Abstract. Motivated by recent numerical findings of Henkel et al (2006 J. Phys. A: Math. Gen. 39 L589) we re-examine via Monte Carlo simulations the linear response function of the two-dimensional Ising model with Glauber dynamics quenched to the critical point. At variance with the results of Henkel et al, we detect discrepancies between the actual scaling behavior of the response function and the prediction of local scale invariance. Such differences are clearly visible in the impulse autoresponse function, whereas they are drastically reduced in the integrated response functions. Accordingly, the scaling form predicted on the basis of local scale invariance simply provides an accurate fitting form for some quantities but cannot be considered to be exact.

Keywords: classical Monte Carlo simulations, slow dynamics and ageing (theory), critical phenomena

ArXiv ePrint: 0711.1527
1. Introduction

The non-equilibrium collective relaxation of pure systems quenched at or below their critical points has recently been the subject of renewed interest in connection with the fact that two-time quantities—such as response and correlation functions—display a scaling behavior similar to the one observed in glassy systems [1]–[3]. In addition, at the critical point, this scaling behavior is characterized by a certain degree of universality [2,3] which renders it largely independent of the microscopic details of the systems and allows its investigation via suitable minimal models, either on the lattice or in the continuum. The former can be easily studied via Monte Carlo simulations (or, in a limited number of cases, exact solutions are available), whereas powerful field-theoretical methods have been developed for the latter.

In what follows we will be concerned with the behavior of the two-time response function. Consider a lattice model characterized by degrees of freedom $\sigma_x$ with $x \in \mathbb{Z}^d$, interacting via a Hamiltonian $\mathcal{H}([\sigma_x]; \{h_x(t)\}) = \mathcal{H}_0([\sigma_x]) - \sum_x \sigma_x h_x(t)$, where $h_x(t)$ is a time-dependent external field. In the case of the Ising model $\sigma_x = \pm 1$, $\mathcal{H}_0([\sigma_x]) = -J \sum_{\langle xy \rangle} \sigma_x \sigma_y$ ($J > 0$), the sum being over pairs $(xy)$ of nearest-neighboring sites. The stochastic dynamics of the model, due to the coupling to a thermal bath of temperature $T$, can be implemented according to different rules and yields a time dependence of the value of the local degree of freedom $\sigma_x(t)$. The linear two-time response function is defined as

$$R_r(t, s) = \frac{\delta \langle \sigma_x(t) \rangle}{\delta h_y(s)} \bigg|_{h=0},$$

where $r(t, s)$ is the response function, $\delta$ denotes a small variation, and the bar denotes an average over the initial conditions. When the quench is performed at the critical point $T = T_c$, the response function displays a scaling behavior similar to that observed in glassy systems, which can be described by a universal scaling function $R_r(t, s) \sim f(x, y)$, where $x = (t - s)^{\beta}$ and $y = s^{\gamma}$ are the scaling variables, and $\beta$ and $\gamma$ are the critical exponents. The scaling function $f(x, y)$ can be expressed in terms of the scaling form $f(x, y) = f_0(x, y/x)$, where $f_0(x, y/x)$ is the scaling function.

References
where $r = |x - y|$, $\langle \ldots \rangle$ indicates the average over the possible realizations of the stochastic dynamics, and invariance under space translations has been assumed. Causality implies that $R_r(t, s)$ vanishes for $s > t$ and therefore we shall assume $t > s$ in what follows. In addition, we shall primarily consider the local response function (also referred to as the auto response function)

$$R(t, s) \equiv R_{r=0}(t, s).$$

If the system is in thermal equilibrium with the bath, the dynamics is invariant under time translations and therefore $R_r(t, s)$ actually depends only on $\tau \equiv t - s$, i.e. $R_r(t, s) = R^{(\text{eq})}_r(\tau; T)$. Time-translational invariance is naturally broken if, at time $t = 0$, the temperature of the bath is suddenly changed from an initial value $T_i$—which we shall assume to be high enough to yield a disordered state in the system—to a final value $T_f \neq T_i$. After the quench, the system undergoes a non-equilibrium relaxation towards the new equilibrium state at the temperature $T_f$, which is attained after a time $t_{\text{eq}}$. In some circumstances, however, $t_{\text{eq}} = \infty$ and the dynamics retains its non-equilibrium character forever. Interestingly enough, a robust scaling behavior emerges in this regime as is revealed by two-time quantities such as the linear response function (1). In the paradigmatic case of ferromagnetic systems, $t_{\text{eq}} = \infty$—in the thermodynamic limit—if the quench occurs at $T_f \leq T_c$, where $T_c$ is the critical temperature of the system. In such a case, the behavior of $R_r(t, s)$ depends on the relation between $t$ and $s$. We restrict our analysis to the case $s, \tau \gg \tau_{\text{micr}}$, where $\tau_{\text{micr}}$ is a microscopic timescale set by the dynamics and such that for $s, \tau < \tau_{\text{micr}}$ non-universal corrections to scaling appear. In the sector $s \gg \tau \gg \tau_{\text{micr}}$, referred to as the short-time separation regime (STSR), time-translational invariance and time-reversal symmetry are recovered in local quantities, resulting in an equilibrium-like dynamics:

$$R(t, s) = R^{(\text{eq})}(\tau; T_f).$$

This quasi-equilibrium behavior is quite generally expected in systems with slow dynamics (see, e.g., [1]–[3]). By contrast, for $s \gg \tau_{\text{micr}}$ and fixed $u \equiv t/s > 1$, referred to as the aging regime, one expects the scaling behavior

$$R(t, s) = R^{(\text{ag})}(t, s) = s^{-1-a} F_R(u),$$

which is characterized by the scaling function $F_R$ and the exponent $a$. These being the behaviors in two different regimes, it remains to be clarified: (a) how the crossover between the forms (3) and (4) actually occurs in $R(t, s)$ and (b) how $F_R(u)$ behaves.

For quenches at the critical temperature these issues can be addressed via scaling arguments [2,4] and the renormalization-group (RG) approach [5], which yield

$$R(t, s) = A_R s^{-1-a} u^\theta (u - 1)^{-1-a} f_R(u),$$

where the exponent $a$ is related to the usual static and dynamic critical exponents $\eta$ and $z$ by

$$a = \frac{d - 2 + \eta}{z},$$

$\theta$ is the so-called initial-slip exponent [5], $A_R$ is a non-universal constant (fixed by the condition $f_R(u \gg 1) = 1$) and $f_R(u)$ is a universal scaling function.
The non-equilibrium response of the critical Ising model

such that

$$f_R(1^+) \neq 0 \quad \text{and} \quad \text{finite.} \quad (7)$$

$f_R(u)$ can be calculated by means of a variety of field-theoretical techniques. As a consequence of equation (7), equation (5) can be cast in the form

$$R(t, s) = R^{(eq)}(\tau; T_c)R^{(off)}(u), \quad (8)$$

where

$$R^{(eq)}(\tau; T_c) = B_0 \tau^{-1-a} \quad (9)$$

is the equilibrium critical response function with $B_0 = A_R f_R(1^+)$ and

$$R^{(off)}(u) = u^0 f_R(u)/f_R(1^+) \quad (10)$$

is the non-equilibrium contribution. In the STSR $R^{(off)}(u) \simeq 1$ and the response function (5) reduces to the form (9), in agreement with what was expected from equation (3). In the aging regime $R^{(off)}(u) \neq 1$ and the invariance under time translations, typical of equilibrium, is broken. Equation (8) shows that in the quench at $T_i = T_c$ the crossover between the quasi-equilibrium $R^{(eq)}$ and the aging $R^{(ag)}$ behavior occurs multiplicatively via the factor $R^{(off)}$.

Unfortunately, no equivalent powerful methods are available for the analytical investigation of the behavior of the response function after a quench to $T_i < T_c$. Nonetheless, the available numerical simulations of the Ising model [6]–[8], the exact results for the Glauber–Ising chain [9, 10] quenched to $T_i = 0$, and the predictions of approximate theories of phase ordering [11]–[13] suggest that the response function for scalar systems in the aging regime can be cast in the form of equation (5) where $a$ is a scaling exponent whose behavior has been investigated in [6, 14], with

$$f_R(u) = (u - 1)^{1/z_g} \quad (11)$$

(See, however, [15, 16] where $f_R(u) \equiv 1$ has been numerically inferred by looking at the so-called thermoremanent magnetization—$\chi(t, [0, s])$ and $\chi_k = 0(t, [0, s])$, see equations (18) and (19) below—for the Ising, 3- and 8-state Potts models.) Here $z_g$ is the growth exponent which controls the time evolution of the typical domain size $L(t) \sim t^{1/z_g}$ in systems with discrete symmetries (e.g. $z_g = 2$ for the Ising model with Glauber dynamics) [17]. Note that, at variance with the prediction of the scaling and RG analysis for the quench to $T_i = T_c$, $f_R(u)$ vanishes for $u \to 1^+$. Let us stress that, while for $T_i = T_c$ scaling arguments and the RG approach predict equation (5) to be obeyed for every $t$ and $s$, for $T_i < T_c$ this expression holds only in the aging regime.

Due to the lack of general predictions for the scaling function $f_R(u)$ of the response function it is particularly interesting the proposal by Henkel et al.—referred to as local scale invariance (LSI) [18]–[20]—stating that the scaling form of the response function is

5 Equation (5) is expected to capture the universal scaling behavior of the response function $R(t, s)$ which, in lattice models, sets in only for $s, \tau \gg \tau_{\text{mix}}$. Accordingly, the notation $f_R(1^+)$ in equation (7) emphasizes the fact that the limit $u \to 1$ of $f_R(u)$ has to be taken in such a way as to satisfy this condition, i.e. $f_R(1^+) = \lim_{s \to \infty} f_R(1 + \tau/s)$ with fixed $\tau \gg \tau_{\text{mix}}$.

6 The one-dimensional Ising model quenched to $T_i = T_c = 0$ displays a breaking of ergodicity and therefore its behavior is expected to be more akin to the one observed during phase ordering than to the critical one.
The non-equilibrium response of the critical Ising model constrained by requiring its covariance under a group of local scale transformations which generalize the global transformations \((b > 0) \ x \mapsto b \cdot x, (t, s) \mapsto (b^2 t, b^2 s)\) underlying the scaling behavior of critical dynamics.

In this paper we investigate the extent to which LSI describes correctly the scaling behavior of the response function \(R(t, s)\), focusing on the two-dimensional Ising model with Glauber dynamics after a quench from the disordered state to the critical point. In particular we revisit the recent findings of [21].

The presentation is organized as follows. In section 2 we summarize the predictions of the different versions of LSI, highlighting their qualitative features and discussing the comparison with the available analytical and numerical results for a variety of different systems undergoing non-equilibrium relaxation after a quench at \(T_f \leq T_c\). In particular we discuss those features of LSI that we shall specifically investigate in the numerical analysis. In section 3 we present the results of our Monte Carlo simulations for quenches to \(T_f = T_c\). After the description of the numerical procedure, we discuss the data for the impulse response function \(R(t, s)\) in section 3.1 and for the associated local and global integrated response functions \(\chi^{(l)}(t, s)\) (cf. equation (17)) and \(\chi^{(g)}(t, s)\) (cf. equation (14)) in sections 3.2 and 3.3, respectively, comparing them with previous results and with the predictions of LSI. In section 4 we briefly present the comparison between what is currently known about the response function \(R(t, s)\), after quenches to \(T_f < T_c\), and LSI. We point out that the aging part of \(R(t, s)\) is actually described by a recently proposed version of LSI. A final summary and our conclusions are presented in section 5.

2. Local scale invariance: scaling forms for the response function

For the impulse autoresponse function \(R(t, s)\), LSI in its original form [18, 20] (which we refer to as LSI.0), predicts \((u = t/s > 1)\)

\[
R(t, s) = A_R s^{-1-\alpha} u^\beta (u - 1)^{-1-\alpha} \tag{12}
\]

and

\[
R_r(t, s) = R(t, s) \Phi(r(t - s)^{-1/z}) \tag{13}
\]

where the exponents \(\alpha, \beta\) and the amplitude \(A_R\) are undetermined whereas \(\Phi\) is defined in terms of special functions in [20]. These predictions are supposedly quite general and they apply to a variety of systems undergoing non-equilibrium relaxation, either due to critical \((T_f = T_c)\) or phase ordering \((T_f < T_c)\) dynamics. As in the case of dynamics at the critical point (see equations (5) and (7)), the structure of equation (12) is such that time-translational invariance is recovered in the STSR: \(R(t = s + \tau, s \gg \tau) = A_R \tau^{-1-\alpha}\) and this stationary part crosses over to the non-equilibrium behavior via a multiplicative factor as in equation (8). Note that, according to LSI, such a multiplicative structure is expected in ferromagnetic systems both for quenches to \(T_c\) and below \(T_c\). The prediction (12) (with \(A_R, \alpha\) and \(\beta\) as fitting parameters) has been tested in a variety of different systems [6]–[8], [18], [22]–[29], with the conclusion that, while it is seemingly successful in a restricted number of instances, it surely fails in the general case. For example, LSI.0 is in agreement with the exact solution of the large-\(N\) (spherical) model [4, 10, 30] quenched to \(T_f \leq T_c\), but fails to reproduce all the available analytical results [9]–[13] obtained for scalar systems quenched to \(T_f < T_c\). In addition, for the \(d\)-dimensional Ising model with Glauber
The non-equilibrium response of the critical Ising model

dynamics quenched to $T_f = T_c$, a field-theoretical calculation in the dimensional expansion $d = 4 - \epsilon$ clearly shows corrections of the order of $\epsilon^2$ to the prediction (12) of LSI.0 [32] for $d < 4$. The comparison of LSI.0 with Monte Carlo simulations, at and below $T_c$, is more controversial since agreement was reported in the study of various systems, such as the two- and three-dimensional Ising model [15, 18], the XY model [31] and the 3- and 8-state Potts model in two dimensions [16], while deviations from equation (12) were detected in the two- and three-dimensional Ising model after a quench to the critical point in [8, 27] and below it in [6, 7]. In particular, the data presented in [27] for the so-called "global intermediate response function"

\[ \chi_I^{(g)}(t, s) = \int_{s/2}^{s} dt' \sum_R R_r(t, t'), \]  

(14)

and in [8] for $R_{r=0}(t, s)$ display deviations from LSI.0 which are actually negligible in $d = 4$ but become significant in $d = 3$ and even larger in $d = 2$, in qualitative agreement with the expectation based on the field-theoretical analysis of [32].

Motivated by these discrepancies, Henkel et al. have reconsidered the original formulation of LSI, coming up with a new version [21, 26]—referred to as LSI.1 in the following—which predicts, in comparison to LSI.0, a less constrained scaling form

\[ R(t, s) = A R_s^{-1-\alpha/2} u^{\beta+\alpha' - \alpha(u - 1)^{-1-\alpha'}}, \]  

(15)

where $\alpha$ and $\alpha'$—yet undetermined—are not necessarily equal. Note, however, that the large-$u$ behavior of equation (15), being actually independent of $\alpha'$, is the same as the one of LSI.0 (see equation (12)) and therefore possible improvements of LSI.1 compared to LSI.0 are restricted to the STSR $u \simeq 1$. (The space dependence of $R_r(t, s)$ within LSI.1 still factorizes according to equation (13), with $R(t, s)$ given by equation (15) [19, 21].)

The introduction of the additional fitting parameter $\Delta\alpha \equiv \alpha - \alpha'$ in equation (15) is expected to reduce discrepancies in those cases in which they were observed with $\Delta\alpha = 0$, i.e. when comparing with LSI.0. A first apparent confirmation of the predictions of LSI.1 came from the comparison with the numerical studies of (i) the two- and three-dimensional critical Ising model (Glauber dynamics) [21], (ii) the three-dimensional Ising spin glass [21, 33], (iii) the non-equilibrium kinetic Ising model in one dimension [24], (iv) the contact process [21], and with the analytical study of the Fredrickson–Andersen model [21]. However, subsequent analyses of the latter two cases have revealed clear discrepancies with LSI.1 [28, 29, 34].

In this paper we revise the statement of [21] according to which the numerical data for $\chi_I^{(g)}(t, s)$ (see equation (14)) in the two-dimensional Ising–Glauber model—though not in agreement with LSI.0 [27]—do scale according to LSI.1 (15) with $\alpha = a - d/z$, $\beta = \theta$ (see after equation (5)) and $\Delta\alpha = 0.187(20)$. More specifically, we shall focus on the fact that the prediction (15) of LSI.1 with $\Delta\alpha \neq 0$ implies a non-stationary behavior of the response function in the STSR:

\[ R(t = \tau + s, s \gg \tau) = A R_s^{-\Delta\alpha} \tau^{-1-\alpha'}, \]  

(16)

which is in qualitative disagreement with what is generally expected (see equation (3)) also on the basis of the scaling and RG analyses (equations (5) and (7)). A conclusive test of LSI.1 for $T_f = T_c$ can therefore be done by looking at the STSR. Accordingly, we performed new extensive Monte Carlo simulations in order to investigate the scaling...
behavior of the response function deep in the short-time separation regime, down to $\tau/s \simeq 5 \times 10^{-4}$. The numerical data presented in section 3 unambiguously show that $R(t, s)$ becomes time-translational invariant in the STSR, in agreement with equation (3) and in stark contrast with the prediction (16) (with $\Delta \alpha \neq 0$) of LSI. Nonetheless, the data for $\chi^{(g)}(t, s)$ reproduce the findings of [21] showing thereby that in passing from $R(t, s)$ to $\chi^{(g)}(t, s)$ the space–time integration drastically reduces the difference between the actual response function and the prediction of LSI.1. We corroborate this statement by studying the scaling behavior of the local intermediate response function

$$\chi^{(l)}(t, s) = \int_{s/2}^{s} dt' R(t, t'),$$

(17)

which involves only one integration over time and which actually deviates from LSI.1 less than in the case of $R(t, s)$ but more than $\chi^{(g)}(t, s)$. Therefore, in spite of the agreement of $\chi^{(g)}(t, s)$ with LSI.1, we conclude that the prediction of local scale invariance simply provides an accurate fitting form for some quantities but cannot be considered to be exact for $T_f = T_c$.

3. Quench to $T = T_c$: Monte Carlo simulations

We consider the Glauber dynamics of the ferromagnetic Ising model on a two-dimensional square lattice with $10^3 \times 10^3$ spins. The system is initially prepared in an infinite-temperature configuration and then it is quenched to the critical temperature $T_f = T_c \simeq 2.269185$. Temperature is measured in units of the ferromagnetic coupling $J$ and time is expressed in Monte Carlo step units (sweeps). Each of the data points we shall present in the following is the result of an average over $10^4 - 5 \times 10^4$ different realizations of the initial condition and of the thermal noise. No finite-size effects were detected in the time range accessed during the simulations.

For later convenience, we introduce the (time) integrated response functions in real and momentum space

$$\chi(t, [t_1, t_2]) \equiv \int_{t_1}^{t_2} dt' R(t, t')$$

and

$$\hat{\chi}_k(t, [t_1, t_2]) \equiv \int_{t_1}^{t_2} dt' \hat{R}_k(t, t'),$$

(19)

respectively, where $\hat{R}_k(t, s) = \sum_r R_r(t, s)e^{ir\cdot k}$ is the Fourier transform of $R_r(t, s)$. The various response functions we are interested in, namely $R(t, s)$, $\chi^{(l)}(t, s)$ and $\chi^{(g)}(t, s)$ are related to $\chi(t, [t_1, t_2])$ and $\hat{\chi}_k(t, [t_1, t_2])$, which are actually computed without applying the external perturbation $h_x(t)$ via the algorithm presented in [35]. In fact, these response functions can be obtained from particular correlation functions of the unperturbed system as [35]

$$2T_c \chi(t, [t_1, t_2]) = C(t, t_1) - C(t, t_2) + D(t, [t_1, t_2])$$

(20)
where \( C(t, t') = \langle \sigma_x(t) \sigma_x(t') \rangle \) is the spin autocorrelation function, \( \langle \cdots \rangle \) being the average over initial conditions and thermal histories, and \( \tilde{C}_k(t, t') = \langle \tilde{\sigma}_k(t) \tilde{\sigma}_{-k}(t') \rangle \) is its momentum counterpart. The additional correlation functions \( D \) and \( \tilde{D} \) in equations (20) and (21) are respectively given by \( D(t, [t_1, t_2]) = \langle \sigma_x(t) B_x([t_1, t_2]) \rangle \) and \( \tilde{D}_k(t, [t_1, t_2]) = \langle \tilde{\sigma}_k(t) \tilde{B}_{-k}([t_1, t_2]) \rangle \), where \( B_x(t, [t_1, t_2]) \) is a function of the transition rates and \( \tilde{B}_k(t, [t_1, t_2]) \) is its Fourier transform. For Glauber dynamics [36] one has

\[
B_x([t_1, t_2]) = \int_{t_1}^{t_2} dt' \left[ \sigma_x(t') - \tanh \left( H^W_x(t') / T_c \right) \right],
\]

where \( H^W_x(t) \) is the Weiss field \( H^W_x(t) = \sum_{\langle xy \rangle} \sigma_y(t) \), the sum being over sites \( y \) nearest neighbors of \( x \). Note that the (auto) response \( \chi \) and the correlation \( C \) appearing in equation (20) do not depend on \( x \) due to space homogeneity. In order to reduce the noise of the resulting numerical data, they have been computed at each lattice site and then averaged over the whole lattice.

3.1. Impulse autoresponse function

The impulse autoresponse function \( R \) can be formally derived from \( \chi(t, [t_1, t_2]) \) (see equation (18)) as \( R(t, s) = \lim_{t_2 \to s} \chi(t, [s, t_2]) / (t_2 - s) \). Numerically, \( R \) is computed as \( R(t, s) = (1/\delta) \chi(t, [s, s + \delta]) \), where the integration over time in \( \chi \) has the effect of reducing the noise-to-signal ratio with the drawback of introducing a systematic error of order \( \delta / s \) [35]. With an appropriate choice of \( s \) and \( \delta \), this error can be made much smaller than the statistical errors and hence neglected. In the range of \( s \) considered in our simulations (\( s > 10^2 \)), \( \delta = 1 \) turns out to be a suitable choice.

The behavior of \( R(t, s) \) for \( t \gg s \), i.e. in the aging regime, is quite well established and numerical results for \( \chi(t, [0, s]) \) (see, e.g., [4, 18]), \( R(t, s) \) [8, 37] and \( \chi^{(k)}(t, s) \) [27] support the validity of the scaling behavior predicted within the scaling and field-theoretical approaches (see equations (5) and (7)): \( R(t \gg s, s) \sim s^{-1-\alpha}(t/s)^\theta \) where the actual exponents are compatible with the expected values in \( d = 2 \) (see equation (6)): \( a = \eta z \approx 0.115 \) (\( \eta = 1/4 \) and \( z = 2.1667(5) \) [38]) and \( \theta = 0.383(3) \) [3, 39]. Accordingly, the comparison of the observed behavior of \( R(t, s) \) in the aging regime with LSI.1 fixes \( \alpha = a \) and \( \beta = \theta \) in equation (15), leaving \( \Delta \alpha \) as the only undetermined exponent. In [21]

\[
\Delta \alpha = 0.187(20)
\]

has been determined as the best parameter value to fit—actually with no visible corrections—the numerical data of \( \chi^{(k)}(t, s) \) with the prediction (15) of LSI.1. As pointed out in section 2, if the scaling behavior of \( R(t, s) \) is actually captured by LSI.1 with \( \Delta \alpha \neq 0 \) then in the short-time separation regime \( \tau \gg s \gg \tau_{\text{micr}} \) one will have \( R(t, s) \sim s^{-\Delta \alpha - 1-\alpha + \Delta \alpha} \) (see equation (16)), instead of the generally expected quasi-equilibrium behavior \( R(t, s) \sim \tau^{-1-\alpha} \) (see equation (3) and (9)). In order to test these two qualitatively different predictions we focus on the behavior of \( T_c R(t, s) \) in the STSR,
The non-equilibrium response of the critical Ising model

Figure 1. Autoresponse function $R(t, s)$ as a function of $\tau = t - s$ for different values of $s = 4 \times 10^3, 5 \times 10^3, 7.5 \times 10^3$ and $10^4$. The dashed line indicates the power-law behavior $R(t, s) \sim \tau^{-1-a}$ with $a = 0.115$ (see equation (6)). The box indicates the points used to fit the value of the exponent $a_{\text{MC}}$ (see the main text). In the inset $R(t, s)$ is plotted as a function of $s$ for fixed $\tau = 10$. The dashed line indicates the behavior $\propto s^{-\Delta \alpha}$ predicted by LSI.1, with $\Delta \alpha$ given by equation (23). The box contains the points also present in the main figure.

reported in figure 1. The scaling behavior is expected to set in for $\tau, s \gg \tau_{\text{micr}}$, i.e. the actual STSR is restricted to $\tau_{\text{micr}} \ll \tau \ll s$. In the inset of figure 1 we report, for fixed $\tau = 10 \gg \tau_{\text{micr}} \simeq 1$, the behavior of $T_c R(t, s)$ upon increasing $s$, eventually probing the STSR. In particular, according to LSI.1, one expects $R(s + 10, s) \sim s^{-\Delta \alpha}$, whereas the actual data seemingly attain a plateau for $s \geq 3 \times 10^3$ (highlighted by a box in the inset) setting an upper bound to the asymptotic value of $\Delta \alpha$: $\Delta \alpha < 0.029(8)$, which definitely excludes the value (23) indicated in the inset as a dashed line. It seems therefore reasonable to conclude that $\Delta \alpha = 0$ for large enough $s$. Note, however, that the behavior of $R(s + 10, s)$ for $s \lesssim 10^3$ could be easily fitted by a power law with an effective exponent $\Delta \alpha_{\text{eff}} \simeq 0.1$ which seemingly increases upon decreasing the largest value of $s$ included in the fit. If this observation carries over to the case of $\chi_f^{(g)}(t, s)$ analyzed in [21], it might explain the quite large $\Delta \alpha$ (23) which has been determined there on the basis of data with $s < 200$. Repeating the previous analysis for different values of $\tau$ we conclude that for $s \geq 3 \times 10^3$ (highlighted by a box in the inset) and $\tau < 10^2$ (corresponding to $\tau/s \leq 0.032$), $R(\tau + s, s)$ is actually very close to its plateau value in the STSR, although small corrections of the order of $\tau/s$ are still present. The data corresponding to this selected range of $\tau$ and $s$, reported in the main plot in figure 1, display a quite good collapse onto a master curve $R(\tau + s, s) \sim \tau^{-1-a_{\text{MC}}}$ with $a_{\text{MC}} \simeq 0.095(2)$ when fitted in the region $5 \leq \tau \leq 30$ (the corresponding points are highlighted by a box in the main plot of figure 1). This value is in reasonable agreement both with $a = 0.115(2)$ and with $a - \Delta \alpha$, which are expected on the basis of equations (3) and (9) of LSI.1 with $\Delta \alpha < 0.02$, respectively. In comparing these values one has to take into account that our Monte Carlo estimate $a_{\text{MC}} \simeq 0.095(2)$ is seemingly affected by a systematic correction which reduces $a_{\text{MC}}$ compared to its asymptotic value for $s \to \infty$.

J. Stat. Mech. (2008) P02013

9
Although the analysis of the scaling behavior of the response function in the STSR does not allow us to rule out the validity of LSI.1, at least it definitely indicates that $\Delta \alpha < 0.02$.

A more effective comparison between the numerical data and the different theoretical predictions can be done by considering the quantity

$$g_R(t, s) \equiv \tau^{1+u} u^{-\theta} R(t, s),$$

for arbitrary $t > s$. According to the general scaling behavior equation (5), one expects

$$g_R(t, s) = A_R f_R(u),$$

i.e. $g_R(t, s)$ depends only on $u = t/s$ and is such that $\lim_{t \to s} g_R(t, s) = A_R$. In addition, within the RG approach, $f_R(u)$ satisfies the condition (7), whereas within LSI.1 $f_R(u)$ is given by

$$f_R^{(LSI.1)}(u) = u^{-\Delta \alpha} (u - 1)^{\Delta \alpha}$$

(compare equation (15) with equation (5)), resulting in two different limiting behaviors for $u \to 1$:

$$\lim_{t \to s} g_R(t, s) = \begin{cases} B_R, & \text{RG,} \\ A_R (u - 1)^{\Delta \alpha}, & \text{LSI.1,} \end{cases}$$

where $B_R = A_R f_R(1^+) \neq 0$ (see after equation (9)). The qualitative difference between RG and LSI.1 in the STSR translates into the fact that, for small values of the abscissa, they predict the occurrence of a plateau and a power-law behavior with exponent $\Delta \alpha$, respectively, when $g_R(t, s)$ is plotted as a function of $u - 1$. The log–log plot of $g_R(t, s)$ is presented in figure 2 for $s = 10^3, 2 \times 10^3, 7.5 \times 10^3$ and $10^4$, which extend considerably the range of times investigated in [21,27], with $s \leq 200$. We report only data with $\tau > 2$ because, as discussed in section 1, scaling sets in only for $\tau \gg \tau_{\text{micr}} \simeq 1$. For a fixed value of $s$, the statistical uncertainty affecting the data points in figure 2 increases upon increasing $u - 1$, i.e. $t$, due to the fact that the value of the response function $R(t, s) \to 0$ becomes increasingly small and therefore comparable with statistical fluctuations. As a consequence of the typical scaling (4), this effect is expected to be more severe upon increasing $s$, as is confirmed by comparing the data points with $s = 10^4$ and $10^2$. The resulting data collapse in figure 2 is quite good (within the error bars) and confirms that no significant corrections to scaling are present. From the behavior of $g_R(t, s)$ at large $u - 1$ one determines the non-universal constant $A_R$:

$$A_R = 0.071(2)$$

(obtained by fitting the data with $s = 100$ and $u > 7$), whereas in the opposite limit $u \to 1^+$ one finds (from the data with $s = 7.5 \times 10^3, 10^4$ and $u - 1 < 1.2 \times 10^{-3}$)

$$B_R = 0.040(1),$$

and therefore one estimates

$$f_R(1^+) = B_R/A_R = 0.56(3).$$
The non-equilibrium response of the critical Ising model

Figure 2. Scaling function $g_R(t, s)$ (see equation (24)) as a function of $u - 1$ ($u = t/s > 1$) for $s = 100$, 2000, 7500 and 10 000. The solid line is the prediction of LSI.0 whereas the dashed and dashed–dotted lines are those of LSI.1 with $\Delta \alpha = 0.187$ and 0.115, respectively. In all these cases the values $\theta = 0.38$, $a = 0.115$ and $A_R = 0.07$ have been used.

3.1.1. Comparison with the available field-theoretical results. Note that $g_R(t, s)/A_R = f_R(u)$ characterizes the universal scaling behavior of the response function within the Ising universality class with purely dissipative dynamics. In turn, this fact can be used in order to determine the associated scaling function in simplified models, e.g. field-theoretical (FT) ones [3,32,40] belonging to this universality class. In particular, in [40] the scaling function for the spatial Fourier transform of $R_r(t, s)$ (equation (1)) was determined up to the first order in $\epsilon = 4 - d > 0$ where $d$ is the spatial dimensionality of the model. This result allows the calculation of $f_R(u)$ (see equations (5) and (24)), yielding

$$f_R^{(\text{FT})}(u) = 1 + O(\epsilon^2),$$

(31)

which actually does not reproduce the non-trivial behavior observed in figure 2 and the actual value of $f_R(1^+)$ determined numerically (see equation (30)). On the other hand, as in the case of the scaling function of $\sum_r R_r(t, s)$ studied analytically in [32], one expects non-trivial corrections to $f_R^{(\text{FT})}(u)$ at $O(\epsilon^2)$ which might reproduce at least the qualitative features of the numerical data (such as the fact that $g_R(t, s) \leq A_R$). The calculation of such corrections, however, is beyond the scope of the present study.

3.1.2. Comparison with LSI. The master curve in figure 2 clearly exhibits a plateau at small $u - 1$ which excludes the power-law behavior predicted in this regime by LSI.1 (or, at least, it reduces significantly the upper bound to $\Delta \alpha$ which results from figure 1)$^7$. This conclusion is also confirmed by comparing the numerical data for $g_R(t, s)$ with the prediction (25), where $f_R(u)$ is given by equation (26) and $A_R$ by the fitted value (28).

$^7$ Fitting the points in the region $u - 1 < 10^{-3}$ with $A_{\alpha 0}(u - 1)^{\Delta \alpha}$ one finds $-0.01 \lesssim \Delta \alpha \lesssim +0.015$ depending on the value of $s$ which corresponds to the selected points.
In figure 2 we present this comparison for $\Delta \alpha = 0$ (solid line), corresponding to LSI.0, $\Delta \alpha = 0.187$ (dashed line), corresponding to the estimate (23) of [21], and $\Delta \alpha = 0.115$ (dashed–dotted line)—which we have determined from the best fit to the actual data. Clearly, both LSI.0 and LSI.1 with the value of $\Delta \alpha$ determined in [21] do not capture correctly the scaling behavior of the response function already for $u \approx 6$ and in particular they overestimate and underestimate the numerical $g_R(t, s)$, respectively. The choice $\Delta \alpha = 0.115$, however, results in a good fit of the numerical data down to $u-1 \approx 2 \times 10^{-2}$. In spite of that, sizable discrepancies are anyhow observed for smaller values of $u-1$ (STSR) and no further improvement is actually possible by varying $\Delta \alpha$. In passing we mention that a similar situation is also encountered when comparing the predictions of LSI.1 with the scaling behavior of the aging response function within the directed percolation universality class [28, 29].

The conclusion we can draw so far is that the scaling behavior of the impulse response function $R(t, s)$ does not agree with the prediction of LSI.1 even though the latter actually provides a good fit to the numerical data for $t/s - 1 \gtrsim 2 \times 10^{-2}$.

### 3.2. Integrated local response functions

In this subsection we discuss the behavior of the local integrated response function (see equation (17)), which is given by

$$
\chi^{(l)}_I(t, s) = \chi(t, [s/2, s])
$$

measured in the simulations. This integrated response function has also been considered in [6, 7].

According to the general scaling behavior of $R(t, s)$ (see equation (5)), one expects

$$
\chi^{(l)}_I(t, s) = A_R s^{-a} u^{\theta-1} (u-1)^{-\alpha} f_{\chi, I}(u),
$$

where the universal scaling function $f_{\chi, I}(u)$ is given, in terms of the scaling function $f_R$, by

$$
f_{\chi, I}(u) = (1 - u^{-1})^a \int_{1/2}^{1} dx x^{-\theta} \left(1 - \frac{x}{u}\right)^{-1-a} f_R(u/x),
$$

and is such that $f_{\chi, I}(u \gg 1) = \kappa_\theta$ with $\kappa_\theta = (1 - 2^{-1+\theta})/(1 - \theta)$ ($\kappa_\theta \approx 0.564$ in two dimensions). In particular, the prediction of LSI.1 is obtained from $f^{(LSI.1)}_R(u)$ given in equation (26):

$$
f^{(LSI.1)}_{\chi, I}(u) = \left(\frac{1 - u^{-1}}{1 - \theta}\right) [\, 2F_1(1 - \theta, 1 + a - \Delta \alpha, 1/u) \right.

- 2^{\theta-1} 2F_1(1 - \theta, 1 + a - \Delta \alpha, 1/(2u))],
$$

where $2F_1$ is the hypergeometric function and the case of LSI.0 is recovered for $\Delta \alpha = 0$.

In order to compare the different theoretical predictions we consider the function

$$
g_{\chi, I}(t, s) \equiv \tau^\alpha u^{1-\theta} \chi^{(l)}_I(t, s),
$$

which, according to equation (32), is a function of $u = t/s$

$$
g_{\chi, I}(t, s) = A_R f_{\chi, I}(u),
$$

doi:10.1088/1742-5468/2008/02/P02013 12
Figure 3. Scaling function $g_{\chi,l}(t, s)$ (see equation (35)) as a function of $u - 1$ ($u = t/s > 1$) for $s = 50, 200, 600$ and $2000$. The solid line is the prediction of LSI.0 whereas the dashed and dashed–dotted lines are those of LSI.1 with $\Delta \alpha = 0.187$ and $0.115$, respectively. In all these cases the values $\theta = 0.38$, $a = 0.115$ and $A_R = 0.07$ have been used. The horizontal dashed line on the left (right) indicates the limiting value $B_R/a$ ($A_R \kappa_\theta$) expected for $u \to 1$ ($u \to \infty$) according to the RG and scaling behavior (see equation (37)) where $A_R$ and $B_R$ have been determined from the behavior of $g_R(t, s)$ (see equations (28) and (29)).

such that $A_{\chi,l} \equiv \lim_{t \gg s} g_{\chi,l}(t, s) = A_R \kappa_\theta$. In the opposite limit, instead,

$$
\lim_{t \to s} g_{\chi,l}(t, s) = \begin{cases} 
B_{\chi,l} = B_R/a, & \text{RG,} \\
A_R(u - 1)^{\Delta \alpha}/(a - \Delta \alpha), & \text{LSI.1},
\end{cases}
$$

which is valid under the assumption $a, a - \Delta \alpha > 0$ and which reflects the different behaviors of $f_R(u \to 1^+)$ within RG and LSI.1 (see equations (7) and (26), respectively). In figure 3 we plot $g_{\chi,l}(t, s)$ for different values of $s$, which are slightly larger than those considered in [21, 27] but smaller than the larger values which figure 2 refers to. For $s \geq 600$ and $u - 1 \gtrsim 10^{-2}$ one observes a rather good collapse onto a single master curve which depends only on $u$, in agreement with the scaling (32). At smaller values of $u - 1$ the actual scaling behavior is accessed only for increasingly larger values of $s$ such that $\tau = t - s > \tau_{\text{micr}}$, i.e. for $s > \tau_{\text{micr}}/(u - 1)$. From the large-$u$ behavior of $g_{\chi,l}(t, s)$ we determine the non-universal constant

$$
A_{\chi,l} = 0.036(3),
$$

in marginal agreement with the expected value $A_R \kappa_\theta = 0.040(1)$ resulting from the estimate of $A_R$ given in equation (28). Note that, while $g_R(t, s) \leq A_R$, here we find $g_{\chi,l}(t, s) \geq A_{\chi,l}$.

3.2.1. Comparison with the available field-theoretical results. The universal scaling behavior of $\chi^{(l)}_I(t, s)$ within the Ising universality class with purely dissipative dynamics is characterized by $g_{\chi,l}(t, s)/A_{\chi,l} = f_{\chi,l}(u)$ which can also be studied within field-theoretical
models [3, 32, 40]. As a consequence of the fact that $f_R^{(FT)}(u) = 1 + O(\epsilon^2) = f_R^{(LSI0)}(u) + O(\epsilon^2)$ (see equations (31) and (26) with $\Delta \alpha = 0$), one finds, from equation (33), $f_{\chi,1}^{(FT)}(u) = f_{\chi,1}^{(LSI0)}(u) + O(\epsilon^2)$, where $f_{\chi,1}^{(LSI0)}(u)$ is given by equation (34) with $\Delta \alpha = 0$. The resulting prediction $A_Rf_{\chi,1}^{(FT)}(u)$ for $g_{\chi,1}(t, s)$ is shown in figure 3 as LSI0: the differences with the numerical data are less severe than in the case of $A_Rf_{\chi,1}^{(FT)}(u)$ for $g_R(t, s)$ in figure 2. In particular, for $u \to 1^+$ one has $f_{\chi,1}^{(FT)}(1^+) = f_{\chi,1}^{(LSI0)}(1^+) + O(\epsilon^2) = 1/\alpha + O(\epsilon^2)$ (see equation (34) with $\Delta \alpha = 0$ and $u \to 1^+$), yielding the plateau in the FT prediction reported in figure 3 as a dashed line, which overestimates the actual numerical value. It would be interesting to see whether the corrections of $O(\epsilon^2)$ to $f_{\chi,1}^{(FT)}(u)$ account for such a difference.

3.2.2. Comparison with LSI. As in the case of the impulse response function, the different qualitative behavior of the LSI1 and RG predictions should be displayed for $u \to 1$ according to equation (37), but the data presented in figure 3 are not actually able to detect such a difference. However, the trend of the data is compatible with the RG prediction $\lim_{s \to s_{\text{eq}}} g_{\chi,1}(t, s) = B_R/\alpha \simeq 0.35$ (see equation (29)). For comparison we plot also equation (36) with $f_{\chi,1}^{(LSI1)}$ predicted by LSI (see equation (34)), $A_R = 0.063$ (note that this is slightly smaller than the previous estimate equation (28)) and for the different values of $\Delta \alpha$ already considered in figure 2: $\Delta \alpha = 0$ (solid line), corresponding to LSI0, $\Delta \alpha = 0.187$ (dashed line), corresponding to the estimate (23) of [21], and $\Delta \alpha = 0.115$ (dashed–dotted line). As in the case of $R(t, s)$, both LSI0 and LSI1 with $\Delta \alpha = 0.187$ do not provide a good approximation of the actual data already for $u \to 1 \lesssim 0.1$ and 1, respectively, whereas LSI1 with $\Delta \alpha = 0.115$ shows visible discrepancies only for $u \to 1 \lesssim 4 \times 10^{-3}$, when compared to the curve with $s = 2000$, which is expected to display smaller corrections to scaling. The result of the integration over time has been to reduce by almost one order of magnitude the value of $u \to 1$ below which LSI1 with $\Delta \alpha = 0.115$ does not agree with the numerical data in the scaling regime (from $\simeq 2 \times 10^{-2}$ for $R(t, s)$ to $\simeq 2 \times 10^{-3}$ for $\chi_{\chi,1}(t, s)$). By looking solely at figure 3 one would naturally conclude that the scaling behavior of $\chi_{\chi,1}(t, s)$ is actually described by LSI1 with $\Delta \alpha = 0.115$: the corrections for $u \to 1 \lesssim 4 \times 10^{-3}$ seemingly vanish upon increasing $s$.

3.3. Integrated global response functions

We finally consider the global intermediate response function $\chi_{\chi,1}^{(g)}(t, s)$ (see equation (14)) which was introduced and studied in [27] in order to highlight discrepancies between the numerical data and the prediction of LSI0 in the case of the two- and three-dimensional Ising model with Glauber dynamics. The same data presented in [27] have later on been found in agreement with the prediction of LSI1 [21]. In terms of the quantity (19) measured in the simulations, $\chi_{\chi,1}^{(g)}(t, s)$ is given by $\chi_{\chi,1}^{(g)}(t, s) = \chi_{k=0}(t, [s/2, s])$ and it is therefore a space-integrated, or global, quantity. In fact, $\sum_{\mathbf{r}} R_{\mathbf{r}}(t, t')$ is the response function of the total magnetization.

8 Within FT, $a = O(\epsilon^2)$ and therefore $f_{\chi,1}^{(FT)}(u)$ up to $O(\epsilon^2)$ would be logarithmically divergent for $u \to 1^+$. On the other hand, one can improve the estimate of $f_{\chi,1}^{(FT)}(1^+)$ by using in equation (34) the actual values of the exponents in two dimensions.
In this subsection we focus on the comparison between $\chi_I^{(g)}(t, s)$ and LSI, being the one with the corresponding field-theoretical predictions [32] already discussed in [27].

According to general scaling arguments (see, e.g., [3, 27]), the global response function $\hat{R}_{k=0}(t, s)$ is predicted to be

$$\hat{R}_{k=0}(t, s) = A_R s^{1-a+d/z} u^\theta (u - 1)^{1-a+d/z} \mathcal{F}_R(u),$$

(39)

where the non-universal constant $A_R$ is fixed by the condition $\mathcal{F}_R(u \gg 1) = 1$, and the function $\mathcal{F}_R(u)$ is universal. Within the RG approach one additionally finds that $\mathcal{F}_R(1^+) \neq 0$ and finite, in analogy to equation (7). As a result of the factorization (13) of the space dependence of $R_r(t, s)$, the scaling behavior of the Fourier transform $\hat{R}_{k=0}(t, s) = \int d\mathbf{r} R_r(t, s)$ is given by equation (39) with

$$\mathcal{F}_R^{(LSI.1)}(u) = u^{-\Delta \alpha} (u - 1)^{\Delta \alpha},$$

(40)

i.e. it has the same expression as in the case of $R(t, s)$ but with the formal substitutions $A_R \rightarrow A_R = A_R \int d\mathbf{x} \Phi(\mathbf{x})$ and $a \rightarrow a - d/z$. Note that, as in the case of the local response function, LSI.1 and scaling arguments predicts two qualitatively different behaviors of $\mathcal{F}_R(u \rightarrow 1^+)$. The scaling form of $\chi_I^{(g)}(t, s)$ is easily calculated on the basis of equation (39), yielding

$$\chi_I^{(g)}(t, s) = A_R t^{-a+d/z} u^{\alpha-1} f_{\chi_{LSI}}(u),$$

(41)

where

$$f_{\chi_{LSI}}(u) = \int_{1/2}^{1} dx x^{-\theta} \left(1 - \frac{x}{u}\right)^{-1-a+d/z} \mathcal{F}_R(u/x),$$

(42)

such that $f_{\chi_{LSI}}(u \gg 1) = \kappa_\theta$. In particular the prediction of LSI.1 is readily found as (see equations (33) and (34))

$$f_{\chi_{LSI}}^{(LSI.1)}(u) = \int_{1/2}^{1} dx x^{-\theta} \left(1 - \frac{x}{u}\right)^{-1-a+d/z+\Delta \alpha} = \left[(1 - u^{-1})^{-a} f_{\chi_{LSI}}^{(LSI.1)}(u)\right]_{a \rightarrow a - d/z}.$$

(43)

As in the previous cases, in order to compare the numerical data with the prediction of LSI.1 we consider the quantity

$$g_{\chi_{LSI}}(t, s) \equiv t^{a-d/z} u^{1-\theta} \chi_I^{(g)}(t, s),$$

(44)

which, according to equation (41), is a function of $u = t/s$:

$$g_{\chi_{LSI}}(t, s) = A_R f_{\chi_{LSI}}(u),$$

(45)

such that $A_{\chi_{LSI}} \equiv \lim_{t \rightarrow s} g_{\chi_{LSI}}(t, s) = A_R \kappa_\theta$. Differently from the previous cases, the behavior of $g_{\chi_{LSI}}(t, s)$ for $t \rightarrow s$ is predicted to be qualitatively the same both by scaling arguments and LSI.1: the integral in equation (42) is finite for $u \rightarrow 1$, whatever the actual behavior of $\mathcal{F}_R(x/u \rightarrow 1^+)$ is, as long as $\mathcal{F}_R(u \rightarrow 1^+) \sim (u - 1)^\sigma$ with $\sigma > a - d/z$, which is the case here. In figure 4 we plot $g_{\chi_{LSI}}(t, s)$ for different values of $s$, which are comparable to those considered in [21, 27] but generally smaller than the values which figures 2 and 3 refer to. The datasets corresponding to $s = 200$ and 400 collapse to a reasonable extent, whereas the set corresponding to $s = 50$ still departs from the previous two because of corrections to the scaling behavior. For larger values of $u - 1$, instead, statistical errors
Figure 4. Scaling function $g_{\chi, g}(t, s)$ (see equation (44)) as a function of $u - 1$ ($u = t/s > 1$) for $s = 50$, 200 and 400. The solid line is the prediction of LSI.0 whereas the dashed and dashed–dotted lines are those of LSI.1 with $\Delta \alpha = 0.187$ and 0.115, respectively. The two additional dashed lines represent the upper and lower bound to $\Delta \alpha$ provided in [21] and resulting from the fit of $\chi_I^{(g)}(t, s)$ with the prediction of LSI.1. In all these cases $\theta = 0.38$, $a = 0.115$, and $A_R = 0.3895$ have been used.

$\Delta \alpha = 0.187$

Figure 4. Scaling function $g_{\chi, g}(t, s)$ (see equation (44)) as a function of $u - 1$ ($u = t/s > 1$) for $s = 50$, 200 and 400. The solid line is the prediction of LSI.0 whereas the dashed and dashed–dotted lines are those of LSI.1 with $\Delta \alpha = 0.187$ and 0.115, respectively. The two additional dashed lines represent the upper and lower bound to $\Delta \alpha$ provided in [21] and resulting from the fit of $\chi_I^{(g)}(t, s)$ with the prediction of LSI.1. In all these cases $\theta = 0.38$, $a = 0.115$, and $A_R = 0.3895$ have been used.

Figure 4. Scaling function $g_{\chi, g}(t, s)$ (see equation (44)) as a function of $u - 1$ ($u = t/s > 1$) for $s = 50$, 200 and 400. The solid line is the prediction of LSI.0 whereas the dashed and dashed–dotted lines are those of LSI.1 with $\Delta \alpha = 0.187$ and 0.115, respectively. The two additional dashed lines represent the upper and lower bound to $\Delta \alpha$ provided in [21] and resulting from the fit of $\chi_I^{(g)}(t, s)$ with the prediction of LSI.1. In all these cases $\theta = 0.38$, $a = 0.115$, and $A_R = 0.3895$ have been used.

increase due to poor statistics. However, our point here is not to determine the scaling function with high accuracy, but to compare its features to those of the prediction of LSI.1. As was already clear from the numerical results presented in figure 2(a) of [27], $g_{\chi, g}(t, s)$ does not vary too much as a function of $u$, being almost flat for $0.3 \lesssim u - 1 \lesssim 10$ while slightly increasing upon decreasing $u - 1 < 0.3$ (about 2% in the interval $0.05 \lesssim u - 1 \lesssim 0.3$) and decreasing upon increasing $u - 1 > 10$ (by less than 2%). Analogous behavior has been observed in the three-dimensional Ising model (see figure 2(b) in [27]). From the large-$u$ behavior of $g_{\chi, g}(t, s)$ we estimate the non-universal constant

$$A_{\chi, g} = 0.221(1)$$

(46)

(which has actually been obtained on the basis of the data with $s = 200$ and $u \geq 3$). In figure 4 we also plot $A_R f_{\chi, g}^{(LSI.1)}(u)$ where $f_{\chi, g}^{(LSI.1)}(u)$ is given by equation (42) and $A_R = A_{\chi, g}/\kappa_\theta$ has been fixed to 0.3895. In particular we report the predictions for $\Delta \alpha = 0$ (solid line), $\Delta \alpha = 0.115$ (dashed–dotted line) and $\Delta \alpha = 0.187(20)$ (dashed and dotted lines). The prediction of LSI.1 with $\Delta \alpha = 0.187$ provides a quite good fit of the actual scaling behavior, in complete agreement with what was found in [21], where this value of $\Delta \alpha$ was determined as the best-fit parameter. By looking at the integral in the expression of $f_{\chi, g}^{(LSI.1)}(u)$ (see equation (43)) it becomes clear why $f_{\chi, g}^{(LSI.1)}(u)$ is so accurate in reproducing the almost constant behavior of the numerical data for $g_{\chi, g}(u)$

9 The raw data for $\chi_I^{(g)}(t, s)$ corresponding to figure 4 do actually reproduce those presented in [21, 27] after a multiplication by a normalization factor $\sim 1.57/T_c \simeq 0.692$. 

doi:10.1088/1742-5468/2008/02/P02013
as a function of \( u \): for \( \Delta \alpha = \Delta \alpha_0 \equiv 1 + a - d/z, f_{x_s}^{(LSI.1)}(u) \) becomes constant. In two dimensions one finds \( \Delta \alpha_0 = 0.192(2) \) which is within the interval determined in [21]. On the other hand, both the prediction of LSI.1 with \( \Delta \alpha = 0.115 \)—which was providing the best fit to \( R(t, s) \)—and of LSI.0 are quite far from the actual numerical data. In particular, the fact that LSI.1 with \( \Delta \alpha = 0.115 \) well describes both \( R(t, s) \) and \( \chi^{(l)}(t, s) \) but not \( \chi^{(g)}(t, s) \) suggests that the factorization of the space dependence (13) might not be a good approximation of the actual scaling behavior.

On the basis of figures 2–4 we can conclude that possible integrations of local quantities over time and over space strongly affect the agreement between numerical data and the corresponding prediction of LSI.1. Accordingly, the exponent \( \Delta \alpha \) which characterizes such a prediction cannot be regarded as an additional model-dependent exponent but simply as a fitting parameter, the optimal value of which depends on the specific quantity considered. Indeed, LSI.1 with \( \Delta \alpha = 0.187(20) \) describes correctly the behavior of \( \chi^{(g)}(t, s) \) but it fails in the case of the related \( \chi^{(l)}(t, s) \). Conversely, LSI.1 with \( \Delta \alpha = 0.115 \) describes very well, for \( t/s - 1 > 10^{-2} \), the behavior of both \( R(t, s) \) and \( \chi^{(l)}(t, s) \) but it fails in the case of the global response function \( \chi^{(g)}(t, s) \).

4. Quenches to \( T_f < T_c \)

In section 1 we have pointed out that the prediction (16) of LSI.1 with \( \Delta \alpha \neq 0 \) does not become stationary in the STSR, in contrast to what the response function actually does. Even arguing that the validity of LSI.1 might be restricted only to the aging regime does not help for quenches at the critical point: The multiplicative structure in equations (8) and (10)—a direct consequence of scale invariance—leaves no room for LSI.1 to describe \( R^{(ag)}(t, s) \) without spoiling the quasi-equilibrium behavior of \( R(t, s) \) in the STSR. For \( T_f < T_c \), however, the crossover between \( R^{(eq)}(\tau; T_f) \) and \( R^{(ag)}(t, s) \) does not occur multiplicatively but additively, as we shall discuss shortly. Then, the criticism moved to LSI.1 for critical quenches does not extend to below \( T_c \).

Indeed, in quenches below \( T_c \), two-time quantities such as the autoresponse function naturally split as [1, 41, 42]

\[
R(t, s) = R^{(eq)}(\tau; T_f) + R^{(ag)}(t, s). \tag{47}
\]

This additive structure is a direct consequence of the phenomenology of phase ordering [17], where a patchwork of compact growing domains, internally in equilibrium, evolve through defect displacement and/or annihilation. Fast equilibrium fluctuations inside domains are responsible for \( R^{(eq)}(\tau; T_f) \), whereas the slow degrees of freedom associated to the dynamics of defects give rise to \( R^{(ag)}(t, s) \). One easily verifies that equation (47) renders equation (3) in the STSR when \( R^{(ag)}(t, s) \) is given by equations (5) and (11) (i.e., by LSI.1): In this sector, in fact, \( u = 1 + \tau/s \rightarrow 1 \) and therefore \( R^{(ag)}(t, s) \sim s^{-\Delta \alpha \tau - 1 - a + \Delta \alpha} \), which, if \( \Delta \alpha > 0 \), becomes negligible for \( s \rightarrow \infty \) in comparison to \( R^{(eq)}(\tau; T_f) \). In the aging regime, instead, the opposite is true: \( R^{(eq)}(\tau; T_f) \) for \( u > 1 \) becomes negligible compared to \( R^{(ag)}(t, s) \). In scalar systems, which we are interested in here, this is due to the fast (exponential) decay of \( R^{(eq)}(\tau; T_f) \) over a timescale \( \tau^{(eq)}(T_f) \sim \xi^{(eq)}(T_f) \), where \( \xi(T_f) \) is the correlation length of the equilibrium state at \( T = T_f \) with broken symmetry. In the aging regime one eventually has \( \tau \gg \tau^{(eq)}(T_f) \) and hence

doi:10.1088/1742-5468/2008/02/P02013

17
The non-equilibrium response of the critical Ising model

$R^{(eq)}(\tau; T_f)$ becomes (exponentially) small compared to $R^{(ag)}(t, s)$ for $u > 1$, yielding $R(t, s) = R^{(ag)}(t, s)$, i.e. the response function is very well approximated by $R^{(ag)}(t, s)$.

Now, as stated in the introduction, in the analytically solved instances of phase ordering such as the $d = 1$ Ising model [9, 10] quenched to $T_f = 0$ (see footnote 6) and the time-dependent Ginzburg–Landau model within the Gaussian auxiliary field approximation [11]–[13], equation (11) holds. This result has also been verified with high accuracy via numerical simulation of the Ising model in 2, 3 and 4 dimensions with Glauber dynamics [6, 7], where $z_g = 2$, and of the one-dimensional Ising model with Kawasaki dynamics [35], where $z_k = 3$. Therefore, in the case of subcritical quenches the form of $R^{(ag)}(t, s)$ predicted by LSI.1 would fit in the analytical and numerical results with

$$\Delta \alpha = 1/z_k.$$  \hfill (48)

It must be stressed that, contrary to the case of critical quenches, $\Delta \alpha \neq 0$ is not in conflict with the time-translational invariant behavior of the response function at short times because of the additive structure of equation (47). Note, however, that numerical results for $\chi(t, [0, s])$ and $\chi_{k=0}(t, [0, s])$ in the two- and three-dimensional Ising model with Glauber dynamics [15], quenched to $T_f < T_c$, are seemingly consistent with $\Delta \alpha = 0$ (see [25] for more details). This conclusion might be biased by the fact that these quantities, at variance with $R(t, s)$ studied in [7], are affected by quite large corrections to scaling [6].

5. Summary and conclusions

We have studied in detail, via Monte Carlo simulations, the impulse autoresponse function $R(t, s)$ (see equations (1) and (2)) and the associated (intermediate) integrated local and global response functions $\chi_l(t, s)$ (equation (17)) and $\chi_g(t, s)$ (equation (14)), respectively, of the two-dimensional Ising model with Glauber dynamics, after a quench from high temperature to the critical point.

We highlighted the universal non-equilibrium scaling behaviors of these quantities and we compared them with the predictions derived from the theory of local scale invariance in its two recently proposed versions, referred to as LSI.0 (equations (12) and (13)) and LSI.1 (equations (15) and (13)). The scaling form of $R(t, s)$ predicted by LSI.1 depends on the additional parameter $\Delta \alpha$, compared to the prediction of LSI.0, which is actually recovered for $\Delta \alpha = 0$ (see section 1). On the basis of our numerical analysis we conclude that:

(i) $T_c R(t, s)$ becomes—as generally expected—time-translational invariant in the short-time separation regime which is accessed by increasing $s \gg \tau_{\text{micr}}$ while keeping fixed $\tau = t - s$ (see figure 1). This behavior is consistent with the prediction of LSI.0 but not with the one of LSI.1 (with $\Delta \alpha \neq 0$, see equation (15)).

(ii) The scaling behavior of $R(t, s)$ (see figure 2 and equation (24)) is correctly captured neither by LSI.0 nor by LSI.1. However, LSI.1 with $\Delta \alpha = 0.115$ yields a good fit of the actual data only for $t/s - 1 > 2 \times 10^{-2}$. Figure 2—properly normalized by $A_R$ (see equation (28))—provides a very accurate numerical determination of the universal

10 Note that in table 2 of [25] these models are questionably listed among those undergoing critical coarsening.
scaling function of $R(t, s)$ in a wider range of times compared to previous numerical studies.

(iii) Apparently, the scaling behavior of $\chi^{(l)}(t, s)$ (see figure 3 and equation (35)) is correctly captured by LSI.1 with $\Delta \alpha = 0.115$. The small discrepancies which are visible for $t/s - 1 < 4 \times 10^{-3}$ can be due either to non-universal correction to scaling (in which case they should disappear upon increasing $s$) or to the fact that the actual scaling function of $\chi^{(l)}(t, s)$ deviates from LSI.1 at smaller values of $t/s - 1$ (as in the case of $R(t, s)$). The data at our disposal do not allow one to discriminate between these two options.

(iv) In agreement with previous studies [27], we find that the scaling behavior of $\chi^{(g)}(t, s)$ (see figure 4 and equation (44)) is encoded in a scaling function $g_{\chi, g}(t, s)$ which varies less than 4% in a wide range of times. Although the quality of the data presented in figure 4 does not allow an accurate determination of the scaling function, it is sufficient in order to conclude that both LSI.0 and LSI.1 with $\Delta \alpha = 0.115$ have no chance to describe it correctly, whereas—as noted in [21]—LSI.1 with $\Delta \alpha = 0.187(20)$ actually provides a better approximation.

The evidence summarized above leads to the conclusion that the scaling forms predicted analytically by LSI.1 for the various quantities related to $R_r(t, s)$ provide, in some cases, accurate fitting forms but cannot be considered to be exact, at least for quenches at the critical point. It would be interesting to compare our numerical determination of the universal scaling function of $R(t, s)$ (see figure 2) with the predictions of different analytical approaches such as, for example, field-theoretical ones.
