Abstract

This paper introduces an assumption-lean method that constructs valid and efficient lower predictive bounds (LPBs) for survival times with censored data. We build on recent work by Candès et al. (2021), whose approach first subsets the data to discard any data points with early censoring times, and then uses a reweighting technique (namely, weighted conformal inference (Tibshirani et al., 2019)) to correct for the distribution shift introduced by this subsetting procedure.

For our new method, instead of constraining to a fixed threshold for the censoring time when subsetting the data, we allow for a covariate-dependent and data-adaptive subsetting step, which is better able to capture the heterogeneity of the censoring mechanism. As a result, our method can lead to LPBs that are less conservative and give more accurate information. We show that in the Type I right-censoring setting, if either of the censoring mechanism or the conditional quantile of survival time is well estimated, our proposed procedure achieves nearly exact marginal coverage, where in the latter case we additionally have approximate conditional coverage. We evaluate the validity and efficiency of our proposed algorithm in numerical experiments, illustrating its advantage when compared with other competing methods. Finally, our method is applied to a real dataset to generate LPBs for users’ active times on a mobile app.

1 Introduction

Survival analysis lies at the core of many important questions in clinical trials (Fleming and Lin, 2000; Singh and Mukhopadhyay, 2011), ecology (Muenchow, 1986), and other applied fields. In particular, one important problem is that of studying the behavior of survival time $T$, and how it relates to other features of the data, which we denote by a potentially high-dimensional feature vector $X$. Modeling the association between $X$ and $T$ can in turn play a crucial role in enabling more useful and reliable policy making. The major challenge is that these survival times are only partially observed due to censoring (Leung et al., 1997), which makes the statistical analysis quite non-routine—we are only able to observe the survival time $T$ if it occurs no later than some censoring time $C$. For example, $T$ may be the survival time of a patient (measured as time since diagnosis), which may be censored at a time $C$ that denotes the endpoint of the study that follows the patient.

One of many goals of survival analysis is to infer the survival function—the probability of survival beyond a given time—given the censored data. The Kaplan-Meier curve (Kaplan and Meier, 1958) can produce such inferences for sub-population with a particular covariate structure while making no assumption on the distribution of survival times, but it requires sufficiently many events in each subgroup (Kalbfleisch and Prentice, 2011). This assumption is no longer realistic in the modern era of big data, where with the ever-increasing ability to collect and store data, we can have access to a large number of (potentially continuous) covariates.

* Authors listed alphabetically.
Over the years, many tools have been developed to cope with such high dimensionality, offering estimation of the conditional survival function. One popular example in that line is the Cox model which posits a proportional hazard model: an unspecified non-parametric baseline is modified via a parametric model describing how the hazard varies in response to explanatory covariates (Cox, 1972; Breslow, 1975). Other popular parametric approaches include the accelerated failure time (AFT) model (Cox, 1972; Wei, 1992) and the proportional odds model (Murphy et al., 1997; Harrell Jr, 2015). More recently, we have witnessed more complex survival analysis methods that are based on machine learning/deep learning (Faraggi and Simon, 1995; Tibshirani, 1997; Gu and Li, 2005; Katzman et al., 2016; Lao et al., 2017; Wang et al., 2019; Li and Bradic, 2020). Despite the success of these methods in many areas, it remains largely unclear how to provide reliable uncertainty quantification for these methods. This is mainly because they posit model assumptions that are hard to verify and/or the algorithms themselves are too complicated to be analyzed. For these reasons, it is desirable to find a more assumption-lean or distribution-free approach towards reliable inference in survival analysis.

The recent work of Candès et al. (2021) proposes such an approach (which we will describe in detail below). As the target of inference, they propose computing a 100(1 − α)% lower prediction bound (LPB) for the survival time of a patient/unit, where α is a pre-specified level; it means that the patient/unit is expected to survive beyond this predicted time with at least 100(1 − α)% probability. The LPB is used to provide a summary of what we can infer about the individual’s survival time given available data, and it is important to note that the LPB can be low when either the true survival time is low or there is not enough information for us to get an informative lower bound; in other words, insufficient data should not lead to an invalid claim, but instead may lead to a less informative output.

### 1.1 Defining the lower prediction bound (LBP)

Let \( X \in \mathcal{X} \) denote the covariate vector, \( T \in \mathbb{R}_{>0} \) the survival time, and \( C \in \mathbb{R}_{\geq 0} \) the censoring time. Under censoring, the survival time \( T \) is observed only if it occurs before the censoring time \( C \). In other words, while the features \( X \) and the censoring time \( C \) are both observed, the survival time is observed only indirectly, via the censored survival time as \( \bar{T} = \min(T, C) \) (which may not be equal to \( T \)).

We now give the formal definition of a marginally calibrated LPB. Throughout, for a joint distribution \( P \) on \((X, C, T)\), we will write \( P_X, P_{(X,T)}, P_{(X,\bar{T})}, \) etc, to denote the corresponding marginal distributions, and \( P_{C|X}, P_{T|X}, P_{\bar{T}|X}, \) etc, to denote the corresponding conditional distributions.

**Definition 1** (Marginally calibrated LPB). Let \((X_i, C_i, T_i) \overset{iid}{\sim} P\) for data points \(i = 1, \ldots, n\), and let \(\hat{L}\) be a function of the observed data \(\mathcal{D} = \{(X_i, C_i, \bar{T}_i) : 1 \leq i \leq n\}\), where \(\bar{T}_i = \min(T_i, C_i)\) is the censored survival time. Then we say that \(\hat{L}\) is a marginally calibrated LPB at level \(1 - \alpha\) if it satisfies

\[
P_{(X,T) \sim P}(T \geq \hat{L}(X)) \geq 1 - \alpha, \tag{1}
\]

where this probability is taken with respect to both the available data \(\mathcal{D}\) and a new data point \((X, T) \sim P_{(X,T)}\).

The marginally calibrated LPB provides guarantee in an average sense—that is, over all the possible draws of the data, the coverage of the LPBs is guaranteed. However, in practical settings, we may be more concerned about the coverage guarantee we can obtain given the data at hand. There, the probably approximately correct (PAC)-type LPB defined below can be more informative (see also Vovk, 2012; Bates et al., 2021; Angelopoulos et al., 2021; Jin et al., 2021).

**Definition 2** (PAC-type LPB). Under the same notation as Definition 1, we say that \(\hat{L}\) is a PAC-type LPB at level \(\alpha\) with tolerance \(\delta\) if, with probability at least \(1 - \delta\) over the draw of \(\mathcal{D}\),

\[
P_{(X,T) \sim P}(T \geq \hat{L}(X) | \mathcal{D}) \geq 1 - \alpha
\]

where the probability is now taken with respect to a new data point \((X, T) \sim P_{(X,T)}\).

Throughout, we adopt the conditionally independent censoring assumption.

**Assumption 1** (Conditionally independent censoring). The joint distribution \(P\) of \((X, C, T)\) satisfies \(C \perp\!\!\!\perp T | X\).

This assumption is standard in the survival analysis literature, in order to ensure identifiability of the problem (see e.g., Kalbfleisch and Prentice, 2011).
1.2 An initial approach: inference on the censored survival time

As discussed by Candès et al. (2021), since the censored survival time $\bar{T}$ cannot be larger than $T$ by definition, any valid lower bound on $\bar{T}$ is trivially a lower bound on $T$. In other words, if an estimated lower bound $\hat{L}$ satisfies $P_{(X,C,T) \sim P}(\bar{T} \geq \hat{L}(X)) \geq 1 - \alpha$, then trivially Definition 1 is satisfied and so $\hat{L}$ is a marginally calibrated LPB. (Similarly, if $P(\bar{T} \geq \hat{L}(X) \mid D) \geq 1 - \alpha$ with probability at least $1 - \delta$, then by Definition 2 $\hat{L}$ is a PAC-type LPB.) Since the censored survival time $\bar{T}$ can be observed in the dataset at hand (and so $\hat{L}$ can be constructed to satisfy this property), this provides a mechanism for providing a valid LPB.

However, if the censoring time $C$ is often substantially smaller than $T$, then a valid lower bound on $\bar{T}$ may be extremely conservative as a lower bound on $T$ itself, thus reducing the utility of the constructed LPB. This suggests that such an approach may not be optimal for most applications. On the other hand, Candès et al. (2021) prove that, in the absence of any assumptions on the distribution $P$ on $(X,C,T)$, it is impossible to improve on this type of approach—specifically, their result (Candès et al., 2021, Theorem 1) proves that, for any construction $\hat{L}$ that satisfies Definition 1 universally over all distributions $P$, $\hat{L}$ must also satisfy $P(\bar{T} \geq \hat{L}(X)) \geq 1 - \alpha$. This motivates their introduction of an additional assumption, as we describe next.

1.3 Candès et al. (2021)’s approach: a cutoff on the censoring time

As described above, constructing an LPB on the censored survival time $\bar{T}$ may be too conservative in applications where the censoring time $C$ is frequently low, leading to censored times $\bar{T}$ that are far smaller than the true target of inference $T$. Candès et al. (2021)’s approach is to avoid this issue by discarding any training data points where $C$ is very low—specifically, for a constant cutoff $c_0$, they subset the data $\mathcal{D}$ to keep only data points $(X_i,C_i,\bar{T}_i)$ for which $C_i \geq c_0$. After this filtering step, any lower bound $\hat{L}$ on the remaining censored survival time $\bar{T}$ is no longer necessarily overly conservative, since the condition $C \geq c_0$ (with a well-chosen $c_0$) ensures that $\bar{T}$ is less likely to be far smaller than $T$. Thus, we can proceed by constructing an LBP $\hat{L}$ that is a lower bound on $\bar{T}$, in this new training sample.

Of course, we must then be careful about biasing the results because of this cutoff. In particular, since the event $C \geq c_0$ may be highly dependent on the covariates $X$, the remaining data is drawn from a distribution that is different from the target distribution $P$. To be more precise, writing $P^{\geq c_0}$ to denote the distribution of a data point $(X,C,T) \sim P$ given the event $C \geq c_0$, we see that the remaining data consists of samples from $P^{\geq c_0}$ while the inference goal is to provide coverage under the original distribution $P$. In other words, we would like to ensure that the marginal coverage bound (1) holds, but calibrating $\hat{L}(\cdot)$ naïvely on the remaining data would instead only ensure that $P_{(X,C,T) \sim P}^{\geq c_0}(T \geq \hat{L}(X)) \geq 1 - \alpha$, or equivalently, $P_{(X,T,C) \sim P}(T \geq \hat{L}(X) \mid C \geq c_0) \geq 1 - \alpha$.

To account for this shift in the distribution, Candès et al. (2021) utilize the method of conformal prediction under covariate shift (Tibshirani et al., 2019), which builds on the well-known conformal prediction framework for distribution-free predictive inference (Vovk et al., 2005). To do so, they additionally assume that we have exact or approximate knowledge of the dependence of censoring time $C$ on the covariates $X$—that is, knowledge of $P_{C \mid X}$, or more specifically, $P(C \geq c_0 \mid X)$. With this additional information, we can reweight the remaining data points to correct for the change in distribution—essentially, similarly to inverse propensity score weighting, weights $1/P_P(C \geq c_0 \mid X)$ can account for the difference between the target distribution $P$ and its filtered version $P^{\geq c_0}$. (Of course, the best value of $c_0$ will depend on the data distribution, and in practice can be chosen on a training set.)

1.4 Our approach: the benefits of a covariate-adaptive cutoff

In the method described above, how should the cutoff $c_0$ be chosen? The choice of $c_0$ presents a tradeoff: if $c_0$ is chosen to be too small, then the inequality $\bar{T} \leq T$ might be quite loose, and the constructed LPB $\hat{L}$ might still be very conservative even after filtering the data with the cutoff. On the other hand, if $c_0$ is chosen to be too large, then $P_P(C \geq c_0 \mid X)$ may be quite small (at least, for many values of $X$), leading to a low effective sample size, large weights $1/P_P(C \geq c_0 \mid X)$ on these data points, and highly unstable behavior. In fact, it is not always possible to find a constant $c_0$ that yields good LPBs, especially in cases when the
censoring time varies substantially with respect to the covariates $X$—selecting a large value of $c_0$ could cause highly unstable LPBs in areas where censoring times are low, whereas selecting a small value of $c_0$ leads to conservative LPBs in areas where censoring times are actually high. To be more specific, think of a simple example where $X \sim \text{Unif}(0,1)$ and $C = a \mathbb{I}\{X \geq \frac{1}{2}\} + b \mathbb{I}\{X < \frac{1}{2}\}$ with $a \gg b$; choosing $c_0$ to be greater than $b$ requires dropping half of the data and leads to increased variability; instead, selecting a $c_0 \leq b$ yields very conservative LPBs for $X \geq \frac{1}{2}$.

From the above discussion, we can see that it may be beneficial to allow $c_0$ to depend on $X$. That is, if $P(C \geq c_0|X)$ is extremely small then we may need to instead choose a lower value of $c_0$ to avoid high variance, but if $P(C \geq c_0|X)$ is close to 1 then we can afford to increase the value of $c_0$, thus avoiding an overly conservative LPB. To illustrate the benefits of this more flexible approach, we show a small simulated example.

We consider a univariate-covariate case, where $T$ and $C$ depend on $X$ via different models (the details are to be given in Section 4). The left panel of Figure 1 visualizes (one realization of) the censoring time and survival time as functions of the covariate. In this example, units with larger values of $X$ tend to have lower censoring times ($P(C|X = \text{Exp}(0.25 + (6 + x)/100))$), and thus we should choose a lower value of $c_0$ to avoid high variance (i.e., to avoid overly large weights $1/P(C \geq c_0|X)$); units with smaller values of $X$, on the other hand, tend to have larger values of $C$ and so we can afford to increase the value of $c_0$, leading to a less conservative LPB.

![Figure 1: Left: an illustration of the training sample for one trial of the experiment. Middle: boxplot of the coverage rate; the red dashed line corresponds to the target coverage rate $1 - \alpha = 90\%$. Right: boxplot of the LPBs. The results are from 100 independent trials.](image)

From this model, $n = 2,000$ independent samples are generated. We compare the baseline method introduced in Section 1.2 (referred to as DFT-baseline, where DFT is short for “distribution-free (LPB) for $T$”), Candès et al. (2021)’s fixed cutoff method (referred to as DFT-fixed cutoff), our new adaptive cutoff method (referred to as DFT-adaptive cutoff and to be defined shortly), and the Cox parametric model. The generated LPBs are then evaluated with an independent dataset of 5,000 test samples, and we display the coverage rate and the resulting LPB in the middle and right panels of Figure 1, respectively, with results gathered from 100 independent trials. The parametric method fails to cover the true survival time with desired probability; the baseline method and, to a lesser extent, the fixed cutoff method are conservative in this setting, returning a low (i.e., less informative) LPB. On the other hand, our adaptive cutoff method is able to avoid under- or over-coverage; it achieves essentially the target coverage rate and returns a higher (i.e., more precise) LPB.

## 2 Background

### 2.1 Covering the censored survival time via CQR

As described in Section 1.2, it is possible to provide an LPB on $T$ with no further assumptions by simply finding a lower bound on the censored survival time $\tilde{T} \leq T$. To do so, one approach is to use the Conformalized Quantile Regression (CQR) framework of Romano et al. (2019). To begin, we first partition the available $n$ data points into two data sets, a training set $I_1$ and a calibration set $I_2$—for instance, into two sets of

![Diagram](image)
random forests. If this quantile regression were fitted accurately, then we could simply use (2019) and Figure 6), leading to a quantile fitted model (see, e.g., the simulation results in Romano et al. (2019); Lei and Candès (2020); Candès et al. 2020). However, due to potential issues of overfitting, model misspecification, etc, we cannot rely on this being the case, and so the calibration set is then used to correct for any errors in the initial model fitting stage. For each \(i \in I_2\) (the calibration points), define a score \(V_i = \tilde{q}_\alpha(X_i) - \tilde{T}_i\), and then define the LPB as

\[
\tilde{L}_{\text{baseline}}(X) = \tilde{q}_\alpha(X) - Q_{1-\alpha}(\sum_{i \in I_2} \frac{1}{1 + |I_2|} \cdot \delta_{V_i} + \frac{1}{1 + |I_2|} \cdot \delta_{+\infty}),
\]

where \(Q_{1-\alpha}(\cdot)\) denotes the \((1-\alpha)\)-quantile of a distribution and where \(\delta_v\) is the point mass at \(v\). The intuition here is that the \(Q_{1-\alpha}(\cdot)\) term adds a correction to the original fitted model to ensure that \(\tilde{L}_{\text{baseline}}(X)\) has the right coverage level on the calibration set drawn i.i.d. from \(P\), and will thus have the right coverage level on a future draw \((X, T)\) from \(P_{(X,T)}\) as well.

Note that the resulting value \(\tilde{L}_{\text{baseline}}(X)\) may be higher (less conservative) or lower (more conservative) than the initial fitted model \(\tilde{q}_\alpha(X)\), depending on whether the original fitted model \(\tilde{q}_\alpha\) is over- or under-covering on the calibration set. In practice, it is likely that we will have undercoverage of the original fitted model (see, e.g., the simulation results in Romano et al. (2019); Lei and Candès (2020); Candès et al. 2021 and Figure 6), leading to a quantile \(Q_{1-\alpha}(\cdot)\) that is positive, and a LPB \(\tilde{L}(X)\) that is lower (more conservative) than the original fitted model.

The following result proves that this is a marginally calibrated LPB:

**Theorem 1** (Adapted from Theorem 1 of Romano et al. (2019)). Suppose \((X_i, C_i, T_i) \overset{iid}{\sim} P\). Then \(\tilde{L}_{\text{baseline}}(X)\) is a marginally calibrated LPB at level \(1 - \alpha\), and moreover, satisfies

\[
P_{(X,T,C)}(\tilde{T} \geq \tilde{L}_{\text{baseline}}(X)) \geq 1 - \alpha.
\]

Since \(\tilde{T}\) may be often much smaller than \(T\) if the censoring is severe, this result indicates that such an LPB may be quite conservative as a lower bound for \(T\). This conservativeness is however inescapable without further assumptions—Candès et al. (2021, Theorem 1) establish that, under mild conditions, for any marginally calibrated LPB \(\tilde{L}\) for the (uncensored) survival time \(T\) which is valid universally over all distributions \(P\) on the data, \(\tilde{L}\) must also be an LPB for \(\tilde{T}\) whenever \(P_{(C,T)}\) is either discrete or continuous.

### 2.2 Using fixed threshold \(c_0\)

Next we give details for Candès et al. (2021)’s proposed method, which uses a fixed threshold \(c_0\) to avoid an overly conservative LPB. As mentioned above, their work shows that, without further assumptions, it is not possible to improve on the LPB for \(\tilde{T}\); therefore, they make the additional assumption that the conditional distribution \(P_{C|X}\) is known (or is estimated accurately).

As for CQR, their method begins by partitioning the data into a training set \(I_1\) and a calibration set \(I_2\), and uses the training set to fit a quantile regression, \(x \mapsto \tilde{q}_\alpha(x)\), for the conditional \(\alpha\)-quantile of \(T\) given \(X\). The cutoff \(c_0\) for the censoring time may also be chosen as a function of the training data. Furthermore, define \(\tilde{w}(x)\) to be an estimate of \(1/P(C \geq c_0|X = x)\) (or, approximately proportional to this quantity), also fitted on the training data.

Next, on the calibration set, we use \(c_0\) to filter the data and define \(I_2' = \{i \in I_2 : C_i \geq c_0\}\). For all these remaining calibration points, note that \(\tilde{T}_i \wedge c_0 = T_i \wedge c_0\) (that is, \(T_i \wedge c_0\) is observed). We then calculate scores \(V_i = \tilde{q}_\alpha(X_i) - \tilde{T}_i \wedge c_0\) for all \(i \in I_2'\), and return the LPB

\[
\tilde{L}_{\text{fixed-cutoff}}(X) = \tilde{q}_\alpha(X) - Q_{1-\alpha}(\sum_{i \in I_2'} \tilde{w}(X_i) \cdot \delta_{V_i} + \tilde{w}(X) \cdot \delta_{+\infty}).
\]

\(^1\)While their proposed method is defined via a more general construction, here we focus on a single version that is most relevant for comparison to our own methods.
The intuition here is that the calibration set $I_2$ consists of data points drawn from the shifted distribution $P^{≥c_0}$, and the likelihood ratio between the target distribution $P$ and this distribution $P^{≥c_0}$ is $P(C ≥ c_0)/P(C ≥ c_0 | X)$; since $\hat{w}(X)$ is an estimate of the likelihood ratio (up to constants), reweighting the calibration data points with weights $\hat{w}(X_i)$ ensures coverage with respect to the actual target distribution $P$.

Building on the framework of conformal prediction with covariate shift (Tibshirani et al., 2019), Candès et al. (2021)’s result proves that this construction yields a valid LPB.

**Theorem 2** (Proposition 1 of Candès et al. (2021)). Suppose $(X, C, T) \overset{iid}{\sim} P$, and suppose $\hat{w}(x) = 1/P(C ≥ c_0 | X = x)$, i.e., this probability was fitted exactly. Then $\hat{L}_{fixed-cutoff}(X)$ is a marginally calibrated LPB for $T ∧ c_0$, and therefore also for $T$.

Moreover, Candès et al. (2021, Theorem 2) establish a double robustness result: if either $\hat{w}(x)$ was fitted accurately (i.e., is a good approximation of $1/P(C ≥ c_0 | X = x)$ or the quantile regression was fitted accurately (i.e., $\hat{q}_a(x)$ is a good approximation of the $a$-quantile of $T | X$), then $\hat{L}_{fixed-cutoff}$ approximately satisfies the criterion for a marginally calibrated LPB.

### 3 Conformalized survival analysis with adaptive cutoffs

#### 3.1 Our procedure

As before, we first partition the data into a training set $I_1$ and a calibration set $I_2$. On the training set, we fit a family of estimated quantile regression functions, $(x, a) \mapsto \hat{q}_a(x)$, mapping $x$ to the estimated $a$-quantile of the conditional distribution of $T$ given $X = x$, for all $a \in [0, 1]$. We assume that, for any $x$, $a \mapsto \hat{q}_a(x)$ is nondecreasing.² (In contrast, for the existing methods defined in Section 2, this regression is run only at a single value of $a$.)

Next, we need to use the calibration set in order to choose a value of $a$, for which returning $\hat{q}_a(X)$ is a valid LPB—that is, we need to find a value $a$ such that $P(T < \hat{q}_a(X)) = \alpha$ (where we implicitly treat the fitted quantile function $\hat{q}_a$ as fixed, and take the probability over $(X, T) \sim P$). Note that, if the original regression were estimated perfectly, then we would expect to return $a = \alpha$, i.e., the estimated $\alpha$-quantile $\hat{q}_\alpha(X)$ would already be a valid LPB. In practice, as discussed earlier, we expect to see overfitting in most real-data settings and thus we expect to return $a < \alpha$. To choose $a$ appropriately, we could consider solving for $a$ in the following expression:

$$
\alpha = P(T < \hat{q}_\alpha(X)) = E[P(T < \hat{q}_\alpha(X) | X)]
$$

$$
= E \left[ P(T < \hat{q}_\alpha(X) | X) \cdot \frac{P(\hat{q}_\alpha(X) ≤ C | X)}{P(\hat{q}_\alpha(X) ≤ C | X)} \right]
$$

$$
≈ E \left[ P(T < \hat{q}_\alpha(X) | X) \cdot P(\hat{q}_\alpha(X) ≤ C | X) \cdot \hat{w}_a(X) \right]
$$

$$
= E \left[ P(T < \hat{q}_\alpha(X) ≤ C | X) \cdot \hat{w}_a(X) \right]
$$

$$
= E \left[ 1 \{ T < \hat{q}_\alpha(X) ≤ C \} \cdot \hat{w}_a(X) \right],
$$

(2)

where now $\hat{w}_a(x)$ is chosen to be (approximately) equal to $1/P(C ≥ \hat{q}_\alpha(X) | X = x)$, and where the next-to-last step holds by Assumption 1. If instead we only assume that our estimate $\hat{w}_a(x)$ is proportional to $1/P(C ≥ \hat{q}_\alpha(X) | X = x)$, then we want to solve for $a$ in the equation

$$
\alpha = P(T < \hat{q}_\alpha(X)) = \frac{E[P(T < \hat{q}_\alpha(X) | X) \cdot P(\hat{q}_\alpha(X) ≤ C | X) \cdot \hat{w}_a(X)]}{E[\hat{w}_a(X)]}
$$

$$
= \frac{E[1 \{ T < \hat{q}_\alpha(X) ≤ C \} \cdot \hat{w}_a(X)]}{E[\hat{w}_a(X)]}.
$$

(3)

²If our estimators $\hat{q}_\alpha$ are computed independently for each $a$ and this constraint is violated, monotonicity can easily be restored via sorting the outputs—see e.g., Koenker (1994). $\hat{q}_\alpha$ is defined to be $-\infty$ at $a = 0$. 

---

6
Now we can note that, while the events \( \mathbb{1}\{T_i < \tilde{q}_a(X_i)\} \) cannot be observed on the calibration set (since we only observe the censored survival time, \( T_i \)), the filtered events \( \mathbb{1}\{T_i < \tilde{q}_a(X_i) \leq C_i\} \) can be observed (since if \( C_i \geq \tilde{q}_a(X_i) \), then \( \mathbb{1}\{T_i < \tilde{q}_a(X_i)\} = \mathbb{1}\{T_i < \tilde{q}_a(X_i)\} \)). Therefore, the calibration set can indeed be used to find a value \( a \) so that the equation (2) or (3) is (approximately) satisfied.

Now we formally describe how to select \( a \) using the calibration set. For each value \( a \), we estimate the miscoverage rate \( P(T < \tilde{q}_a(X)) \) as follows:

\[
\hat{\alpha}(a) = \frac{\sum_{i \in I_2} \tilde{w}_a(X_i) \cdot \mathbb{1}\{T_i < \tilde{q}_a(X_i) \leq C_i\}}{\sum_{i \in I_2} \tilde{w}_a(X_i) \cdot \mathbb{1}\{\tilde{q}_a(X_i) \leq C_i\}}
\]

This empirical quantity estimates \( \alpha^*(a) = P(T < \tilde{q}_a(X)) \). Since our aim is to find a value of \( a \) sufficiently small so that \( \alpha^*(a) \leq \alpha \), we will instead search for \( a \) satisfying \( \hat{\alpha}(a) \leq \alpha \). However, while \( \alpha^*(a) \) is monotone in \( a \) (since \( \tilde{q}_a(x) \) is monotone in \( a \)), this property may not hold for the estimator \( \hat{\alpha}(a) \); we therefore define \( \tilde{a} = \sup \{a \in [0, 1] : \sup_{a' \leq a} \hat{\alpha}(a') \leq \alpha\} \). Finally, we output the LPB \( \tilde{L}(X) := \tilde{q}_{\tilde{a}}(X) \).

Below, we will give a double robustness result proving that this choice of \( \tilde{L} \) is (approximately) a marginally calibrated LPB, as long as either the weights \( \tilde{w}_a \) or the quantiles \( \tilde{q}_a \) are fitted accurately; furthermore, when the quantiles are fitted accurately, the LPBs are (approximately) conditionally valid. Before giving our theoretical results, we first present a more general form of this procedure.

### 3.2 A generalized procedure

The procedure described above tends to perform well in settings where \( \tilde{q}_a(x) \) (for relevant values of \( a \)) is not too large—so that \( P(C \geq \tilde{q}_a(x) \mid X = x) \) is not close to zero and the weights \( \tilde{w}_a(X_i) \) on the calibration points are not too large. In other settings, however, the procedure may be somewhat unstable. Specifically, in scenarios where \( C \) is often much smaller than \( T \) (as in the example given in Section 1.4 above), we might have a very small probability \( P(C \geq \tilde{q}_a(X) \mid X = x) \); this is problematic since the inverse weight \( \tilde{w}(x) \) will then be extremely large. To alleviate this, we now generalize the procedure sketched above to allow for a more stable and robust method. Define a family of functions for \( x \in \mathcal{X} \) and \( a \in \mathcal{A} \), \( (x, a) \rightarrow \tilde{f}_a(x) \), which are fitted on the training set, such that for each fixed \( x \) this map is nondecreasing in \( a \) (note that the estimated quantiles, \( \tilde{q}_a(x) \), are simply a special case). Our aim is now to use the calibration set in order to choose \( a \) so that \( \tilde{L}(X) = \tilde{f}_a(X) \) offers a calibrated LPB. With the same rationale as before, we wish to find \( a \) to satisfy

\[
\alpha = P(T < \tilde{f}_a(X)) \approx \frac{\mathbb{E}\left[P(T < \tilde{f}_a(X) \mid X) \cdot P(\tilde{f}_a(X) \leq C \mid X) \cdot \tilde{w}_a(X)\right]}{\mathbb{E}[P(\tilde{f}_a(X) \leq C \mid X) \cdot \tilde{w}_a(X)]} = \frac{\mathbb{E}\left[\mathbb{1}\{T < \tilde{f}_a(X) \leq C\} \cdot \tilde{w}_a(X)\right]}{\mathbb{E}[\mathbb{1}\{\tilde{f}_a(X) \leq C\} \cdot \tilde{w}_a(X)]},
\]

where \( \tilde{w}_a \) is again fitted on the training data but is now chosen to be (approximately) proportional to \( 1/P(C \geq \tilde{f}_a(X) \mid X = x) \).

From this point on, we proceed exactly as before, but with \( \tilde{f}_a \) in place of \( \tilde{q}_a \)—we define

\[
\hat{\alpha}(a) = \frac{\sum_{i \in I_2} \tilde{w}_a(X_i) \cdot \mathbb{1}\{T_i < \tilde{f}_a(X_i) \leq C_i\}}{\sum_{i \in I_2} \tilde{w}_a(X_i) \cdot \mathbb{1}\{\tilde{f}_a(X_i) \leq C_i\}},
\]

which estimates \( \alpha^*(a) = P(T < \tilde{f}_a(X)) \). As before, we compute

\[
\tilde{a} = \sup \left\{ a \in [0, 1] : \sup_{a' \leq a} \hat{\alpha}(a') \leq \alpha \right\},
\]

and return the LPB \( \tilde{L}(X) := \tilde{f}_a(X) \).

**Choosing the family of bounds.** In this more general procedure, how should the family \( \tilde{f}_a(x) \) be chosen? The LPB will be approximately valid regardless of our choice, but the utility of the method will depend strongly on choosing a reasonable family of functions. We consider two goals when choosing the family:
We would like to closely approximate the “oracle” LPB, \( L(X) = q_a(X) \), where \( q_a(x) \) is the true \( \alpha \)-quantile of \( T \) given \( X = x \). As a result, for \( a \) such that \( \hat{q}_a(x) \) is close to \( q_a(x) \), we would like to have \( \hat{f}_a(x) = \hat{q}_a(x) \), our estimated quantiles for \( T \) given \( X \).

On the other hand, we would like for the weights \( \hat{\omega}_a(x) \) to not be too large, or equivalently, for \( \mathbb{P}(C \geq \hat{f}_a(X)|X = x) \) to not be too small for any \( a \). Consequently, we might want to require \( \hat{f}_a(x) \leq \hat{q}^C_{1-\beta}(x) \), where \( \hat{q}^C_{1-\beta}(x) \) estimates the conditional quantile of \( C \) given \( X = x \), and we choose some constant value \( \beta \).

To balance between these two goals, we propose selecting \( \hat{f}_a(x) = \min \{ \hat{q}_a(x), \hat{q}^C_{1-\beta}(x) \} \). As for the choice of \( \beta \), we use \( \beta = 1/\log |\mathcal{I}_2| \) in our implementation such that \( \bar{a}_a(X_i) \leq \log |\mathcal{I}_2| = o(\sqrt{|\mathcal{I}_2|}) \). In the simulations, we will compare this choice against the “canonical” version of the method with \( \hat{f}_a(x) = \hat{q}_a(x) \), to see how this new choice adds stability to the method.

**Implementation details.** Next we describe how the threshold \( \hat{a} \) in (4) can be computed efficiently in practice. We note that \( \sup_{a' \leq a} \bar{a}(a') \) is a non-decreasing piecewise constant function in \( a \), with no more than \( 2n \) knots—values of \( a \) at which the indicators \( 1\{T_i < \hat{f}_a(X_i) \leq C_i\} \) or \( 1\{\hat{f}_a(X_i) \leq C_i\} \) change signs. Denote \( \bar{a}_i = \sup_{a \in [0,1]} \{ \hat{f}_a(X_i) \leq \bar{T}_i \} \), \( \bar{a} = \sup_{a \in [0,1]} \{ \hat{f}_a(X_i) \leq C_i \} \) and \( \mathcal{A}_1 = \{ \bar{a}_i : i = 1, \ldots, n \}, \mathcal{A}_2 = \{ \bar{a}_i : i = 1, \ldots, n \} \). Then by definition, the breakpoints of the piecewise constant map \( a \mapsto \bar{a}(a) \) must all lie in \( \mathcal{A}_1 \cup \mathcal{A}_2 \). In the implementation, in order to obtain \( \bar{a} \), we only need to search through the finite grids

\[
\mathcal{A} = \mathcal{A}_1 \cup \mathcal{A}_2 \cup \{0\}.
\]

A complete description of the general procedure can be found in Algorithm 1.

**Algorithm 1 Conformalized survival analysis with adaptive cutoffs**

**Input:** Level \( \alpha \); data \( \mathcal{D} = (X_i, \bar{T}_i, C_i)_{i \in [n]} \).

**Procedure:**
1. Split the data into two folds: the training fold \( \mathcal{I}_1 \) and the calibration fold \( \mathcal{I}_2 \).
2. Using \( \mathcal{I}_1 \) as input, apply any algorithm to fit the candidate LPBs \( \{ \hat{f}_a(\cdot) \}_{a \in [0,1]} \).
3. Using \( \mathcal{I}_2 \) as input, apply any algorithm to construct estimates \( \hat{\omega}_a(x) \) of \( \mathbb{P}(C \geq \hat{f}_a(X) \mid X = x) \).
4. Determine \( \mathcal{A} \) according to (5).
5. For \( a \) in \( \mathcal{A} \) do: Compute the estimated miscoverage rate

\[
\bar{a}(a) = \frac{\sum_{i \in \mathcal{I}_2} \hat{\omega}_a(X_i) \cdot 1\{T_i \leq \hat{f}_a(X_i) \leq C_i\}}{\sum_{i \in \mathcal{I}_2} \hat{\omega}_a(X_i) \cdot 1\{\hat{f}_a(X_i) \leq C_i\}}.
\]

6. Compute the threshold: \( \bar{a} = \sup \{ a \in \mathcal{A} : \sup_{a' \leq a,a' \in \mathcal{A}} \bar{a}(a') \leq \alpha \} \).

**Return:** The calibrated LPB: \( \tilde{L}(\cdot) = \hat{f}_{\bar{a}}(\cdot) \).

**Computational complexity.** The computational cost of our proposed procedure can be decomposed into the cost of model fitting on \( \mathcal{I}_1 \) and that of finding \( \bar{a} \) on \( \mathcal{I}_2 \). The cost of the first stage heavily depends on the type of models chosen by the user. For the second stage, we first need to find the set of “knots” \( \mathcal{A} \) defined in (5). For each \( i \in \mathcal{I}_2 \), finding \( \bar{a}_i \) (resp. \( \bar{a}_i \)) requires finding the supremum over \( a \) such that \( \hat{f}_a(X_i) \leq \bar{T}_i \) (resp. \( \hat{f}_a(X_i) \leq C_i \)). Since \( \hat{f}_a(X_i) \) is nondecreasing in \( a \), finding \( \bar{a}_i \) or \( \bar{a}_i \) can be done efficiently via binary search. More specifically, given a tolerance level \( \epsilon \), we can obtain an \( \epsilon \)-accurate solution within \( O(\log(1/\epsilon)) \) runs. Repeating the above for all \( i \in \mathcal{I}_2 \) requires \( O(|\mathcal{I}_2| \cdot \log(1/\epsilon)) \) runs. Finally, evaluating \( \bar{a}(a) \) for \( a \in \mathcal{A} \) and finding \( \bar{a} \) requires \( O(|\mathcal{I}_2| \cdot (1 + \log(1/\epsilon))) \) runs. Overall, the computational complexity of the second stage is of the order \( O(|\mathcal{I}_2| \cdot (1 + \log(1/\epsilon))) \).

### 3.3 Theoretical guarantee: a double robustness result

In this section, we establish the theoretical guarantees for the LPB's produced by Algorithm 1. In particular, we show that the LPB's enjoy a double-robustness property in the following sense: the LPB's are
approximately marginally calibrated if either the censoring mechanism or the conditional quantile of survival times can be estimated well; when the latter is true, the LPBs are furthermore approximately conditionally calibrated.

Given the class of functions \( \{ \hat{f}_a(\cdot) \}_{a \in [0,1]} \), we define the oracle weights \( w_a(x) = (\mathbb{P}\{ C \geq \hat{f}_a(X) | I_1, X = x \})^{-1} \), (here we condition on \( \hat{f}_a \), i.e., the function is treated as fixed), and the following oracle quantity for any \( \beta \in [0,1] \):

\[
a(\beta) = \sup \{ a \in [0,1] : \mathbb{P}(T < \hat{f}_a(X) | I_1) \leq \beta \}.
\]

Theorem 3 and 4 develop the coverage guarantee for the LPBs.

**Theorem 3.** Fix any \( \delta, \alpha \in (0,1) \). Assume that \( \hat{f}_a(x) \) is continuous in \( a \), and that for any \( a \in [0,1] \), there exists some constant \( \tilde{\gamma}_a > 0 \) such that \( \hat{w}_a(x) \leq \tilde{\gamma}_a \) for \( P_X \)-almost all \( x \). Then with probability at least \( 1 - \delta \) over the draw of \( D \), the LPB produced by Algorithm 1 satisfies

\[
\mathbb{P}_{(X,T) \sim P}(T \geq \hat{L}(X) | D) \geq 1 - \alpha
\]

\[
- \sup_{a \in [0,1]} \left( \mathbb{E} \left[ \frac{\hat{w}_a(X)}{w_a(X)\tilde{\gamma}_a} - 1 \right] | I_1 \right) + \sqrt{1 + \frac{\tilde{\gamma}_a^2}{\pi_a^2} + \max(1, \frac{\tilde{\gamma}_a - 1}{\pi_a})} \cdot \log \left( \frac{1}{\delta} \right),
\]

where the probability is taken with respect to a new data point \((X,T) \sim P_{(X,T)}\), and where we define \( \hat{\pi}_a = \mathbb{E}_{X \sim P_X} \left[ \frac{\hat{w}_a(X)}{w_a(X)} | I_1 \right] \) for any \( a \in [0,1] \).

The proof of Theorem 3 if deferred to supplementary material. In other words, if the estimates \( \hat{w}_a \) are accurate approximations of \( w_a \) (up to rescaling by a constant), then we have \( \hat{w}_a(X)/w_a(X)\tilde{\gamma}_a \approx 1 \), and approximate coverage is guaranteed.

Next, we show that we also achieve approximate coverage when \( T | X \) can be accurately modeled.

**Theorem 4.** Fix any \( \delta, \alpha \in (0,1) \). Assume the same conditions as Theorem 3, and assume further that the conditional distribution of \( T | X \) is continuous, with its conditional density upper bounded by a constant \( B > 0 \), and that there exists a constant \( r > 0 \) such that

(a) \( \sup_{\xi \in [a(\alpha),a(\alpha+r)+\psi]} w_\xi(x) \leq \gamma \) and \( \sup_{\xi \in [a(\alpha),a(\alpha+r)+\psi]} \hat{w}_\xi(x) \leq \tilde{\gamma} \) for some constants \( \psi, \gamma, \tilde{\gamma} > 0 \);

(b) \( \sup_{\beta \in [a, a+r]} \sup_{x \in X} \left\{ \max(B, 1) \cdot |\hat{f}_a(\beta)(x) - q_\beta(x)| \right\} \leq \gamma \sqrt{\frac{\log(1/\delta)}{|I_2|}} \leq r \), where \( q_\beta(x) \) is the \( \beta \)-quantile of \( T \) conditional on \( X = x \).

Then with probability at least \( 1 - \delta \) over the draw of \( D \), the LPB produced by Algorithm 1 satisfies that for \( P_X \)-almost all \( x \),

\[
\mathbb{P}_{(X,T) \sim P}(T \geq \hat{L}(x) | D, X = x) \geq 1 - \alpha
\]

\[
- \sup_{\beta \in [a, a+r]} \sup_{x \in X} \left\{ 2B \cdot |\hat{f}_a(\beta)(x) - q_\beta(x)| \right\} - \tilde{\gamma} \sqrt{\frac{1}{|I_2|}} \cdot \log \left( \frac{1}{\delta} \right).
\]

The proof of Theorem 4 is deferred to the supplementary material, where we in fact prove a more general version. The implication of Theorem 4 is that if \( T | X \) can be modeled well, the conditional miscoverage rate will be small (which also implies that the marginal coverage rate will be small).

**Remark 1.** The assumption on the continuity \( \hat{f}_a(x) \) in \( a \) and the boundedness on the estimated weights can simply be satisfied by choosing the appropriate class of functions in the training stage (i.e., the fitting procedure using \( I_1 \)). The additional assumption (a) requires the oracle weights \( w_\beta(x) \) is bounded as least in a neighborhood of \( a(\alpha) \); (b) is satisfied when \( T | X \) is estimated uniformly well in a neighborhood of \( \alpha \) and when \( |I_2| \) is sufficiently large.
4 Simulations

We set up six synthetic experiments, and under each setting we generate $N = 100$ i.i.d. datasets. Each dataset consists of the training set $\mathcal{I}_1$, calibration set $\mathcal{I}_2$, and the test set $\mathcal{I}_3$, where $|\mathcal{I}_1| = 1,000$, $|\mathcal{I}_2| = 1,000$ and $|\mathcal{I}_3| = 5,000$. For all experiments, the target level is $1 - \alpha = 90\%$. In these experiments, we implement our proposed method with two families of bounds:

- DFT-adaptive-T: the candidate LPB is given by $\widehat{f}_a(x) = \widehat{q}_a(x)$, where $\widehat{q}_a(x)$ is the estimated $a$-th conditional quantile of $T$ given $X = x$.
- DFT-adaptive-CT: the candidate LPB is given by $\widehat{f}_a(x) = \min\{\widehat{q}_a(x), \widehat{q}_{1-\log(1/|\mathcal{I}_2|)}(x)\}$, where $\widehat{q}_a(x)$ is as before and $\widehat{q}_b(x)$ is the estimated $b$-th conditional quantile of $C$ given $X = x$.

We also obtain LPBs based on parametric models and other distribution-free methods:

- Cox: LPBs generated by the estimated Cox model that is implemented as in Therneau (2020)
- RandomForest: LPBs returned by the censored quantile regression forest (Li and Bradic, 2020; Athey et al., 2019); the implementation is based on Li and Bradic (2020).
- DFT-baseline: The distribution-free LPBs obtained by applying conformal quantile regression (Romano et al., 2019) to generating bounds for $\widehat{T}$.
- DFT-fixed: conformalized LPB with a fixed thresholded $c_0$; the implemental details are as suggested by Candès et al. (2021).

For all conformalized method, the base algorithm for fitting conditional quantile of $T \mid X$ is the Cox model, and a Gaussian process model is fitted to approximate $C \mid X$ (this is implemented by the Gaussian Pro R-package (Erickson, 2021)). For each dataset, we compute the following two quantities with the test set:

$$\text{Empirical coverage} = \frac{1}{|\mathcal{I}_3|} \sum_{i \in \mathcal{I}_3} \mathbb{1}\{\widehat{L}(X_i) < T_i\}, \quad \text{Average LPB} = \frac{1}{|\mathcal{I}_3|} \sum_{i \in \mathcal{I}_3} \widehat{L}(X_i).$$

An ideal method would have empirical coverage $\approx 1 - \alpha$, and average LPB as low as possible. We shall demonstrate boxplots of the empirical coverage and average LPB resulting from the 100 datasets.

4.1 Synthetic setup

We consider six data generating models, where settings 1–4 concern univariate $X$ and settings 5–6 multivariate $X$. For all settings, the marginal distribution of the covariates is given by $P_X = \text{Unif}[0, 4]^p$; conditional on $X$, we generate $T$ and $C$ via distributions $\log T \mid X \sim \mathcal{N}(\mu(X), \sigma^2(X))$ and $C \mid X \sim P_C \mid X$.

In settings 1 and 2, $p = 1$ and $C \mid X \sim \text{Exp}(0.1)$—the censoring mechanism is completely exogenous; in settings 3 and 4, $p = 1$ and we allow $C$ to depend on $X$. In particular, setting 3 corresponds to the example shown in the introduction. Settings 5 and 6 consider multivariate $X$, where $p = 10$; in setting 5, $\sigma(x) = 1$, and in setting 6 $\sigma(x)$ depends on $X$. Table 1 summarizes the parameters used in the six settings.

Figure 2 shows the scatterplots of the survival time $T$ and censoring time $C$ against the univariate covariate $X$ in univariate experimental settings. Settings 2–4 are more challenging than setting 1, as they all have scenarios where there are roughly two sub-populations: the sub-population with smaller values of $X$ has relatively higher censoring time, leading to a low censoring zone while the sub-population with larger values of $X$ has comparatively higher survival time, hence a very high censoring zone. In settings 5–6, there is a similar challenge: the distribution $P_C \mid X$ depends on $X_{10}$ and thus we will have low censoring times for certain values of $X$ and higher censoring times for others.

\footnote{The code for reproducing all numerical results from the simulation and the real data analysis can be found at https://github.com/zhimeir/adaptive_conformal Survival_paper.}
Table 1: Parameters used in the six experimental settings: 
\( P_X = \text{Unif}([0, 4]^p), \ P_{T|X} = \exp(\mathcal{N}(\mu(X), \sigma^2(X))). \)
Figure 3: Empirical coverage (top) and average LPBs (bottom) of all the candidate methods under settings 1–4, where $X$ is univariate. The boxplot shows results from 100 independent draw of datasets. The dashed red line corresponds to the target coverage level $1 - \alpha = 90\%$.

Figure 4: Boxplots of empirical coverage (left) and average LPBs (right) in the multivariate experimental settings. The details are otherwise the same as in Figure 3.

5 Real data application

In this section, we apply our proposed method to predicting users' active time on a mobile app with a publicly available dataset. This dataset records the time stamps of pings for a cohort of 2,476 users in a

---

4The data is downloaded from https://www.kaggle.com/datasets/bhuvanchennoju/mobile-usage-time-prediction?select=pings.csv.
shared window of three weeks, where a ping represents a login activity or a received message. As is shown in Figure 6(a), a user’s pings gathered during an active day form a line segment, whose length is proportional to the span of active time during that day (the time span is standardized so that the total time window is mapped to the interval $[0, 21]$ to represent the total number of days). The number of line segments and the length of line segments vary for different users, reflecting different types of user behavior. For each user, the time is recorded from the user’s first active day, i.e., if the first active time for a particular user is $1.5$, then the sequence of active time for this user is shifted by $\lfloor 1.5 \rfloor = 1$ and is censored at time $C = 21 - 1 = 20$.

With this dataset, we focus on predicting the beginning of a user’s 14th active day. In practice, the prediction lower bounds can be informative if, for instance, the mobile app wishes to launch a promotion, offering a discount for in-app purchases at the beginning of a user’s 14th active day. For a user who is active for less than 14 days within the time window, the survival time is therefore censored and only $T = \min(C, T)$ can be observed. Figure 6(b) is the histogram of the censored survival time. Besides the time stamps, there are three covariates in this dataset related to users’ characteristics: $X_1$ (gender), $X_2$ (age), and $X_3$ (number of children).

To implement the method, we begin by choosing $|I_1| = 500$ data points as the training set, and keep this set fixed throughout. Among the remaining data points, for 50 independent random trials, we sample $|I_2| = 500$ data points as the calibration set and another $|I_3| = 500$ as the test set, uniformly without replacement. All the methods are applied with the target level $1 - \alpha$ at 90%. Since the true survival time for censored data points are not available, we instead empirically evaluate the upper and lower bounds of the coverage rate: we compute $\beta_{lo} := \Pr(T \geq \hat{L}(X)) \leq \Pr(T \geq \hat{L}(X))$, and also $\beta_{hi} := 1 - \Pr(T < \hat{L}(X), T \leq C) \geq \Pr(T \geq \hat{L}(X))$, so that, by construction, $\beta_{lo}$ is an underestimate of our target coverage rate, and $\beta_{hi}$ is an overestimate.

The upper and lower bounds for methods in comparison are reported in Figure 7. Since this setting has a low censoring rate (19.7%), the difference between DFT-adaptive-T and DFT-adaptive-CT is negligible. Both DFT-adaptive-T and DFT-adaptive-CT attain nearly exact coverage at 90%, while Cox and Random Forests have coverage below the target level. In comparison, although DFT-baseline has only slightly inflated
coverage, the average LPB is lower than our methods and is thus less accurate in practice; in the meantime, DFT-fixed has coverage rate slightly higher than 90% and shows larger variance than our methods with adaptive cutoffs.

6 Discussion

This paper offers a data-adaptive tool for conformalized survival analysis. By using covariate-dependent cutoff event to subset the data, i.e., considering data satisfying $C \geq f(X)$ for an appropriately chosen function $f$, our method enables higher power in a broader range of scenarios, where the distribution of $C \mid X$ can vary highly with $X$ without creating overly conservative bounds, to improve on earlier work using a fixed cutoff, $C \geq c_0$ (Candès et al., 2021).

As in Candès et al. (2021), this work has been primarily focusing on the Type I censoring, where the censoring time for each individual is assumed observable; this is typically the case when the censoring time is the termination of a study. Another common type of censoring time is the loss-to-follow-up censoring. When the event is death, the loss-to-follow-up censoring time is not observed for patients who did not survive, and our method no longer applies. As discussed in Candès et al. (2021), our method can however provide informative LPBs beyond the setting of Type I censoring: when we have both the end-of-study censoring time $C_{\text{end}}$ and the loss-to-follow-up censoring time $C_{\text{loss}}$, the censored survival time is then given by $T = T \wedge C_{\text{end}} \wedge C_{\text{loss}}$. Under the assumption that $(T, C_{\text{loss}}) \perp \!\!\!\perp C_{\text{end}} \mid X$, we can treat $T' := T \wedge C_{\text{loss}}$ as the true survival time and apply our procedure, producing an LPB on $T'$. We can thus alleviate the conservativeness caused by $C_{\text{end}}$, especially in studies with short duration.

We close the paper by a discussion on extensions and interesting directions for future work. First, the theoretical guarantees shown in this work focus on constructing the PAC-type LPB. It can also be of interest to see if one can derive marginal guarantees for the proposed method, where the weighted conformal inference technique is not applicable. (Recent work by Angelopoulos et al. (2022) on a related problem suggest tools for converting a PAC-type bound to a finite-sample bound in expectation, and may be applicable to the survival analysis setting as well.) Second, as with many double-robustness type results, our theoretical guarantees rely on high accuracy of our estimate of either the conditional distribution of $C \mid X$ or of $T \mid X$, but it may be possible to establish a better bound where moderately accurate estimates of both distributions contribute multiplicatively to a single unifying bound; this may be more relevant to practical settings, where we might expect moderate accuracy for each estimation problem. Finally, as discussed earlier, the cutoff introduces
a variance-bias tradeoff—with a large cutoff, the observed survival time is closer to the true survival time but the effect sample size is reduced, and vice versa. It is interesting to quantitatively characterize this phenomenon, and derive an optimal choice of candidate LPBs based on this characterization.

A Proofs

A.1 Proof of Theorem 3

For notational convenience, we define the error term to be

\[ \Delta = \sup_{a \in [0,1]} \left( \mathbb{E} \left[ \left| \frac{\hat{w}_a(X)}{w_a(X)\pi_a} - 1 \right| \mathbb{I}_1 \right] + \sqrt{\frac{1 + \frac{1}{\pi_a^2} + \max(1, \frac{3}{\pi_a} - 1)^2}{|I_2|} \cdot \log \left( \frac{1}{\delta} \right)} \right). \]

Recall that we have defined the oracle quantity

\[ a(\alpha + \Delta) = \sup \{ a \in [0,1] : \mathbb{P}(T < \hat{f}_a(X) \mid I_1) \leq \alpha + \Delta \}. \]

Suppose that we can show \( 1 - \delta \leq \mathbb{P}(\hat{a} \leq a(\alpha + \Delta) \mid I_1) \). Then we have with probability at least \( 1 - \delta \) that the event \( \{ \hat{a} \leq a(\alpha + \Delta) \} \) holds and

\[
\mathbb{P}(T \geq \hat{f}_a(X) \mid \mathcal{D}) \\
\geq \mathbb{P}(T \geq \hat{f}_{a(\alpha + \Delta)}(X) \mid \mathcal{D}) \\
\geq 1 - \alpha - \Delta
\]

\[= 1 - \alpha - \sup_{a \in [0,1]} \left\{ \mathbb{E} \left[ \left| \frac{\hat{w}_a(X)}{w_a(X)\pi_a} - 1 \right| \mathbb{I}_1 \right] + \sqrt{\frac{1 + \frac{1}{\pi_a^2} + \max(1, \frac{3}{\pi_a} - 1)^2}{|I_2|} \cdot \log \left( \frac{1}{\delta} \right)} \right\}, \]

where the first inequality is by the monotonicity of \( \hat{f}_a(\cdot) \) and the second inequality uses the left-continuity of \( \mathbb{P}(T < \hat{f}_a(X) \mid \mathcal{D}) \) in \( a \).

The rest of the proof is devoted to establishing \( 1 - \delta \leq \mathbb{P}(\hat{a} \leq a(\alpha + \Delta) \mid I_1) \). Fix an arbitrary \( \varepsilon > 0 \). By the definition of \( \hat{a}(a(\alpha + \Delta) + \varepsilon) \), we have

\[
\mathbb{P} \left( \hat{a}(a(\alpha + \Delta) + \varepsilon) \leq \alpha \mid I_1 \right) = \mathbb{P} \left( \sum_{i \in I_2} \hat{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot \mathbb{I}\{ T_i < \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \leq C_i \} \right) \\
\leq \alpha \sum_{i \in I_2} \hat{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot \mathbb{I}\{ \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \leq C_i \} \bigg\lvert I_1 \bigg) \\
= \mathbb{P} \left( \sum_{i \in I_2} \hat{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot \left( \mathbb{I}\{ T_i < \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \} - \alpha \right) \mathbb{I}\{ \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \leq C_i \} \leq 0 \bigg\lvert I_1 \right). \tag{6}
\]

For any \( t > 0 \), we apply Markov’s inequality and get

\[
(6) \leq \mathbb{E} \left[ \exp \left( t \cdot \sum_{i \in I_2} \hat{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \left( \alpha - \mathbb{I}\{ T_i < \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \} \right) \right) \mathbb{I}\{ \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \leq C_i \} \mid I_1 \right] \\
= \mathbb{E} \left[ \exp \left( t \cdot \sum_{i \in I_2} \hat{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot \left( \alpha - p_{a(\alpha + \Delta) + \varepsilon}(X_i) + p_{a(\alpha + \Delta) + \varepsilon}(X_i) \right) \right. \right. \\
\left. \left. - \mathbb{I}\{ T_i < \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \} \cdot \mathbb{I}\{ \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \leq C_i \} \right) \mid I_1 \right],
\]

where we define \( p_a(x) := \mathbb{P}(T < \hat{f}_a(X) \mid X = x, I_1) \) for any \( a \in [0,1] \). Further conditioning on \( (X_i, C_i)_{i \in I_2} \),
and using the fact that $C \parallel T \mid X$ (Assumption 1), we have

$$
\mathbb{E} \left[ \exp \left( t \sum_{i \in I_2} \hat{w}_a(\alpha + \Delta) + \varepsilon(X_i) \mathbb{I} \{ \hat{f}_a(\alpha + \Delta)(X_i) \leq C_1 \} \right. \right.

\times \left. \left( p_a(\alpha + \Delta) + \varepsilon(X_i) - \mathbb{I} \{ T_i < \hat{f}_a(\alpha + \Delta) + \varepsilon(X_i) \} \right) \right| (X_i, C_i)_{i \in I_2}, I_1]

\leq \exp \left( \frac{t^2}{8} \sum_{i \in I_2} \hat{w}_a(\alpha + \Delta) + \varepsilon(X_i) \cdot \mathbb{I} \{ \hat{f}_a(\alpha + \Delta) + \varepsilon(X_i) \leq C_1 \} \right)

\leq \exp \left( \frac{|I_2| \cdot \hat{\gamma}^2_a(\alpha + \Delta) + \varepsilon^2}{8} \right). \quad (7)
$$

Above, step (a) uses the $1/4$-sub-gaussianity of $p_a(\alpha + \Delta) + \varepsilon - \mathbb{I} \{ T_i \leq \hat{f}_a(\alpha + \Delta) + \varepsilon(X_i) \}$; step (b) follows from the boundedness assumption on the estimated weights. Combining (6) and (7) leads to

$$
(6) \leq \exp \left( \frac{|I_2| \cdot \hat{\gamma}^2_a(\alpha + \Delta) + \varepsilon^2}{8} \right) \cdot \mathbb{E} \left[ \exp \left\{ t \sum_{i \in I_2} \hat{w}_a(\alpha + \Delta) + \varepsilon(X_i) \mathbb{I} \{ \hat{f}_a(\alpha + \Delta) + \varepsilon(X_i) \leq C_1 \} \right. \right.

\times \left. \left( \alpha - p_a(\alpha + \Delta) + \varepsilon(X_i) \right) \right] \bigg| I_1 \bigg]. \quad (8)
$$

We then condition on $(X_i)_{i \in I_2}$ and use the sub-gaussianity of $\mathbb{I} \{ \hat{f}_a(\alpha + \Delta) + \varepsilon(X_i) \leq C_1 \} - w_a(\alpha + \Delta) + \varepsilon(X_i)^{-1}$ to obtain the following bound:

$$
\mathbb{E} \left[ \exp \left\{ t \sum_{i \in I_2} \hat{w}_a(\alpha + \Delta) + \varepsilon(X_i) \left( \mathbb{I} \{ \hat{f}_a(\alpha + \Delta) + \varepsilon(X_i) \leq C_1 \} - w_a(\alpha + \Delta) + \varepsilon(X_i)^{-1} \right) \right. \right.

\times \left. \left( \alpha - p_a(\alpha + \Delta) + \varepsilon(X_i) \right) \right] \bigg| (X_i)_{i \in I_2}, I_1 \bigg]

\leq \exp \left( \frac{t^2}{8} \sum_{i \in I_2} (\alpha - p_a(\alpha + \Delta) + \varepsilon(X_i))^2 \cdot \hat{w}_a(\alpha + \Delta) + \varepsilon(X_i)^2 \right) \leq \exp \left( \frac{|I_2| \cdot \hat{\gamma}^2_a(\alpha + \Delta) + \varepsilon^2}{8} \right),
$$

where we again use the boundedness of $\hat{w}_a(\cdot)$ in the last step. With the above, we bound (8) as

$$
(8) \leq \exp \left( \frac{|I_2| \cdot \hat{\gamma}^2_a(\alpha + \Delta) + \varepsilon^2}{4} \right) \mathbb{E} \left[ \exp \left\{ t \sum_{i \in I_2} \hat{w}_a(\alpha + \Delta) + \varepsilon(X_i) \left( \alpha - p_a(\alpha + \Delta) + \varepsilon(X_i) \right) \right. \right.

\bigg| I_1 \bigg]. \quad (9)
$$

Recall that we have defined for any $a \in [0, 1]$ that

$$
\pi_a = \mathbb{E}_{X \sim P_X} \left[ \frac{\hat{w}_a(X)}{w_a(X)} \bigg| I_1 \right].
$$

We subsequently bound (9) as

$$
(9) \leq \exp \left( \frac{|I_2| \cdot \hat{\gamma}^2_a(\alpha + \Delta) + \varepsilon^2}{4} \right) \cdot \mathbb{E} \left[ \exp \left\{ t \sum_{i \in I_2} \pi_a(\alpha + \Delta) + \varepsilon \left( \alpha - p_a(\alpha + \Delta) + \varepsilon(X_i) \right) \right. \right.

\bigg| I_1 \bigg]

\leq \exp \left( \frac{|I_2| \cdot \hat{\gamma}^2_a(\alpha + \Delta) + \varepsilon^2}{4} \right) \cdot \mathbb{E} \left[ \exp \left\{ 2t \cdot \pi_a(\alpha + \Delta) + \varepsilon \sum_{i \in I_2} (\alpha - p_a(\alpha + \Delta) + \varepsilon(X_i)) \right. \right.

\bigg| I_1 \bigg]^1/2 \bigg]

\times \mathbb{E} \left[ \exp \left\{ 2t \sum_{i \in I_2} \frac{\hat{w}_a(\alpha + \Delta) + \varepsilon(X_i)}{w_a(\alpha + \Delta) + \varepsilon(X_i)} - \pi_a(\alpha + \Delta) + \varepsilon \right. \right.

\bigg| I_1 \bigg]^1/2 \bigg], \quad (10)
$$

18
where the last step follows from the Cauchy-Schwarz inequality. By the definition of \(a(\alpha + \Delta)\), it holds that
\[
P(T < \tilde{f}_{a(\alpha + \Delta) + \varepsilon}(X) \mid I_1) \geq \alpha + \Delta.
\]
Using the above inequality, we have
\[
E \left[ \exp \left\{ 2t \cdot \pi_{a(\alpha + \Delta) + \varepsilon}(X_i) - p_{a(\alpha + \Delta) + \varepsilon}(X_i) \right\} \right] \Bigg| I_1 \leq E \left[ \exp \left\{ 2t \cdot \pi_{a(\alpha + \Delta) + \varepsilon}(X) - \Delta - p_{a(\alpha + \Delta) + \varepsilon}(X) \right\} \right] \Bigg| I_1
\]
\[
= \exp \left( -2t \pi_{a(\alpha + \Delta) + \varepsilon}(X) \right) \times E \left[ \exp \left\{ 2t \cdot \pi_{a(\alpha + \Delta) + \varepsilon}(X) - \Delta \right\} \right] \Bigg| I_1
\]
\[
\leq \exp \left( \frac{|I_2| \cdot t^2 \pi_{a(\alpha + \Delta) + \varepsilon}(X)}{2} - 2t \cdot \pi_{a(\alpha + \Delta) + \varepsilon}(X) \cdot |I_2| \right).
\]
Above, the last inequality uses that \(P(T < \tilde{f}_{a(\alpha + \Delta) + \varepsilon}(X) - p_{a(\alpha + \Delta) + \varepsilon}(X) \mid I_1)\) is \(\frac{1}{2}\)-sub-gaussian. Note that for any \(i \in I_2\),
\[
\left| \frac{\tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X)}{w_{a(\alpha + \Delta) + \varepsilon}(X)} - \pi_{a(\alpha + \Delta) + \varepsilon}(X) \right|
\]
\[
\leq \tilde{\gamma}(a(\alpha + \Delta) + \varepsilon) := \max \left\{ \tilde{\gamma}_{a(\alpha + \Delta) + \varepsilon}, \pi_{a(\alpha + \Delta) + \varepsilon} \right\}.
\]
We then have
\[
E \left[ \exp \left\{ 2t \left( \sum_{i \in I_2} \left| \frac{\tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X)}{w_{a(\alpha + \Delta) + \varepsilon}(X)} - \pi_{a(\alpha + \Delta) + \varepsilon} \right| \right) \right] \Bigg| I_1
\]
\[
\leq \exp \left( \frac{|I_2| \cdot t^2 (a(\alpha + \Delta) + \varepsilon)}{2} \right).
\]
Combining (11) and (12), we have the following upper bound on (10):
\[
(10) \leq \exp \left( \frac{|I_2| \cdot t^2}{4} \cdot \left( \frac{\pi_{a(\alpha + \Delta) + \varepsilon}^2 + \tilde{\gamma}_{a(\alpha + \Delta) + \varepsilon}^2 + \tilde{\gamma}_{a(\alpha + \Delta) + \varepsilon}^2}{\pi_{a(\alpha + \Delta) + \varepsilon} + \tilde{\gamma}_{a(\alpha + \Delta) + \varepsilon} + \tilde{\gamma}_{a(\alpha + \Delta) + \varepsilon}} \right) \right)
\]
\[
+ |I_2| \cdot t \cdot E \left[ \left| \frac{\tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X)}{w_{a(\alpha + \Delta) + \varepsilon}(X)} - \pi_{a(\alpha + \Delta) + \varepsilon} \right| \Bigg| I_1 \right] - \pi_{a(\alpha + \Delta) + \varepsilon}(X) \right) \Bigg| I_1 \right]
\]
\[
= \exp \left( \frac{|I_2| \cdot t^2 (a(\alpha + \Delta) + \varepsilon)}{2} \right).
\]
We now take
\[
t = \frac{2(\Delta \cdot \pi_{a(\alpha + \Delta) + \varepsilon} + \tilde{\gamma}_{a(\alpha + \Delta) + \varepsilon})}{\pi_{a(\alpha + \Delta) + \varepsilon} + \tilde{\gamma}_{a(\alpha + \Delta) + \varepsilon} + \tilde{\gamma}_{a(\alpha + \Delta) + \varepsilon} \cdot (a(\alpha + \Delta) + \varepsilon)}.
\]
This gives us
\[
(13) \leq \exp \left( - \frac{|I_2| \cdot (\Delta \cdot \pi_{a(\alpha + \Delta) + \varepsilon}(I_1) - \pi_{a(\alpha + \Delta) + \varepsilon}(I_1) - \pi_{a(\alpha + \Delta) + \varepsilon}(I_1) \right)^2}{\pi_{a(\alpha + \Delta) + \varepsilon} + \tilde{\gamma}_{a(\alpha + \Delta) + \varepsilon} + \tilde{\gamma}_{a(\alpha + \Delta) + \varepsilon} \cdot (a(\alpha + \Delta) + \varepsilon)} \right) \leq \delta.
\]
The last inequality is due to the choice of \(\Delta\). As a result,
\[
1 - \delta \leq P \left( \hat{a}(a + \alpha + \varepsilon) > a \mid I_1 \right) \leq P \left( \hat{a} < a(\alpha + \Delta) + \varepsilon \mid I_1 \right).
\]
Since the above holds for any \(\varepsilon > 0\), we can take \(\varepsilon \to 0\) and by the continuity of the probability measure, we have \(1 - \delta \leq P \left( \hat{a} < a(\alpha + \Delta) \mid I_1 \right)\) and thus complete the proof.
A.2 Proof of Theorem 4

Instead of proving Theorem 4 directly, we prove a more general theorem that implies Theorem 4.

Theorem 5. Fix any \( \delta, \alpha \in (0, 1) \). Under the same condition of Theorem 3, assume further that there exists a constant \( r > 0 \) such that

(a) \( \sup_{\xi \in [a(\alpha), a(\alpha+r)+\psi]} w_\xi(x) \leq \gamma \) and \( \sup_{\xi \in [a(\alpha), a(\alpha+r)+\psi]} \hat{w}_\xi(x) \leq \gamma \), for some constants \( \gamma, \hat{\gamma}, \psi > 0 \);

(b) for any \( \eta \in [0, r] \), for any \( \beta \in [\alpha, \alpha + r] \), and \( P_X \)-almost all \( x \),

\[
\begin{align*}
P(T < q_\beta(X) + \eta | X = x) &\leq \beta + B\eta, \\
P(T < q_\beta(X) - \eta | X = x) &\geq \beta - B\eta,
\end{align*}
\]

for some family of oracle functions \( \{q_\alpha(\cdot)\}_{\alpha \in [0,1]} \) and some constant \( B > 0 \);

(c) \( \sup_{\beta \in [\alpha, \alpha+r]} \sup_{x \in X} \left\{ \max(B, 1) \cdot |\hat{f}_\beta(x) - q_\beta(x)| \right\} + \bar{\gamma}\gamma \sqrt{\frac{\log(1/\delta)}{|I_2|}} \leq r. \)

Then with probability at least \( 1 - \delta \) over the draw of \( D \), the LPB produced by Algorithm 1 satisfies that for \( P_X \)-almost all \( x \),

\[
P_{(X,T) \sim \mathcal{P}}(T \geq \hat{L}(x) | D, X = x) \geq 1 - \alpha - \sup_{\beta \in [\alpha, \alpha+r]} \sup_{x \in X} \left\{ 2B \cdot |\hat{f}_\beta(x) - q_\beta(x)| \right\} - \bar{\gamma}\gamma \sqrt{\frac{1}{|I_2|} \cdot \log \left( \frac{1}{\delta} \right)},
\]

To see why Theorem 5 implies Theorem 4, note that when we take \( q_\beta(x) \) to be the \( \beta \)-quantile of \( T \) conditional on \( X = x \), and when the conditional distribution of \( T \mid X \) is continuous with conditional density bounded by \( B \), assumption b required by Theorem 5 is satisfied. We now proceed to prove Theorem 5.

Proof. Here, for notational convenience we define

\[
\mathcal{E} = \sup_{\beta \in [\alpha, \alpha+r]} \sup_{x \in X} |\hat{f}_\beta(x) - q_\beta(x)| \text{ and } \Delta = B\mathcal{E} + \bar{\gamma}\gamma \sqrt{\frac{\log(1/\delta)}{|I_2|}}.
\]

By Assumption c, \( \mathcal{E} \leq r \) and \( \Delta \leq r \). If we can show w.p. at least \( 1 - \delta \) that \( a(\alpha + \Delta) \geq \tilde{a} \), then by the monotonicity of \( \hat{f}_\beta(\cdot) \) in \( a \),

\[
P(T < \hat{f}_\tilde{a}(X) | D) \leq P(T < \hat{f}_a(\alpha+\Delta)(X) | D) \leq a + \Delta,
\]

where the last inequality uses the left-continuity of \( P(T < \hat{f}_a(X) | D) \). Furthermore, for a given \( x \in X \),

\[
P(T < \hat{f}_\tilde{a}(x) | X = x, D) \leq P(T < \hat{f}_a(\alpha+\Delta)(x) | X = x, D) \leq P(T < q_{\alpha+\Delta}(x) + \mathcal{E} | X = x, I_2) \leq a + \Delta + B\mathcal{E},
\]

where the second inequality follows from the definition of \( \mathcal{E} \) (and that \( \Delta \leq r \)), and the last inequality is due to Assumption b (and that both \( \Delta \) and \( \mathcal{E} \) are bounded by \( r \)). We have therefore arrived at our desired conclusion.

It remains to show that \( P(a(\alpha + \Delta) \geq \tilde{a}) \geq 1 - \delta \). As before, we fix an arbitrary \( \varepsilon \in (0, \psi] \). Then for any
\( t > 0, \)
\[
\mathbb{P}
\left( \tilde{\alpha}(a(\alpha + \Delta) + \varepsilon) \leq \alpha \mid I_1 \right)
= \mathbb{P}
\left( \alpha \sum_{i \in I_2} \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot 1 \{ C_i \geq \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \}
- \sum_{i \in I_2} \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot 1 \{ C_i \geq \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \geq 0 \mid I_1 \}
\right)
\leq \mathbb{E}
\left[ \exp \left\{ t \cdot \left( \alpha \sum_{i \in I_2} \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot 1 \{ C_i \geq \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \}
- \sum_{i \in I_2} \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot 1 \{ C_i \geq \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \} \right) \right\} \mid I_1 \right],
\]  
(14)

where the inequality follows from Markov’s inequality. Next, we condition on \((X_i, T_i)_{i \in I_2}\) and have
\[
\mathbb{E}
\left[ \exp \left\{ t \sum_{i \in I_2} \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot 1 \{ C_i \geq \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \} \cdot (\alpha - 1 \{ T_i < \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \}) \right\} \mid (X_i, T_i)_{i \in I_2}, I_1 \right]
\leq \exp \left\{ \frac{t^2}{8} \sum_{i \in I_2} \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) (\alpha - 1 \{ T_i < \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \})^2 \right\}
\leq \exp \left\{ \frac{|I_2| \cdot \tilde{\gamma}^2 t^2}{8} \right\},
\]  
(15)

where step (a) is due to the \( \frac{1}{4} \)-sub-Gaussianity of \( 1 \{ C_i \geq \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \} \), and step (b) the boundedness of \( \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(\cdot) \). Combining (14) and (15), we have
\[
(14) \leq \mathbb{E}
\left[ \exp \left\{ t \sum_{i \in I_2} \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot \left( p_{a(\alpha + \Delta) + \varepsilon}(X_i) - 1 \{ T_i < \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \} \right) \right\} \mid (X_i)_{i \in I_2}, I_1 \right]
\leq \exp \left\{ \frac{t^2}{8} \sum_{i \in I_2} \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X_i)^2 \right\}
\leq \exp \left\{ \frac{|I_2| \cdot \tilde{\gamma}^2 t^2}{8} \right\},
\]  
(16)

Next, recall that \( p_a(x) = \mathbb{P}(T < \hat{f}_{a}(x) \mid X = x) \). We now condition on \((X_i)_{i \in I_2}\):
\[
\mathbb{E}
\left[ \exp \left\{ t \sum_{i \in I_2} \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot \left( p_{a(\alpha + \Delta) + \varepsilon}(X_i) - 1 \{ T_i < \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \} \right) \right\} \mid (X_i)_{i \in I_2}, I_1 \right]
\leq \exp \left\{ \frac{t^2}{8} \sum_{i \in I_2} \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X_i)^2 \right\}
\leq \exp \left\{ \frac{|I_2| \cdot \tilde{\gamma}^2 t^2}{8} \right\},
\]  
(16)

where step (a) uses the sub-Gaussianity of \( p_a(X_i) - 1 \{ T_i < \hat{f}_{a}(X_i) \} \) and step (b) is due to the boundedness of \( \tilde{w}_a(\cdot) \). Combining the above, we now have
\[
(16) \leq \mathbb{E}
\left[ \exp \left\{ t \sum_{i \in I_2} \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot \left( \alpha - p_{a(\alpha + \Delta) + \varepsilon}(X_i) \right) + \frac{|I_2| \cdot \tilde{\gamma}^2 t^2}{4} \right\} \mid I_1 \right]
\leq \mathbb{E}
\left[ \exp \left\{ t \sum_{i \in I_2} \tilde{w}_{a(\alpha + \Delta) + \varepsilon}(X_i) \cdot \left( \alpha - \mathbb{P}(T_i < \hat{f}_{a(\alpha + \Delta) + \varepsilon}(X_i) \mid X_i, I_1) \right) + \frac{|I_2| \cdot \tilde{\gamma}^2 t^2}{4} \right\} \mid I_1 \right],
\]  
(17)
By Assumption c, $\Delta \leq r$, and by the definition of $E$, $|q_{\alpha + \Delta}(x) - \hat{f}_{a(\alpha + \Delta)}(x)| \leq E$; Consequently,

$$P(T_i < \hat{f}_{a(\alpha + \Delta) + \varepsilon}(x_i) \mid X_i, I_1) \geq P(T_i < \hat{f}_{a(\alpha + \Delta)}(x_i) \mid X_i, I_1) \geq P(T_i < q_{\alpha + \Delta}(x_i) - E \mid X_i, I_1).$$

Then,

$$\begin{align*}
\text{(17)} & \leq E \left[ \exp \left( t \sum_{i \in I_2} \frac{\hat{w}_{a(\alpha + \Delta) + \varepsilon}(x_i)}{w_{a(\alpha + \Delta) + \varepsilon}(X_i)} \cdot (\alpha - P(T_i < q_{\alpha + \Delta}(x_i) - E \mid X_i, I_1)) + \frac{|I_2| \gamma^2 t^2}{4} \right) \mid I_1 \right] \\
& \overset{(a)}{\leq} E \left[ \exp \left( t \sum_{i \in I_2} \frac{\hat{w}_{a(\alpha + \Delta) + \varepsilon}(x_i)}{w_{a(\alpha + \Delta) + \varepsilon}(X_i)} \cdot (\alpha - (\alpha + \Delta - BE)) + \frac{|I_2| \gamma^2 t^2}{4} \right) \mid I_1 \right] \\
& \overset{=}{=} E \left[ \exp \left( -t(\Delta - BE) \cdot \sum_{i \in I_2} \frac{\hat{w}_{a(\alpha + \Delta) + \varepsilon}(x_i)}{w_{a(\alpha + \Delta) + \varepsilon}(X_i)} + \frac{|I_2| \gamma^2 t^2}{4} \right) \mid I_1 \right] \\
& \overset{(b)}{\leq} \exp \left( -\frac{|I_2| t(\Delta - BE)}{\gamma} + \frac{|I_2| \gamma^2 t^2}{4} \right),
\end{align*}$$

where step (a) is due to that $E \leq r$ and Assumption b; step (b) follows from the boundedness of $w_a(\cdot)$ and that $\Delta - BE \geq 0$. Taking $t = \frac{2}{\gamma^2}(\Delta - BE)$, we have

$$\text{(17)} = \exp \left( -\frac{1}{\gamma^2 \gamma^2} \cdot (\Delta - BE)^2 |I_2| \right) \leq \delta,$$

where the last inequality is due to the choice of $\Delta$. As a result, we have with probability at least $1 - \delta$ that $\hat{a}(a(\alpha + \Delta) + \varepsilon) > a$, which implies that $a(\alpha + \Delta) + \varepsilon > \hat{a}$. That is,

$$P(a(\alpha + \Delta) + \varepsilon > \hat{a}) \geq 1 - \delta.$$

Again, taking $\varepsilon \to 0$ and using the continuity of probability measures, we have w.p. at least $1 - \delta$ that $a(\alpha + \Delta) \geq \hat{a}$, and thus complete the proof. \qed
