Dimensionality Control of Electronic Phase Transitions in Nickel-Oxide Superlattices

The competition between collective quantum phases in materials with strongly correlated electrons depends sensitively on the dimensionality of the electron system, which is difficult to control by standard solid-state chemistry. We have fabricated superlattices of the paramagnetic metal lanthanum nickelate (LaNiO₃) and the wide-gap insulator lanthanum aluminate (LaAlO₃) with atomically precise layer sequences. We used optical ellipsometry and low-energy muon spin rotation to show that superlattices with LaNiO₃ as thin as two unit cells undergo a sequence of collective metal-insulator and antiferromagnetic transitions as a function of decreasing temperature, whereas samples with thicker LaNiO₃ layers remain metallic and paramagnetic at all temperatures. Metal-oxide superlattices thus allow control of the dimensionality and collective phase behavior of correlated-electron systems.

In principle, the dimensionality of the electron system can thus be tuned from $D = 2$ to 3 by increasing $N$. In practice, however, the synthesis requirements become rapidly more demanding for large $N$, and many Ruddlesden-Popper phases have turned out to be unstable.

Recent advances in the synthesis of TMO heterostructures with atomically sharp interfaces indicate an alternative route toward control of correlated-electron systems (1). In principle, the carrier concentration in a heterostructure can be tuned by a gate voltage in a field-effect arrangement, without introducing substitutional disorder, and the dimensionality can be modified by means of the deposition sequence of electronically active and inactive TMO layers. In practice, however, attempts to implement this approach have faced many of the same difficulties encountered in the chemical synthesis of bulk materials. For instance, defects created by interdiffusion or strain relaxation can influence the transport properties of the interfacial electron system in an uncontrolled manner. These difficulties are compounded by the paucity of experimental methods capable of probing the collective phase behavior of electrons in TMO heterostructures. Whereas ferromagnetism and ferroelectricity can be detected on the basis of the macroscopic magnetic- or electric-field distribution, the identification of two of the most common collective ordering phenomena of correlated electrons—namely, charge order and antiferromagnetism—in TMO heterostructures and superlattices is much more difficult.

Motivated by the desire to overcome these difficulties and to realize the potential of TMO heterostructures in controlling collective quantum phases, we have carried out a comprehensive experimental study of superlattices based on the correlated metal LaNiO₃, in which the dimensionality of the electron system was used as a control parameter, but the influence of epitaxial strain and defects was carefully monitored. An extensive body of earlier work on bulk nickelates provides an excellent background for our study. Whereas bulk LaNiO₃ is a three-dimensional (3D) Fermi liquid (4) that remains paramagnetic.

Fig. 1. Reciprocal-space maps of 100-nm-thick LaNiO₃ ($N$ unit cells (u.c.))/LaAlO₃ (N u.c.) superlattices grown under compressive strain on LaSrAlO₄ (001) with (A) $N = 4$, (B) $N = 2$, and (C) under tensile strain on SrTiO₃ (001) with $N = 2$. The black vertical lines indicate the in-plane ($Q_x$) position of the LaSrAlO₄ (109) and SrTiO₃ (103) reflections. The strain state of the perovskite epilayers is identified by the intensity distribution in the vicinity of the (103) layer Bragg peak and its superlattice satellite, which are delineated by solid- and dashed-line triangles, respectively. The reciprocal spacings of 103 strain-free pseudocubic LaNiO₃ (LNO) and LaAlO₃ (LAO) are indicated by the red circles. The red arrows point toward the origin.

and metallic at all temperatures, other lanthanide nickelates (RNiO$_3$) with smaller electronic bandwidths exhibit collective metal-insulator transitions with decreasing temperature (3). In the insulating low-temperature phase, they exhibit a periodic superstructure of the valence-electron charge and a noncollinear antiferromagnetic ordering pattern of spins on the Ni atoms (5–8). This implies that the itinerant conduction electrons of LaNiO$_3$ are highly correlated and on the verge of localization. Experiments on a controlled number of atomically thin LaNiO$_3$ layers separated by the electronically inactive wide-gap insulator LaAlO$_3$ are thus well suited for attempts to control the phase behavior of a correlated-electron system via its dimensionality. We have used wide-band spectroscopic ellipsometry to accurately determine the dynamical electrical conductivity and permittivity, which (in contrast to the dc conductivity) are not influenced by misfit dislocations. Low-energy muons, which are stopped in the superlattice (SL) before they reach the substrate, served as a sensitive probe of the internal magnetic field distribution. Two consecutive, sharp phase transitions in the charge and spin sector revealed by this experimental approach demonstrate that the electronic properties of our SLs are determined by electron correlations and not by interfacial disorder. By changing the LaNiO$_3$ layer thickness, we demonstrate full dimensionality control over the collective phase behavior.

The SLs were grown by pulsed-laser deposition (9, 10) and comprised $N$ consecutive layers of LaNiO$_3$ and the LaAlO$_3$. To discriminate between the influence of dimensionality and epitaxial strain, we have grown SLs on both SrTiO$_3$, which induces tensile strain in the overlay, and LaSrAlO$_4$, which induces compressive strain. Figure 1 shows contour maps of the diffracted x-ray intensity distribution in the vicinity of the 103 perovskite Bragg peak for three representative samples: $N = 4$ and $N = 2$ SLs grown on LaSrAlO$_4$ (001) and an $N = 2$ SL on SrTiO$_3$ (001). Both the position and shape of the overlay layer reflection are strongly affected by inversion of the type of substrate-induced strain (Fig. 1, B and C), but they remain essentially unchanged by varying the individual layer thicknesses $N$ (Fig. 1, A and B). A detailed analysis of the substrate-induced strain and relaxation effects is provided in the Supporting Online Material (SOM) (10). In the following text, we show that the transport and magnetic properties of the SLs are only weakly influenced by the strain-induced local structural distortions and interfacial defects, but they are qualitatively transformed by varying the number of consecutive unit cells within the LaNiO$_3$ layers.

The charge transport properties of the SLs were determined by spectral ellipsometry, which yields the frequency-dependent complex dielectric function $\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega)$, related to the optical conductivity $\sigma(\omega)$ by $\varepsilon(\omega) = 1 + 4\pi\sigma(\omega)/\omega$. This method is very sensitive to thin-film properties because of the oblique incidence of light, and it is insensitive to the influence of strain-induced extended defects on the current flow through the atomically thin layers (10, 11). Figure 2, A and B, shows the infrared spectra of $\varepsilon_2(\omega)$ for $N = 4$ and 2 SLs grown on LaSrAlO$_4$ and SrTiO$_3$, respectively, which are representative of the in-plane dielectric response of the metallic LaNiO$_3$ layers. The insets show the corresponding temperature dependencies of $\varepsilon_2$ at a fixed photon energy $\hbar\omega = 30$ meV ($h$, Planck’s constant $h$ divided by $2\pi$). The gradual evolution of $\varepsilon_2$ with temperature over the far-infrared range confirms that the $N = 4$ SLs remain metallic at all temperatures. The $N = 2$ SLs, on the other hand, show clear evidence of a metal-insulator (MI) transition upon cooling, with a sharp onset at the transition temperatures $T_{MI} = 150$ and 100 K for SLs grown on LaSrAlO$_4$ and SrTiO$_3$, respectively. For $T \gtrsim T_{MI}$, the infrared $\varepsilon(\omega)$ spectrum of $N = 2$ SL is well described by a broad Drude response $\varepsilon(\omega) = \varepsilon_{\infty} - \omega_p^2/\left(\omega^2 + i\gamma\right)$ with a ratio of scattering rate and plasma frequency $\gamma/\omega_p \approx 0.2$ (lower shaded line in Fig. 2A) that is typical for bulk complex oxides. The effective mass enhancement $m^*/m_i$ is estimated from the plasma frequency as $m^*/m_i = 4\pi\epsilon_{\infty}/\omega_p^2$, where $\epsilon_{\infty} = \frac{1}{2} \times 1.7 \times 10^{22}$ cm$^{-3}$, by assuming one electron per Ni atom. With $\omega_p \approx 1.1$ eV [Fig. 2A and fig. S7 (10)] the Drude model fit to $\varepsilon_2(\omega)$ at 175 K for the $N = 2$ (4) SL with $\omega_p = 1.05$ eV (1.10 eV) and $\gamma = 200$ meV (90 meV). The insets provide the corresponding temperature dependencies of $\varepsilon_2$ at a photon energy of $\hbar\omega = 30$ meV for the $N = 2$ (circles) and $N = 4$ (triangles) SLs. C and D: Temperature dependence of the as-measured pseudodielectric permittivity $\varepsilon_1(\omega)$ at $\hbar\omega = 0.8$ eV in the $N = 2$ (blue) and $N = 4$ (black) SLs on (C) LaSrAlO$_4$ and (D) SrTiO$_3$. E: The difference between the optical conductivity spectra $\sigma_1(100$ K, $\omega)$ and $\sigma_1(10$ K, $\omega)$ (shaded area) quantifies the reduction of the effective charge density, $\Delta N = 0.03$ per Ni atom, within the gap energy range below 0.43 eV at the charge ordering transition in the $N = 2$ superlattice on SrTiO$_3$. F: Temperature dependence of $\varepsilon_2^* \approx 0.8$ eV of reference 100-nm films of LaNiO$_3$ (black) and NdNiO$_3$ (blue).
in the SOM (10), we obtain \( m^*/m = 10 \), which is in good agreement with the value for bulk LaNiO\(_3\) obtained from specific heat measurements (12). Using the Fermi energy \( E_F = 0.5\) eV derived from the thermopower of LaNiO\(_3\) (12) and \( \gamma \) from the Drude model fit to the infrared spectra, we estimate the mean free path as \( l = \frac{1}{\pi e \gamma} \sqrt{2E_F / m^*} \) (c, speed of light). For the \( N = 2 \) and \( N = 4 \) SLs on both substrates, we obtain \( l = 5 \) to 6 Å and 10 to 12 Å, respectively (10). Remarkably, the mean free path correlates with the individual LaNiO\(_3\) layer thickness, testifying to the high quality of the interfaces.

The charge-carrier localization at lower temperature can be readily identified through a rapid drop in \( \varepsilon\) (T) and progressive deviation of \( \varepsilon\) (T) from the Drude function due to the formation of a charge gap. The temperature evolution of the real part of the dielectric function provides complementary information about the optical spectral-weight redistribution at \( T_{MI} \). Figure 2, C and D, show the temperature dependence of the as-measured permittivity, \( \varepsilon_1^* \), at an energy above the gap (\( \hbar \omega = 0.8\) eV). In the metallic phase, \( \varepsilon_1^* \) decreases with decreasing temperature, following the temperature dependence of the scattering rate \( \gamma(T) \). This is characteristic of a narrowing of the Drude peak where the spectral weight is removed from the high-energy tail and transferred to the far-infrared range near the origin. The charge-gap formation below \( T_{MI} \) in \( N = 2 \) SLs leads to the reverse spectral-weight transfer from the inner-gap region to excitations across the gap and, as a consequence, to an increase in \( \varepsilon_1^* \).

The consistent temperature evolution of \( \varepsilon_1 \) and \( \varepsilon_2 \) over a broad range of photon energies demonstrates the intrinsic nature of the charge-localization transition observed in SLs with \( N = 2 \) and provides clues to its origin. The spectral-weight reduction within the gap can be quantified in terms of the effective number of charge carriers per Ni atom and extracted from a sum-rule analysis as \( \Delta S\)WF = \( \frac{\gamma}{2\pi \omega} \int_{T_{MI},0}^{T} (1 - \varepsilon_1(T)) d\omega \), where \( \hbar \) is the free-electron mass, \( \varepsilon \) is the charge on the electron, and \( n_{Ni} \) is the density of Ni atoms. The upper integration limit, \( \Omega_N \approx 0.43 \) eV, is a measure of the charge gap and can be identified with the equal- (or isoelastic) point, where \( \varepsilon_1 \) (or \( \omega \)) curves at different temperatures intersect (Fig. 2E). The charge-gap formation on this energy scale can be attributed to a charge-ordering instability, as in the case of bulk lanthanide nickelates (RNiO\(_3\)) with smaller \( R \)-ion radius (5–8). The spectral weight \( \Delta S\)WF = 0.03 below \( \Omega_N \approx 0.43 \) eV determined for the \( N = 2 \) SLs (Fig. 2E) is of the same order as, albeit somewhat lower than, the corresponding quantity \( \Delta S\)WF = 0.058 below \( \Omega_N \approx 0.3 \) eV reported at the metal-insulator transition in bulk NdNiO\(_3\), which is known to be due to charge order (13). To highlight the analogy to the behavior in bulk nickelates, Fig. 2F shows reference measurements on single 100-nm-thick films of NdNiO\(_3\) and LaNiO\(_3\), measured under the same conditions as in Figs. 2, C and D. Because \( \varepsilon_1^* \) at 0.8 eV for the single NdNiO\(_3\) film displays closely similar temperature dependence as found for \( N = 2 \) SLs, we conclude that the gap formation in the latter case also reflects charge ordering. In NdNiO\(_3\), the metal-insulator transition occurs as a first-order transition with a concomitant noncollinear antiferromagnetic ordering at the Neel temperature \( T_N = T_{MI} \) (6–8). The thermal hysteresis in the \( \varepsilon_1^* (T) \) curve in Fig. 2F is consistent with the first-order character of the transition, with uniform and charge-ordered phases coexisting over a broad temperature range. In contrast, there is no discernible hysteresis observed in \( \varepsilon_1^* (T) \) of \( N = 2 \) SLs (Figs. 2, C and D), which suggests a second-order transition. Continuing the analogy with the bulk nickelate series, one would then expect another second-order transition due to the onset of antiferromagnetic ordering at \( T_{MI} \sim T_N \) in the \( N = 2 \) SLs, as in RNiO\(_3\) with small \( R \) (Lu through Sm).

To test this hypothesis, we carried out low-energy muon spin rotation (\( \mu\)SR) measurements using the \( \mu\)SR beamline at the Paul Scherrer Institute (10, 14), where positive muons with extremely reduced velocity can be implanted into specimens and brought to rest between the substrate and the LaAlO\(_3\) capping layer. Because the muons decay into positrons preferentially along the spin direction, they act as highly sensitive local magnetic probes. Figure 3A shows muon decay asymmetry data from a SL with \( N = 2 \) at selected temperatures with no external field. At \( T > 50 \) K, the asymmetry is described by a Gaussian with relatively slow relaxation, \( \sigma \), given by \( A(0) \times \exp(-\sigma^2 t^2) \), where \( t \) is time (solid lines in Fig. 3A), typical of dipolar magnetic fields generated by nuclear moments of La and Al. As the temperature decreases, there is a gradual increase in \( \sigma \) from 0.17 \( \mu \)s\(^{-1}\) at 250 K to 0.27 \( \mu \)s\(^{-1}\) at 20 K. Below 50 K the asymmetry drops sharply, and the \( \mu\)SR spectra can be fitted well by introducing an additional exponential relaxation \( \exp(-\Lambda t) \). The fast depolarization rate \( \Lambda \) reaches a value of \( \approx 17 \mu \)s\(^{-1}\) at 5 K, implying a resulting Lorentzian distribution of local fields with half width at half maximum \( \Delta B = 0.75 \gamma_\mu B = 150 \) G, where \( \gamma_\mu = 2\pi \times 13.55 \) MHz/kG is the muon’s gyromagnetic ratio (10). The fast increase in \( \Lambda \) with decreasing temperature below 50 K is similar to the behavior in bulk NdNiO\(_3\) (15) and (Y,Lu)NiO\(_3\) (16) below \( T_N \), caused by static internal fields from ordered Ni magnetic moments. The wide field distribution \( \Delta B \) and the absence of a unique muon precession frequency reflects the SL structure with several inequivalent muon stopping sites in the alternating magnetic (LaAlO\(_3\)) and nonmagnetic (LaNiO\(_3\)) layers, probably composed by a complex noncollinear spin structure as in the bulk nickelates (15, 16).

We used 100-G transverse field (TF) measurements to determine the fraction of muons, \( f_{m} \), experiencing static local magnetic fields \( B_{loc} > B_{TF} \) (i.e., showing no detectable precession with \( \omega = \gamma_\mu B_{TF} \) (10)). Figure 3C indicates that the \( N = 2 \) SL shows a transition from an entirely paramagnetic muon environment (\( f_{m} = 0 \)) to a nearly full volume of static internal fields, with a sharp onset at \( T_N \sim 50 \) K. The magnetic state at 5 K is robust against externally applied transverse fields up to 3 kG (not shown in Fig. 3), which is the limit of time resolution of our setup. The continuous temperature dependence of \( f_{m} \) (Fig. 4) and the absence of thermal hysteresis indicate that the magnetic transition for the \( N = 2 \) SLs is second-order. At the same time, Fig. 3, B and D, show that SLs with thicker LaNiO\(_3\) layers remain paramagnetic down to the lowest temperatures, as in bulk LaNiO\(_3\). An additional slow exponential relaxation with \( \Lambda = 0.9 \mu \)s\(^{-1}\) is seen only at \( T = 5 \) K (black symbols and curve in Fig. 3B). This results in a small increase in relaxation rate, but no loss in asymmetry of the TF \( \mu\)SR signal (Fig. 3D). The effect is probably due to weak dynamical spin correlations that are quenched already in a field of 100 G, in clear contrast to the long-range static magnetic order observed in the \( N = 2 \) samples.

As a local probe, \( \mu\)SR does not allow definite conclusions about the magnetic ordering pattern in the \( N = 2 \) SLs. However, we can rule out ferromagnetism on the basis of an estimate of the ordered moment, \( \mu_{s,\mbox{Ni}} \), on the Ni sites from the distribution of local fields experienced by the muons. The highest local field at the shortest \( \mu\)-Ni distance, \( c/4 \) (where \( c \) is the lattice parameter of the orthorhombic unit cell) \( \approx 1.92 \) A (15), is to 5 times \( \Delta B \), which corresponds to \( \mu_{s,\mbox{Ni}} \geq 0.5 \mu_B \). If these moments were co-aligned in the ordered state, the corresponding total moment \( M = \mu_{s,\mbox{Ni}} B \) \( \geq 7.7 \times 10^{-6} \) emu (where \( B \) is the volume of the superlattice) would have been readily detected in magnetization measurements. The absence of such an effect is confirmed in magnetometric measurements with sensitivity \( \sim 10^{-7} \) emu.
Figure 4 summarizes the phase behavior of the SLs with $N = 2$, which undergo a sequence of two sharp, collective electronic phase transitions upon cooling. We have provided strong evidence that the two transitions correspond to the onset of charge and spin order. By showing that the $N = 4$ counterparts remain uniformly metallic and paramagnetic at all temperatures, we have demonstrated full dimensionality control of these collective instabilities. The higher propensity toward charge and spin order in the 2D systems probably reflects enhanced nesting of the LaNiO$_3$ Fermi surface. The phase behavior is qualitatively similar to the one observed in bulk RNiO$_3$ with small radius of the $R$ anions, which results from bandwidth narrowing due to rotation of NiO$_6$ octahedra, but the transition temperatures and the order parameters are substantially lower, probably because of the reduced dimensionality. Because the transitions occur in the $N = 2$ SLs, regardless of whether the substrate-induced strain is compressive (Fig. 1B) or tensile (Fig. 1C), structural parameters such as rotation and elongation of the NiO$_6$ octahedra can be ruled out as primary driving forces. We note, however, that the infrared conductivity is higher (Fig. 2, A and B) and the transition temperatures are lower (Fig. 4) in the $N = 2$ SL grown under tensile strain. The more metallic response of these SLs, compared with those grown under compressive strain, may reflect a widening of the Ni 3$d$-electron bandwidth and/or an enhanced occupation of the Ni $d_{x^2−y^2}$ orbital polarized parallel to the LaNiO$_3$ layers. A small orbital polarization was indeed detected by soft x-ray reflectometry in our superlattices (17). This indicates further opportunities for orbital control of the collective phase behavior of the nickelates, which may enable experimental tests of theories predicting high-temperature superconductivity (18, 19) or multifricity (20) in these systems.

Competition of Superconducting Phenomena and Kondo Screening at the Nanoscale

K. J. Franke,* G. Schulze, J. I. Pascual

Magnetic and superconducting interactions couple electrons together to form complex states of matter. We show that, at the atomic scale, both types of interactions can coexist and compete to influence the ground state of a localized magnetic moment. Local spectroscopy at 4.5 keV shows that the spin-1 system formed by manganese-phthalocyanine (MnPC) adsorbed on Pb(111) can lie in two different magnetic ground states. These are determined by the balance between Kondo screening and superconducting pair-breaking interactions. Both ground states alternate at nanometer length scales to form a Moiré-like superstructure. The quantum phase transition connecting the two (singlet and doublet) ground states is thus tuned by small changes in the molecule-lead interaction.

When a magnetic atom or molecule is adsorbed on the surface of a superconductor, its magnetic moment can interact with itinerant electrons (with spin $s = 1/2$) and with Cooper pairs ($s = 0$). Normal-state electrons tend to screen the local magnetic moment and form a many-particle ground state with a total spin $S = 0$. A fingerprint of this so-called Kondo effect ($I$) is a resonance at the Fermi level, whose width reflects the energy scale of the magnetic coupling. The magnetic impurity can also weaken the local coherence of the superconducting state by the creation of spin-polarized bound states in its proximity (2–4). They appear as narrow resonances inside the superconducting energy gap (5–10). The energy position of these intragap states reflects the pair-breaking exchange interaction strength of the magnetic impurity with Cooper pairs (9, 10).

These interactions compete to produce two different magnetic ground states depending on their relative strength. A Kondo singlet is formed if the screening energy scale is larger than the pairing energy of the Cooper quasiparticles, that is, $k_B T_K \gg \Delta$, where $k_B$ (the Boltzmann constant), $T_K$ (the Kondo temperature) determines the energy scale of the screening, and the order parameter $\Delta$ governs the superconductor pairing interaction. When $k_B T_K \ll \Delta$, the opening of the superconducting energy gap reduces the density of normal electrons available for screening, and the Kondo effect is incomplete (11). The poorly screened magnetic impurity creates bound quasiparticle states that locally reduce the pairing strength of the superconducting quasiparticles and drive the system into a magnetic ground state ($S > 0$) (12).

In the limit of $k_B T_K \sim \Delta$, both Kondo screening and superconducting pairing are predicted to coexist (12–14). Changes in their relative strength can drive the system through a quantum phase transition separating the two different magnetic ground states. Here we experimentally elucidate this competition between pair-breaking and Kondo screening on individual magnetic manganese-phthalocyanine (MnPc) molecules deposited on top of a superconducting Pb(111) substrate. Using scanning tunneling microscopy (STM) and spectroscopy (STS) at 4.5 K, we resolved a complex Kondo fingerprint coexisting with localized bound states within the superconducting gap. On the Pb(111) surface, the MnPc molecule lies in a spin-1 state and is screened by two separate Kondo channels with different strength. The weaker channel competes with the creation of spin-polarized bound states. This competition leads to two different magnetic
