intensity distribution of the hollow Bessel beam calculated by numerical propagation of the phase front through the optical system of Fig. 1 (b) Same as (a), but now calculated from Eq. (7) using the HOBG method calculated with order \( \nu = 30 \), waist radius \( w_0 = 0.41 \) mm and \( k_\rho = 2.68 \times 10^{-3} k \). The red dash-dotted curve shows the optical potential for \( \Delta \rho = 41 \) mm and transverse wavenumber \( k = 6 \times 10^{-3} \). Therefore, \( \rho/\rho_{\text{max}} \) must be equal to \( \Delta \rho/\rho_{\text{max}} \).

The optical dipole potential is calculated from the intensity distribution of the hollow beam, as indicated by the coordinates \( p \) in a MOT can be described as a damped harmonic oscillation with a spring constant \( \kappa_{\text{mot}} \) and a friction coefficient \( \gamma_{\text{mot}} \).

\[
\begin{align*}
\vec{F}_{\text{mot}}(\vec{r}, \vec{p}) &= -\kappa_{\text{mot}} \vec{r} - \gamma_{\text{mot}} \vec{p}, \\
\langle \vec{\xi}(t) \rangle &= 0, \\
\langle \vec{\xi}(t) \vec{\xi}(t + \tau) \rangle &= \frac{m^2}{k^2} \gamma_{\text{mot}}^2 D_T \delta(\tau) = 8 \gamma_{\text{mot}} m k_B T \delta(\tau),
\end{align*}
\]

where \( D_T = \frac{\sigma^2}{\gamma_{\text{mot}}} \) is the diffusion coefficient and \( \sigma = 2k\sqrt{k_B T/m} \) the width of the Maxwell-Boltzmann distribution. \( \lambda = 2\pi/k = 2\pi c/\omega = 461 \) nm is the wavelength.

### 3 Forces acting on the atoms

Let us now take a closer look at the layout of the proposed experiment schematized in Fig. 1. The vacuum system consists of two chambers: a preparation chamber and a science chamber. In the preparation chamber, atoms are ejected from a heated dispenser and subject to several laser beams (i) for trapping and cooling them in a 2D-MOT, (ii) for pushing them via radiation pressure along the symmetry axis toward the science chamber, and (iii) for guiding them inside a blue-detuned hollow laser beam.

To understand quantitatively how the atoms are transferred between the 2D and 3D-MOT and, in particular, the role of a hollow guiding beam, we perform simulations of atomic trajectories under the influence of the forces exerted by the laser beams and of gravity.

As can be seen in Fig. 3(c), the BB forms, near the origin and for a total power of \( P_{\text{bs}} = 10 \) mW, a wall high enough to radially confine atoms having a kinetic energy below \( k_B T = 600 \) \( \mu \)K. In a typical strontium MOT with its cloud at thermal equilibrium, however, temperatures can be as hot as 10 mK, which means that out of the Boltzmann energy distribution only a fraction of atoms will be affected by this potential barrier. Furthermore, in a MOT the atoms are also subject to a restoring force, which adds potential energy to the system. We account for this complicated situation by a simple but realistic model, assuming that the friction force exerted by the MOT is maintained at balance with a fluctuating Langevin force imparted to the atoms upon light scattering. This balance is what determines the temperature of the cloud, as long as it interacts with the 2D-MOT cooling beams.

Let us now write down the forces.

#### 3.1 2D-MOT (i)

The 2D-MOT generally captures atoms from a background gas or a dispenser and cools them down to the Doppler limit of the employed cooling transition. In a simple linearized approach the atomic motion [indicated by the coordinates \( (r,p) \)] in a MOT can be described as a damped harmonic oscillation with a spring constant \( \kappa_{\text{mot}} \) and a friction coefficient \( \gamma_{\text{mot}} \).

\[
\begin{align*}
\vec{F}_{\text{mot}}(\vec{r}, \vec{p}) &= -\kappa_{\text{mot}} \vec{r} - \gamma_{\text{mot}} \vec{p}, \\
\langle \vec{\xi}(t) \rangle &= 0, \\
\langle \vec{\xi}(t) \vec{\xi}(t + \tau) \rangle &= \frac{m^2}{k^2} \gamma_{\text{mot}}^2 D_T \delta(\tau) = 8 \gamma_{\text{mot}} m k_B T \delta(\tau),
\end{align*}
\]

Typical values are \( \kappa_{\text{mot}} \approx 4 \times 10^{-19} \) N/m and \( m \gamma_{\text{mot}} \approx 2 \times 10^{-22} \) Ns/m, where \( m \) is the mass of the \( 88 \text{Sr} \) atoms. Being subject only to these forces, the atoms would quickly cool down to zero temperature. However, the temperature is limited by spontaneous photon scattering processes leading to a random walk of the atoms in momentum space. For a cloud at thermal equilibrium at temperature \( T \), using the fluctuation-dissipation theorem, we describe this diffusion by an additional stochastic Langevin force \( \xi(t) \), which is \( \delta \)-correlated [13].

\[
\begin{align*}
\langle \vec{\xi}(t) \rangle &= 0, \\
\langle \vec{\xi}(t) \vec{\xi}(t + \tau) \rangle &= \frac{m^2}{k^2} \gamma_{\text{mot}}^2 D_T \delta(\tau) = 8 \gamma_{\text{mot}} m k_B T \delta(\tau),
\end{align*}
\]
of strong cooling transition $^1S_0-^1P_1$ of strontium, whose linewidth is $\Gamma = (2\pi) 30.5$ MHz.

In practice, we set the capture region of the 2D-MOT to $|\rho|, |z + 30 \text{ mm}| < 8 \text{ mm}$ (left red circle in Fig. [1]), i.e. the forces $F_{\text{mot}}$ and $\xi(t)$ are assumed to be present only within this volume.

### 3.2 Push beam and gravity (ii)

Many 2D-MOT schemes make use of an additional ‘push beam’, directed along the symmetry axis of the atomic cloud. Being tuned to resonance, it exerts a radiation pressure force, which can be described by \cite{30},

$$ F_{\text{push}}(\mathbf{p}) = \hbar \mathbf{\hat{e}}_z \gamma_{\text{push}}(\mathbf{p}) , \quad (15) $$

where

$$ \gamma_{\text{push}}(\mathbf{p}) = \frac{6\pi}{k^2} \left( \frac{s_{\text{push}}(\mathbf{p})}{1 + s_{\text{push}}(\mathbf{p})} \right) \frac{I_{\text{sat}}}{\hbar \omega} . \quad (16) $$

is the scattering rate, which depends on the atomic velocity along the optical axis, $p_z/m$, because of the Doppler shift sensed by the accelerated atoms. The saturation parameter is given by,

$$ s_{\text{push}}(\mathbf{p}) = \frac{I_{\text{push}}/I_{\text{sat}}}{1 + (2kp_z/m\Gamma)^2} . \quad (17) $$

Here, the push laser is assumed to be a plane wave with homogeneous intensity $I_{\text{push}}$ limited to a radius of $\rho < 1 \text{ mm}$, and its goal is to accelerate the atoms toward the science chamber.

The radiation pressure force is always accompanied by heating of the atomic cloud due to the randomness of spontaneous emission. The average heating rate can be estimated by,

$$ R_{\text{push}}(\mathbf{p}) = \hbar \omega_{\text{rec}} \gamma_{\text{push}}(\mathbf{p}) , \quad (18) $$

where $\omega_{\text{rec}} = \hbar^2/2m$ is the recoil shift.

When the transfer is too slow (for example, if the push beam intensity is too weak), the atoms deviate from the optical axis due to gravity acting perpendicularly to the optical axis:

$$ F_{\text{grav}} = mg\mathbf{\hat{e}}_x . \quad (19) $$

### 3.3 Dipolar potential and radiation pressure (iii)

If not otherwise stated, we assume a total power provided by the laser from which the BB is generated of $P_{bs} = 10$ mW, and we tune it by $\Delta_{bs} = 10\Gamma$ to the blue of the cooling transition. The dipolar potential sensed by the atoms is then,

$$ U_{bs}(\mathbf{r}) = \frac{\hbar}{2} \frac{\Delta_{bs}}{2} \ln [1 + s_{bs}(\mathbf{r})] \quad (20) $$

where we defined the local velocity-dependent saturation parameter

$$ s_{bs}(\mathbf{r}) = \frac{I_{bs}(\mathbf{r})/I_{\text{sat}}}{1 + (2\Delta_{bs}/\Gamma)^2} \quad (21) $$

with $I_{\text{sat}} = 2\pi^2 c\hbar\Gamma/(3\lambda^3)$ being the saturation intensity and $\int_{\mathbb{R}^3} I_{bs}(\mathbf{r}) d\mathbf{x} d\mathbf{y} = P_{bs}$. The inhomogeneity of this potential gives rise to a conservative force,

$$ F_{bs}(\mathbf{r}) = -\nabla U_{bs}(\mathbf{r}) . \quad (22) $$

On the other hand, when the laser is not tuned very far from atomic resonance, the atoms will also sense a radiation pressure force oriented in the propagation direction of the laser beam and being proportional to the local scattering rate,

$$ \gamma_{bs}(\mathbf{r}) = \frac{6\pi}{k^2} \frac{s_{bs}(\mathbf{r})}{1 + s_{bs}(\mathbf{r})} \frac{I_{\text{sat}}}{\hbar \omega} . \quad (23) $$

The radiation pressure force can be expressed by

$$ F_{\text{rp}}(\mathbf{r}) = \hbar \mathbf{\hat{e}}_z \gamma_{bs}(\mathbf{r}) . \quad (24) $$

Again, spontaneous emission from the Bessel beams lead to heating estimated by the rate,

$$ R_{bs}(\mathbf{r}) = \omega_{\text{rec}} \gamma_{bs}(\mathbf{r}) . \quad (25) $$

The intensity distribution of the BB, which is required to determine the forces from Eq. (23) and Eq. (24) is calculated numerically, as explained in Sec. II.A, or approximated analytically from the expression (3). In the appendix we also derive an analytical expression for the dipolar force.

### 3.4 Implementation of the Monte-Carlo simulation

The Langevin equations for the motion of $N$ (non-interacting) atoms (labeled by an index $n$) subject to the light forces exerted by the BB, the resonant push beam, and the MOT beams are now,

$$ \dot{\mathbf{r}}_n(t) = \frac{1}{m} \mathbf{p}_n(t) \quad (26) $$

$$ \dot{\mathbf{p}}_n(t) = \mathbf{F}(\mathbf{r}_n, \mathbf{v}_n) = \mathbf{F}_{\text{mot}}(\mathbf{r}_n, \mathbf{p}_n) + \mathbf{F}_{\text{push}}(\mathbf{p}_n) $$

$$ + F_{\text{grav}} + F_{bs}(\mathbf{r}_n) + F_{\text{rp}}(\mathbf{r}_n) + \zeta_n(t) . $$

We implement the simulation of the atomic motion by a stochastic Runge-Kutta algorithm \cite{23}. The simulations have been carried out in two dimensions within the $y = 0$ plane,

$$ \mathbf{r}_n(dt) = \mathbf{r}_n(0) + \frac{dt}{2m} [\mathbf{p}_n(0) + \mathbf{p}_n(1)] $$

$$ \mathbf{p}_n(dt) = \mathbf{p}_n(0) + \frac{dt}{2} [\mathbf{F}(\mathbf{r}_n(0), \mathbf{p}_n(0)) + \mathbf{F}(\mathbf{r}_n(1), \mathbf{v}_n(1))] $$

$$ + \zeta_n \sqrt{8\gamma_{\text{mot}} m k_B T_{\text{dt}}} . \quad (27) $$

with

$$ \mathbf{r}_n(1) = \mathbf{r}_n(0) + \frac{1}{m} \mathbf{p}_n(0) dt $$

$$ \mathbf{p}_n(1) = \mathbf{p}_n(0) + \mathbf{F}(\mathbf{r}_n(0), \mathbf{p}_n(0)) dt + \zeta_n \sqrt{8\gamma_{\text{mot}} m k_B T_{\text{dt}}} . $$

The Cartesian components of $\zeta$ are $\delta$-correlated random numbers satisfying $\langle \zeta_n \rangle = 0$ and $\langle \zeta_n(t) \zeta_m(t + \tau) \rangle = \delta_{nm} \delta(\tau)$. Heating of the atomic cloud by spontaneous emission from the push and the Bessel beam is incorporated by the following procedure. After each time step of the simulation ($dt = 10 \mu$s) a direction $k_{\text{push},n}$ is randomly generated for every atom, accounting for the randomness of the direction into which the light from the push beam is scattered. The same procedure is repeated for the Bessel beam, $k_{bs,n}$. The momentum change due to recoil is calculated for every atom by,

$$ \mathbf{p}_n(t + dt) = \mathbf{p}_n(t) + k_{\text{push},n} \sqrt{2mR_{\text{push}}(\mathbf{p}_n)} dt $$

$$ + k_{bs,n} \sqrt{2mR_{bs}(\mathbf{r}_n)} dt . $$
We verified that this procedure generates the expected temperature increase due to heating.

Atoms hitting the walls of the funnel located at $|\rho| > 1$ mm and $|z| < 10$ mm are removed from the simulation. Only atoms passing through the capture region of the 3D-MOT, which is set to $|\rho|, |z - 190$ mm$| < 3$ mm, contribute to the transfer efficiency $\eta \equiv N_{\text{trap}}/N$, where $N_{\text{trap}}$ is the number of recaptured atoms. Finally, the transfer process is aborted after 20 ms, time after which atoms still flying around in the vacuum chamber are assumed not to make it to the 3D-MOT region.

3.5 Results of the simulation

In order to evaluate the impact of the BB on the transfer efficiency from the 2D to the 3D-MOT, we run simulations of the Eqs. (27) with $N = 1,000$ atoms assumed to be at equilibrium in the 2D-MOT at temperatures between $T = 1$ mK and 100 mK, and we vary the intensity of the BB and the push beam. We verified that the number of simulated atoms is sufficient to generate reproducible dependencies. In the simulations, we let the 2D-MOT equilibrate at this temperature before switching on the push and BBs. We noticed that, the simultaneous presence of a strong BB can shield the central 2D-MOT region, reduce its loading efficiency, and thus spoil the transfer efficiency of the 3D-MOT.

The results are shown in Figs. 4 which reproduce the number of recaptured atoms as a function of various parameters. The curves of Fig. 4(a) demonstrate clearly that higher BB intensities help to guide the atoms and thus to enhance the transfer efficiency. This is particularly important, when the temperature of the atomic cloud is high. With the chosen beam geometry and for a laser detuning of $\Delta_{bb} = 10^\circ$ total beam powers higher than $P_{\text{box}} = 10$ mW seem to be necessary. Above 100 mW beam power an increase of the transfer efficiency from below 20% to more than 80% can be expected for an atomic cloud as hot as $T = 10$ mK.

At $T = 10$ mK the mean radial velocity of the atoms in the 2D-MOT is $\bar{v} = \sqrt{2k_BT/m} = 1$ m/s. This is far too slow for the atoms to reach the 3D-MOT, which is distant by 23 cm. By the time atoms with this velocity arrive at the recapture region via ballistic flight, they will have suffered a gravitational sag of more than 20 cm! The benefit of pushed atomic transfer has been confirmed by experimental observations [22]. A resonant push beam with an intensity of $I_{\text{push}} = 6.4$ mW/cm$^2$ is able to accelerate the atoms to 30 m/s by the time they arrive at the 3D-MOT, despite the fact that the acceleration decreases as soon as the Doppler shift exceeds the natural linewidth. This reduces the gravitational sag to only a few 10 $\mu$m. The BB now helps to defeat gravity, i.e. even at very weak push beam intensities atoms may slowly drift across the hollow BB toward the 3D-MOT. This explains the increase of the loading efficiency observed in Fig. 4(b) even for very low push beam intensities of below 0.6 mW/cm$^2$. Higher push beam intensities decrease the transfer time. However, at intensities exceeding the saturation intensity, $I_{\text{sat}} = 43$ mW/cm$^2$, heating starts to spoil the transfer efficiency, as verified in Fig. 4(b).

We point out that the curve of Fig. 4(b) corresponding to 64 mW/cm$^2$ must be taken as an upper bound, because other effects, such as the perturbation of the 3D-MOT by resonant push light is not captured by our model. The radiation pressures exerted by the BB and heating are included in the simulation via the expressions [24] and [25]. At small detunings, radiation pressure assists the transfer by accelerating the atoms toward the science chamber. On the other hand, heating tends to increase the transverse velocity components and cause atomic losses. However, being guided by the dark hollow channel of the BB, the atoms spend only little time exposed to the BB light, so that heating is limited.

4 Conclusion and perspectives

We presented and evaluated numerically, as well as analytically, a very simple scheme for enhancing the loading efficiency of a 3D magneto-optical trap by guiding a precooled atomic cloud from a preparation chamber through a differential pumping tube to a science chamber via a hollow BB. We quantitatively verified the intuition that higher temperatures of the precooled cloud require a higher potential depth of the BB. At the example of $^{88}$Sr atoms precooled to 10 mK, we found that it should be feasible to increase the loading efficiency from 20% to 80% using, e.g., a BB of total power $P_{\text{box}} = 500$ mW tuned 50$\Gamma$ above the atomic transition at 461 nm. While the obtained results are specific for the considered experimental scheme, the general procedure of the simulations can easily be adapted to other schemes and geometries.

A problem may occur when trying to thread the BB through a narrow differential pumping tube: Even when the beam clearly passes through the tube, the external partial waves blocked by the tube lead to interference filling the interior of the tube with non-negligible light intensity. In our case, this does not represent a major problem, as it merely leads to a slight increase in the radiation pressure accelerating the atoms towards the 3D-MOT. Nevertheless, it should be noted that this interference may be reduced by reducing the BB diameter, which, however, requires axicons with smaller base angle, $\alpha < 0.5^\circ$, or inverted axicons, i.e. conical lenses with radically diminishing thickness. Both are not readily available on the market. However, such configurations can be realized with spatial light modulators (SLM). An interesting extension of our waveguiding scheme could...
be the use of recently discovered non-diffracting superpositions of BBs called “Frozen Waves” [1] [2] [3] [4]. These are stationary localized wave fields with high transverse localization and a longitudinal intensity pattern which can assume any desired shape within long distances.

\[ \nabla I_{bs} = \hat{e}_\rho \frac{\partial I_{bs}}{\partial \rho} + \hat{e}_\phi \frac{1}{\rho} \frac{\partial I_{bs}}{\partial \phi} + \hat{e}_z \frac{\partial I_{bs}}{\partial z} \simeq \hat{e}_\rho \frac{\partial I_{bs}}{\partial \rho}, \tag{28} \]

neglecting \( \partial_z I \). The radial gradient is hence,

\[ \frac{\partial I_{bs}}{\partial \rho} = \frac{ce_\rho E_0^2}{2} \left( \frac{1}{2kz|q|} \right)^2 \exp \left( 2Re \left( -\frac{k^2 u^2 q}{4k^2 q} + \frac{k^2 u^2 q}{k^2} \right) \right) \times \left\{ 2J_\nu(u)J_\nu(u^*) \frac{\partial}{\partial \rho} Re \frac{k^2 u^2 q}{k^2} + J_\nu(u) \frac{\partial u^*}{\partial \rho} \frac{\partial J_\nu(u)}{\partial u} \right\}, \tag{29} \]

6 Appendix

6.1 Calculation of the dipolar force exerted by a Bessel-Gauss beam

In order to obtain the dipolar force exerted by the Bessel-Gauss beam, we need to take the gradient of the intensity distribution in Eq. [5].

\[ \nabla I_{bs} = \hat{e}_\rho \frac{\partial I_{bs}}{\partial \rho} + \hat{e}_\phi \frac{1}{\rho} \frac{\partial I_{bs}}{\partial \phi} + \hat{e}_z \frac{\partial I_{bs}}{\partial z} \simeq \hat{e}_\rho \frac{\partial I_{bs}}{\partial \rho}, \tag{28} \]
where we used \( J^*_\nu (u) = J_\nu (u^*) \) for holomorphic functions. Using the recursion relation \( \frac{\partial J_\nu (u)}{\partial u} = \frac{1}{2} [J_{\nu-1} (u) - J_{\nu+1} (u)] \) we find,

\[
\frac{\partial I_{bs}}{\partial \rho} = \frac{c \epsilon_0 E_0^2}{2} \left( \frac{1}{2kz|q|} \right)^2 \exp \left[ 2 \text{Re} \left( \frac{-k^2 \rho^2}{4k^2 q} + \frac{k^2 u^2 q}{k^2 \rho} \right) \right] \times \left\{ 2J_\nu (u)J_\nu (u^*) \frac{\partial}{\partial \rho} \text{Re} \left( \frac{-\rho^2}{4z^2 q} - \frac{k^2 }{2kz} \right) + J_{\nu-1} (u) - J_{\nu+1} (u) \right\} \\
= -\frac{c \epsilon_0 E_0^2}{2} \frac{k^4 u_0^2}{(2z^2/w_0^4 + k^2 w_0^4/2)^2} \exp \left( \frac{-k^2 \rho^2 z^2 - k^2 \rho^2}{2z^2/w_0^4 + k^2 w_0^4/2} \right) \times \left\{ \rho |J_\nu (u)|^2 + \frac{1}{2} k w_0^2 k^2 \rho z \text{Im} q^* J^*_\nu (u) \times \left[ J_{\nu-1} (u) - J_{\nu+1} (u) \right] \right\}.
\]

(30)

Finally, the radial force exerted by the Bessel-Gauss beam is according to Eq. (22),

\[
F_\rho = -\frac{\partial U_{bs}}{\partial \rho} = -\frac{h \Delta_{bs}}{2} \frac{1}{1 + s(r) + (2\Delta_{bs}/\Gamma)^2} \frac{1}{I_{sat}} \frac{\partial I_{bs}}{\partial \rho} \left. \right|_{\Delta \gg \Gamma} \frac{3\pi \epsilon_0}{2} \frac{1}{\Delta_{bs}} \frac{1}{1 + s(r)} \frac{\partial I_{bs}}{\partial \rho}.
\]

(31)

Fig. 5 shows the forces calculated from Eq. (30). Obvi-

![Figure 5](image)

Figure 5: (color online) Calculation of the dipolar potential (a,c) and force (b,d) exerted by a Bessel-Gauss beam of order \( \nu = 30 \) at the Fourier plane \( z = 0 \) for a beam power of \( P_{bs} = 10 \) mW, a waist radius of \( w_0 = 0.41 \) mm and transverse wavenumber \( k_\rho = 2.68 \times 10^{-3} k \). The blue solid line in (d) represents the numerical gradient of the potential in (c). The pink dotted line is a calculation of the force according to Eq. (31).

ously, the forces calculated in Figs. 5(b,d) are large enough to compensate for gravity.
