We present experimental evidence for a hitherto unconfirmed type of angle-dependent magnetoresistance oscillation caused by magnetic breakdown. The effect was observed in the organic superconductor $\kappa$-(BEDT-TTF)$_2$Cu(NCS)$_2$ using hydrostatic pressures of up to 9.8 kbar and magnetic fields of up to 33 T. In addition, we show that similar oscillations are revealed in ambient pressure measurements, provided that the Shubnikov-de Haas oscillations are suppressed either by elevated temperatures or filtering of the data. These results provide a compelling validation of Pippard’s semiclassical picture of magnetic breakdown.

Recently, the measurement of angle-dependent magnetoresistance oscillations (AMROs) has emerged as a powerful technique in the elucidation of the fine details of Fermi surfaces in reduced-dimensionality metals [1, 2, 3]. In contrast to de Haas-van Alphen oscillations, AMROs can be observed in rather low-quality samples [4, 5], or when temperatures are relatively high [6]; they have therefore been measured in a wide variety of systems, including crystalline organic metals [1, 7], ruthenates [2], semiconductor superlattices [8], and cuprate superconductors [4]. AMROs can, in most cases [5], be attributed to the time-evolution of the quasiparticle velocities as they traverse the Fermi surface under the influence of the magnetic field. Consequently, and based on the topologies of the orbits involved, several distinct species of AMRO have been identified, including Lebed [8, 9] and Danner-Chaikin-Kang (DCK) oscillations [10] due to orbits on quasi-one-dimensional (Q1D) sections of Fermi surface, and Yamaji oscillations [11, 12, 13], associated with closed orbits on quasi-two-dimensional (Q2D) Fermi-surface sections (for a detailed description of the differences between these effects see [1]). In this Letter we report the measurement of a further class of AMROs, observed only at high magnetic fields and caused by magnetic breakdown.

The crystalline organic metal $\kappa$-(BEDT-TTF)$_2$Cu(NCS)$_2$ was chosen for the experiments because its Fermi surface both resembles the coupled network model for magnetic breakdown first proposed by Pippard [14] and is very well characterized by theory [15] and experiment [6, 16, 17, 18]. The Fermi surface is shown in Fig. 1; it comprises a Q2D pocket and a pair of Q1D sheets. The Q2D and Q1D sections are separated in $k$-space at the Brillouin-zone boundary owing to a weak periodic potential caused by the translational symmetry of the anion layers [7]. At sufficiently high magnetic fields $B$, mixing between the states on the two Fermi surface sections leads to magnetic breakdown, in which a quasiparticle “tunnels” in $k$-space between them [14, 17, 18]. In Pippard’s semiclassical picture [14], this enables quasiparticles to execute the large $\beta$ orbit (Fig. 1) and other more complex orbits about the Fermi surface, leading to the observation of high-frequency Shubnikov-de Haas (SdH) and de Haas-van Alphen oscillations [17, 20, 21]. The probability

\[
P(\theta) = \exp(-B_0/B)
\]

of magnetic breakdown is parameterized by $B_0$, the characteristic breakdown field [14, 17, 18]. In this Letter, we show that magnetic breakdown can additionally produce a new type of AMRO in $\kappa$-(BEDT-TTF)$_2$Cu(NCS)$_2$. The origin of this phenomenon is similar to that of Yamaji oscillations [6] but in the present case, the quasi-particle trajectories responsible are magnetic breakdown orbits, rather than closed paths on Q2D Fermi-surface sections. In order to distinguish the new features from the more conventional Lebed or Yamaji oscillations we will refer to them as breakdown-AMROs or BAMROs.

Four-wire magnetotransport experiments are performed on single crystals of $\kappa$-(BEDT-TTF)$_2$Cu(NCS)$_2$ in quasistatic fields produced by 33 T Bitter coils and the 45 T hybrid magnet at NHMFL Tallahassee. A two-axis goniometer allows continuous rotation of the angle $\theta$ between the applied magnetic field and the normal to the highly conductive planes of the sample, as well as discrete changes in the plane of rotation parameterized by the azimuthal angle $\phi$. (In $\kappa$-(BEDT-TTF)$_2$Cu(NCS)$_2$ we define the $\phi = 0^\circ$ plane of rotation as being perpendicular to the Q1D sheets.) The goniometer is placed within a $^3$He cryostat allowing temperatures $T$ as low as 500 mK. Electrical contacts are applied to the samples using 12.5 $\mu$m Au or Pt wires attached using graphite paint. For the high pressure measurements, the samples are
and the Fourier transforms. The frequencies found were tum interference effect [7, 17, 20, 21] are observed in F 2D metal [17, 19]. In this way the effective mass about the Q2D pocket (\(\beta\)) and other magnetic breakdown orbits [17]. The 9.8 kbar data are enhanced by a factor of 5 and the curves are offset for clarity.

Data such as those in Fig. 1 were Fourier-analysed to reveal the SdH oscillation frequencies \(F\) present. In addition to frequencies due to the classically-allowed \(\alpha\) orbit about the Q2D pocket \((F_\alpha)\), and the \(\beta\) breakdown orbit \((F_\beta)\), combination frequencies such as \(F_\beta - F_\alpha\) and \(F_\beta - 2F_\alpha\) caused by the Shiba-Fukuyama-Stark quantum interference effect [6, 17, 20, 21] are observed in the Fourier transforms. The frequencies found were \(F_\alpha = 750 \pm 20\) T and \(F_\beta = 4030 \pm 60\) T at \(p = 9.8\) kbar, and \(F_\alpha = 610 \pm 10\) T and \(F_\beta = 3950 \pm 30\) T at ambient pressure. In addition, the \(B\) and \(T\) dependences of the \(F_\alpha\) frequency Fourier amplitudes were fitted using the standard Lifshitz-Kosevich formalism appropriate for a 2D metal [17, 19]. In this way the effective mass \(m^*_\alpha\) at \(\theta = 0^\circ\) and “Dingle” scattering time \(\tau_\alpha\) [18, 24] of the \(\alpha\)-pocket quasiparticles at 9.8 kbar were determined to be 2.0 \pm 0.1 \(m_e\) and 0.81 \pm 0.05 ps, respectively, where \(m_e\) is the electron rest mass; equivalent values for the ambient-pressure experiments were 3.5 \pm 0.1 \(m_e\) and 2.3 \pm 0.2 ps. These masses and frequencies are in reasonable agreement with previous high-pressure SdH data [18].

An earlier study of AMROs in ambient-pressure \(\kappa-(BEDT-TTF)_2Cu(NCS)_2\) [6] found that the magnetoresistance features for angles \(\theta \geq 70^\circ\) may be attributed to Lebed, Yamaji or DCK oscillations, depending on the azimuthal angle \(\phi\). It was also found that the Lebed and Yamaji oscillations do not tend to coexist at the same \(\phi\). The Lebed oscillations dominate when the plane of rotation of the field is roughly perpendicular to the Q1D sheets (\(\phi \approx 0^\circ\)); the Yamaji oscillations are more prominent when the plane of rotation of the field is close to that containing the short axis of the Q2D \(\alpha\) pocket (\(\phi \approx 90^\circ\)). Applying the same analysis [6] to the \(p = 9.8\) kbar AMRO data in this paper, the \(\phi\) angles...
at which the Lebed or Yamaji oscillations dominate are found to be comparable to those at ambient pressure.

However, an additional series of AMROs is observed for all $\phi$ when $\theta \leq 70^\circ$. Like the Yamaji and Lebed oscillations, the extra series is periodic in $\tan \theta$, but its frequency is considerably higher. To illustrate this, Fig. 2(a) shows AMRO data at $p = 9.8$ kbar. Two sets of oscillations are clearly seen, both periodic in $\tan \theta$. The frequency of the features appearing at $\tan \theta \gtrsim 3$ show them to be the Lebed oscillations expected for this value of $\phi$ [2]. The faster oscillations are only observed at $\tan \theta \lesssim 3$ ($\theta \lesssim 70^\circ$); it is these oscillations that we will identify below as BAMROs. The fact that the latter oscillations are observed with a similar frequency at all planes of rotation suggests that they result from a rather isotropic, Q2D quasiparticle orbit.

Given such an orbit, the $\tan \theta$ frequency of the resulting AMROs at a given $\phi$-angle should be proportional to $k^\text{max}_{\parallel}^2$, the maximum in-plane wavevector of the orbit projected on to the plane of rotation of the field [22]. For oscillations arising from an elliptical cross-section orbit $k^\text{max}_{\parallel}(\phi)$ can be fitted to the equation

$$k^\text{max}_{\parallel}(\phi) = [k^2_a \cos^2 (\phi - \zeta) + k^2_b \sin^2 (\phi - \zeta)]^{1/2}.$$ (2)

where $k_a$ and $k_b$ are the major and minor semi-axes of the ellipse respectively and $\zeta$ is the angle between its major axis and the $\phi = 0^\circ$ direction [22].

The $k^\text{max}_{\parallel}(\phi)$ values for the higher frequency AMROs ($\tan \theta \lesssim 3$) at 9.8 kbar are plotted in Fig. 2(b) (red circles). An unconstrained fit to Eq. 2 implies that the orbit that gives rise to the oscillations is almost circular in cross-section with an area $3.8 \pm 0.1 \times 10^{19}$ m$^{-2}$. Within the experimental errors this value agrees with the area of the $\beta$-orbit determined from the SdH frequency ($3.84 \pm 0.05 \times 10^{19}$ m$^{-2}$) measured at 9.8 kbar. The good agreement strongly suggests that the high-frequency AMROs are BAMROs caused by $\beta$ orbits that completely traverse the Q1D and Q2D Fermi-surface sections; i.e. they are only made possible by magnetic breakdown.

For comparison, Fig. 2(b) also presents the values of $k^\text{max}_{\parallel}$ determined from the Yamaji oscillations due to the $\alpha$ pocket (tending to occur at $\tan \theta \gtrsim 3$) [6]. These data (blue squares) are plotted against $\phi$ for all planes of rotation at which they are observed; at the others the Lebed oscillations dominate [6]. The dashed line is a fit to Eq. 2 where the area is constrained by $F_B$ from the SdH data. The semi-major and minor axes of the $\alpha$ pocket obtained in this manner are $2.2 \pm 0.2$ nm$^{-1}$ and $1.06 \pm 0.09$ nm$^{-1}$ respectively. Therefore, in good quantitative agreement with earlier work [18, 27], we find the effect of increased pressure is to make the $\alpha$ pocket less elongated.

Increased hydrostatic pressure is known to reduce the breakdown field $B_0$ in $\kappa$-(BEDT-TTF)$_2$Cu(NCS)$_2$ [18], enhancing the likelihood of magnetic breakdown (see Eq. 1). Having identified BAMROs at $p = 9.8$ kbar, it is instructive to see if the same effect occurs at ambient pressure where the breakdown probability is lower. Fig. 3(a) shows the angle-dependent magnetoresistance measured at ambient pressure, $B = 42$ T, $T = 1.5$ K and $\phi = 160^\circ$. The upper curve comprises raw data; as in Fig. 2 Lebed oscillations are seen at $\tan \theta \gtrsim 3$. However, at lower values of $\tan \theta$ the data are dominated by SdH oscillations from the $\alpha$-orbit [6]. The lower curve in Fig. 3(a) shows the same data after numerical processing to remove the SdH oscillations (the abscissa is converted to $B \cos \theta$ and the data passed through a low-pass Fourier transform filter with a 100 T cut-off frequency). The filtering reveals the presence of AMROs, previously hidden by the SdH, that are periodic in $\tan \theta$ and almost identical to the BAMROs seen at 9.8 kbar. A fit to Eq. 2 of the $\phi$-dependence of the frequency of these oscillations gives an orbit area of $3.4 \pm 0.3 \times 10^{19}$ m$^{-2}$ in reasonable agreement with that obtained from $F_B$ in the ambient-pressure SdH data ($3.76 \pm 0.03 \times 10^{19}$ m$^{-2}$).

Fig. 3(b) shows data taken at a similar $\phi$ to those in (a) but at higher $T$. AMROs are known to be robust at lower $B/T$ than magnetic quantum oscillations as they do not depend so strongly on thermal smearing of the Fermi surface [7, 20]. Thus at $T = 4.2$ K the SdH are no longer visible, whereas both the BAMROs and Lebed oscillations are clearly observed. Indeed, both are still discernible at $T = 10.6$ K, albeit with a reduced amplitude [26].

Thus, it appears that BAMROs are observable in $\kappa$-(BEDT-TTF)$_2$Cu(NCS)$_2$ at ambient pressure. A comparison of Fig. 3(a), in which the BAMROs appear to be more prominent compared to the background than the features seen in the filtered data of Fig. 3(a), measured at the same temperature but at a higher magnetic field, indeed suggests that the enhanced breakdown probability at higher pressures promotes the BAMRO mechanism. However, a more significant factor in explaining why the BAMROs are so clear in the high pressure data, but somewhat concealed in ambient pressure data, is the relative strength of the SdH oscillations. The sample used in the pressure studies exhibits a significantly lower Dingle scattering time ($\tau_D \approx 0.81$ ps) than the sample used for the ambient-pressure experiments ($\tau_D \approx 2.3$ ps). Even though $m_e$ decreases from $3.5m_e$ to $2.0m_e$ on going from ambient pressure to 9.8 kbar (see above and Ref. 18) the Dingle scattering time is reduced by a greater factor, greatly suppressing the SdH oscillations in the 9.8 kbar experiments.

Elevated $T_s$ also suppress SdH oscillations [26] (Fig. 3(b)), revealing the underlying BAMROs. The fact the BAMRO features survive at scattering times and $T_s$ at which the SdH cannot be observed is further evidence that their mechanism is related to semiclassical quasiparticle trajectories across the Fermi surface, similar to those invoked to explain Yamaji oscillations [6, 26].

Therefore, we believe that, although present, BAM-
ROs have not previously been identified in \( \kappa- \text{(BEDT-TTF)}_2 \text{Cu(NCS)}_2 \) because, in general, angle-dependent magnetotransport measurements are performed at low T\( s \) with the cleanest possible samples. Under these conditions the data at the \( \theta \)-angles where BAMROs are observed are dominated by the SdH oscillations.

All AMROs are progressively damped as \( \theta \) increases. In \( \kappa- \text{(BEDT-TTF)}_2 \text{Cu(NCS)}_2 \), this is known to occur because the amplitude of the Yamaji and Lebed oscillations is governed by the value of \( \omega \tau \), where \( \omega \) is an angular frequency of the orbit responsible and \( \tau \) is a scattering time. The orbit frequency depends on the projection of the magnetic field, and so \( \omega \propto \cos \theta \), leading to a decrease in \( \omega \tau \) and hence AMRO amplitude as \( \theta \) increases. However, compared to conventional AMROs, BAMROs will have an additional damping factor due to Eq. 1 because in Q2D systems such as \( \kappa- \text{(BEDT-TTF)}_2 \text{Cu(NCS)}_2 \), \( B_0 \) is found to be inversely proportional to \( \cos \theta \). The factor of \( \cos \theta \) leads to additional attenuation as \( \theta \) increases, so that the BAMROs are only noticeable for \( \theta \leq 70^\circ \).

In summary we have shown conclusive experimental evidence of BAMROs, angle-dependent magnetoresistance oscillations caused by magnetic breakdown. Magnetic breakdown has been interpreted semiclassically in terms of quasiparticle orbits that jump gaps between Fermi surfaces in \( k \)-space. This model has been extensively explored via a detailed analysis of the magnetoresistance oscillations that arise in Mg due to the quantum interference of the quasiparticle orbits (see [28] and references therein). The observation of BAMROs provides a further compelling validation of this picture of magnetic breakdown, and in addition represents the only experimental manifestation of magnetic breakdown that can be described in purely semiclassical terms.
