Objective: This study aimed to investigate the effect of timing of surgery on neurological recovery for patients with metastatic spinal cord compression (MSCC).

Methods: According to the timing of surgery, 75 patients with incomplete paraplegia caused by MSCC were assigned to 3 groups: within 3 days (group A), between 4 days and 7 days (group B), and after 7 days (group C). T-test, one-way ANOVA, Mann–Whitney U-test, and Chi-square test were used to evaluate the difference in the improvement of American Spinal Injury Association Impairment Scale (AIS) and ambulatory status, the incidence of perioperative complications, surgical site infection, and the length of hospital stay between 3 groups.

Results: Patients with incomplete paraplegia treated in our department had an average of 17.4±1.8 days delayed and most occurred before hospitalization (4.0±0.4 vs 13.2±1.8, P<0.001). There was no significant difference in the AIS improvement between patients with different pre-op AIS. The timing of surgery was significantly correlated with AIS improvement (correlation coefficient=−0.257, P=0.019). Sub-analysis showed that patients who underwent surgery within 7 days (group A and group B) had significantly better AIS improvement compared with group C (improved at least 1 grade, P=0.043; improved more than 1 grade, P=0.039) and the surgery timing was more important for patients with AIS B and C. The timing of surgery was significantly correlated with the length of hospital stay (correlation coefficient=0.335, P=0.003). Patients of group C had the longest length of hospital stay (P=0.002). The incidence of perioperative complications and surgical site infection did not differ significantly between the 3 groups.

Conclusion: Delay surgery was common in incomplete paraplegia patients with MSCC. Patients with AIS B and C who underwent surgery within 7 days had better AIS improvement.

Keywords: timing of surgery, metastatic spinal cord compression, incomplete paraplegia, neurologic function

Introduction

Metastatic spinal cord compression (MSCC) is one of the most severe complications for patients with cancer. The number of patients with MSCC has remarkably increased in recent years.1,2 Treatment of MSCC is dependent upon global performance status, expected survival, neurological and mechanical factors of the patients.3–5 Spinal cord injury caused by MSCC is a major challenge for spinal surgeons. The timing of surgery is considered to be a key factor affecting neurological recovery. For patients with acute complete paraplegia caused by MSCC or trauma, surgery should be performed as soon as possible.6–9 However, it is not clear...
when the surgery should be performed for patients with incomplete paraplegia caused by MSCC.

More evidence is needed to confirm the relationship between the timing of surgery and neurological recovery for patients with incomplete paraplegia caused by MSCC. Most studies have only focused on patients’ survival or just report the results of the neurological outcomes. Relatively few studies investigated neurological prognostic factors for patients with MSCC. These studies had either small sample size or enrolled patients with lumbar and sacral metastases. Besides, there was no independent analysis of paraplegia and incomplete paraplegia among these studies. Fürstenberg et al just reviewed 35 patients. Although a total of 153 patients were included in the study performed by Quraishi et al, 30 patients with lumbar and sacral metastases without spinal cord were also included. These studies’ results cannot truly reflect the relationship between the timing of surgery and the neurological recovery of patients with incomplete paraplegia caused by MSCC.

We performed this study to investigate the effect of the timing of surgery on neurological recovery for patients with incomplete paraplegia caused by MSCC. Meanwhile, we evaluate its impact on patients’ perioperative complications, wound infections, and the length of hospital stay.

Materials and Methods
Study Design and Selection Criteria
This study was a single-centered retrospective, non-randomized cohort study of patients with spinal metastases who performed decompression surgery from November 2010 to September 2017. A total of 211 patients were included as our initial cases. We excluded those patients with incomplete data (4), lumbar spine metastases (49), normal spinal cord function and ambulatory status (78), complete paraplegia (3), and spinal cord function deteriorated within 2 weeks after surgery due to tumor progression (2). At least, 75 patients with incomplete spinal cord injury were included in this study. They were assigned to 3 groups according to the surgery timing (counted from the onset of the symptom: weakness or numbness): group A comprised patients who underwent surgery within 3 days; group B comprised patients who underwent surgery between 4 and 7 days, and group C comprised patients who underwent surgery after 7 days. Only the first round was analyzed for patients who underwent multiple-round surgery at the same site due to tumor recurrence.

All patients underwent a physical examination. X-ray and Magnetic Resonance Imaging (MRI) were performed to confirm the location of the lesion. Their blood samples were taken before surgery. The choice of surgical treatment mainly depends on the patients’ Tokuhashi score. Usually, patients with a life expectancy of less than 6 months (Tokuhashi score >8) received palliative treatment, while other patients received surgical treatment. However, with the development of targeted therapy, the prognosis of some patients has been improved, such as patients with adenocarcinoma of lung and these patients (Tokuhashi score <8) tend to receive surgical treatment. For patients with a life expectancy of more than 12 months, a total or subtotal spondylectomy was carried out, while other patients received decompression surgery. Tumour debulked at the same time when patients underwent decompression surgery. All the tumors on the dorsal and bilateral sides of dura were removed. Tumors on the ventral sides of dura were partially removed and the space between tumor and dura should be kept at least 1 mm to ensure that the spinal cord compression was completely relieved. The surgery option was determined by multidisciplinary cooperation, composing of an experienced neuroradiologist, a spinal tumor surgeon, and an oncologist. Our institute’s research ethics boards approved the study protocol and required neither patient approval nor informed consent for review of patients’ images and medical records. Moreover, this study was conducted in accordance with the declaration of Helsinki. The flow of patient enrolment is shown in Figure 1.

Data Collection
Patients’ characteristics, including demographic information, comorbidities (cardiovascular and respiratory system), primary tumor pathology, ambulatory status, and neurological function according to American Spinal Injury Association Impairment Scale (AIS) recorded pre-op and 2 weeks post-op, Karnofsky score, Eastern Cooperative Oncology Group (ECOG), and Tokuhashi score were carefully extracted from their electronic medical records. Surgery related data such as the location (cervical; upper thoracic: T1-T6; lower thoracic: T7-T12) and the number of decompression segment, the grade of epidural compression (Bilsky), perioperative complications, surgical site infection, and the length of hospital stay were also collected.
Treatment Method
Surgery was performed via the median posterior approach by three experienced spinal tumor surgeons under general anesthesia. Laminectomy or corpectomy combined with or without bone cement was performed based on the location of the tumor. Patients were given methylprednisolone 500 mg on the day of surgery and then gradually reduced to stop 4 days after surgery. Patients received adjuvant radiotherapy postoperatively as required.

Measurement of Outcomes
Five clinical outcome measures were included in this study: 1) spinal cord function, 2) ambulatory status, 3) perioperative complications, 4) surgical site infection, 5) the length of hospital stay. The change in AIS evaluated spinal cord functional outcomes at 2 weeks after surgery. Perioperative complications included surgical or postoperative complications, such as dural sac injury and respiratory system complications.

Statistical Analysis
Quantitative variables were presented as mean (standard deviation) when they were in a normal distribution and median (range) when they were not. Categorical variables are presented as frequencies and constituent ratios. Independent t-test, one-way ANOVA, and Mann–Whitney U-test were used to detect the quantitative variables’ difference. The differences among the categorical variables were analyzed using the Fisher’s exact test or Pearson Chi-square test. The relationship between surgery timing and outcome measures was evaluated using the Kendall tau rank and Spearman correlation analysis. All tests were 2-sides. Delete cases with missing values during the statistical process. A p-value <0.05 was considered statistically significant. All statistical analyses were performed with the IBM SPSS Statistics 25 (IBM Corporation, Armonk, NY.).

Results
Sample Baseline Characteristics
In total, 75 patients were enrolled in the study. There are 8 patients in group A, 14 in group B, and 53 in group C. Patients’ baseline characteristics are shown in Table 1. The demographic, primary tumor, Tokuhashi score, compression grade of the spinal cord, location, and the number of decompression segments did not differ significantly between 3 groups. The sub-analysis showed group C had...

| Time delayed from onset of the symptom (day) | | | | | |
| Before Hospitalization         | 0.9±0.2      | 3.9±0.5       | 17.5±2.2      | <0.001                   | <0.001          |
| After Hospitalization          | 1.8±0.3      | 2.1±0.4       | 4.9±0.5       | 0.002                    | <0.001          |
significantly more comorbidity (P=0.039), higher Karnofsky score (P=0.012), and ECOG (P=0.005) compared with group A and B. Patients with incomplete paraplegia treated in our department had an average of 17.4 ±1.8 days delayed and most occurred before hospitalization (4.0±0.4 vs 13.2±1.8, P<0.001). Patients in group C had significantly more time delayed before and after hospitalization compared with group A and B (P<0.001).

### American Spinal Injury Association Impairment Scale (AIS) and Ambulatory Status

Group C had significantly more patients with AIS at grade D (P<0.001). The improvement of AIS and ambulatory status did not differ significantly between the three groups (Table 2, Figures 2 and 3). However, surgery timing was significantly negatively correlated with AIS improvement (Correlation coefficient=−0.257, P=0.019) (Table 3). The sub-analysis showed that group C had a significantly better AIS improvement (at least 1 grade, P=0.043; more than 1 grade, P=0.039) compared with group A and B (Table 2, Figures 2 and 3). The analysis of the patients with different pre-op AIS grade showed that the surgery timing was more important for patients with AIS B and C, and did not even reach statistical significance (Table 3). There was no significant difference in the AIS improvement between patients with different pre-op AIS (Table 4).

### Perioperative Complications, Surgical Site Infection, and the Length of Hospital Stay

There was no significant difference in the incidence of perioperative complication and surgical site infection between 3
The surgery timing (days) was significantly positively correlated with the length of hospital stay (Correlation coefficient=0.355, P=0.003) (Table 3). The sub-analysis showed that group C had a significantly longer length of total hospital stays and post-op hospital stays than group A and B (P=0.002, P=0.019) (Table 2).

Figure 2 Change of American Spinal Injury Association Impairment Scale (AIS) 2 weeks after surgery between 3 groups, as indicated by co-plotting the postoperative AIS against the preoperative AIS. (A), group A; (B), group B; (C), group C. (D), group A+B.

Although several studies had investigated the prognostic factors of the spinal cord’s neurological recovery for patients with MSCC, the present study, including a relatively large number of patients, clearly exclude patients with lumbar, 10, 12, 14, 15 or sacrum spine and only focuses on patients with incomplete paraplegia.

The study of Fürstenberg et al and Quraishi et al showed that patients with MSCC and neurological deficit underwent surgery within 48 hours to recover better. 12, 14 However, the

| ASIA D        | 3        | 4            |          |
| Group C       | 0.131    |              |          |
| ASIA B and C  | 10       | 5            |          |
| ASIA D        | 16       | 23           |          |

The mechanism of spinal cord injury can be divided into primary and secondary injuries. The primary injury appears immediately after the damage, mainly due to tissue destruction, while the secondary injury is caused by a series of complicated pathophysiological processes, including edema, demyelination, apoptosis of nerve cells, scar formation, etc. Spinal cord edema appears within a few hours after injury and reaches its maximum degree between 3 and 6 days after injury, accompanied by demyelination. For patients with complete paraplegia, spinal cord injury rapidly progressed. When the edema began to recover, the damaged tissue was gradually replaced by central hemorrhage and necrosis, which are more likely to be irreversible. Unlike complete paraplegia, incomplete paraplegia caused by MSCC usually progresses slowly, and neurological function is more likely to be compensated and reversible. Park et al showed that although Bilsky's compression grade was at 2 or 3, some patients with MSCC still had no signs of neurological deficit. So, it was reasonable to restrict more “cut-off value (2 days)” for previous studies, including patients with complete paraplegia. However, patients with spinal metastasis at the lumbar and sacrum might affect the validity of their results.

These findings encourage us to conduct a thorough analysis of our database of patients with MSCC and incomplete paraplegia. Patients with incomplete paraplegia treated in our department had an average of 17.4±1.8 days delayed. We classify our retrospective cohort into different groups depending on the surgery timing. Patients in group C had more comorbidities, less Karnofsky score and ECOG, and need more time to complete the preoperative preparations. Most time delay occurred before hospitalization and the result was consistent with previous results. The results of the present study showed that the surgery timing was negatively correlated with AIS improvement. However, our results differed from the previous study at the “cut-off value (7 days vs 2 days)” performed by Fürstenberg et al and Quraishi et al.

In our study, group C had more patients with AIS at grade D. A similar situation appeared in Quraishi et al’s report. This condition explained why patients’ ambulatory status in group C improved best in our study, although did not reach the statistical level. On the other hand, the more patients who were ASIA D with multi-comorbidities in group C, meaning they did not have as much neurological deficit and had less capacity to improve, might skew the results. We analyzed the AIS improvement in patients with different pre-op AIS grades. There was a tendency for patients with ASIA D to improve poorly compared with patients with ASIA B and C. In addition, our results showed that the surgery timing was more important for patients with AIS B and C compared with patients with AIS D. In the following study, we will expand the sample size and analyze patients with different AIS grades separately. Other than preoperative AIS grades, ambulatory status before surgery, the time of developing motor deficits and the quality of decompression also affected the ambulatory recovery.

Yousefifard et al and Bourassa-Moreau et al reported that the incidence of complications after early surgery was significantly lower than that of delayed surgery for patients with acute traumatic spinal cord injury. Similar to Quraishi et al’s study, perioperative complications and surgical site infections did not differ between 3 groups in our study. Based on the results of the present study, although delayed surgery was safe in terms of...
perioperative complications and surgical site infection, the surgery timing had a positive correlation with the length of hospital stay and a negative correlation with the AIS improvement. Patients in group C had the longest length of hospital stays, including pre-op and post-op hospital stays. This result might be related to the more comorbidity of patients in group C. These patients needed more time for the optimization of their comorbidities and recovery.

We acknowledge some limitations of the present study. First, it was limited by its retrospective and non-randomized design. Second, due to the limited sample size, patients with different ASIA grades were not analyzed separately. Next, the speed of deterioration of spinal cord function was not taken into account because of its retrospective nature. However, this study provides essential information regarding surgery timing for patients with incomplete paraplegia caused by MSCC.

In conclusion, this study showed that delay surgery was common in incomplete paraplegia patients with MSCC. Patients with AIS B and C who underwent surgery within 7 days had better AIS improvement.
