\textit{Draft version March 20, 2022}

1. INTRODUCTION

The excess ultraviolet radiation from early-type galaxies arises from hot stars in late stages of stellar evolution (O’Connell 1999). Whether the so-called UV-upturn depends on the detailed galaxy morphology (ellipticals vs. lenticulars) and, among ellipticals, on luminosity (dEs vs. giant Es) is yet unknown. It would not be surprising if the UV properties of dwarf elliptical galaxies would differ from those of giants, given that other structural (Gavazzi et al. 2005) and kinematic (Van Zee et al. 2004) properties depend on luminosity, due to different star formation histories (single episodic vs. burst) (Ferguson & Binggeli 1994; Grebel 1999).

Due to morphological segregation (Whitmore et al. 1993), nearby clusters are the ideal targets for assembling complete, volume limited samples of early-type objects. As part of a study aimed at analyzing the environmental dependence of galaxy evolution, we observed large portions of the Virgo cluster with GALEX (Boselli et al. 2005). Owing to the superior quality of the photographic material obtained by Sandage and collaborators, an extremely accurate and homogeneous morphological classification exists for Virgo galaxies, down to $m_B \leq 18$ mag ($M_B \leq -13$ assuming a distance of 17 Mpc), allowing a detailed discrimination among different subclasses of early-type galaxies (ellipticals, lenticulars, dwarfs) and an exclusion of quiescent spirals. Furthermore a wealth of ancillary data for many Virgo members, covering a large portion of the electromagnetic spectrum from the visible to the infrared is available from the GOLDMine database (Gavazzi et al. 2003).

2. DATA

The analysis presented in this work is based on an optically selected sample of early-type galaxies including giant and dwarf systems (E, S0, S0a, dE and dS0) extracted from the Virgo Cluster Catalogue of Binggeli et al. (1985), which is complete to $m_B \leq 18$ mag ($M_B \leq -13$). The Virgo cluster region was observed in spring 2004 as part of the All Imaging Survey (AIS) and of the Nearby Galaxy Survey (NGS) carried out by the Galaxy Evolution Explorer (GALEX) in two UV bands: FUV ($\lambda_{\text{eff}} = 1530 \, \AA$, $\Delta \lambda = 400 \, \AA$) and NUV ($\lambda_{\text{eff}} = 2310 \, \AA$, $\Delta \lambda = 1000 \, \AA$), covering 427 objects. Details of the GALEX instrument and data characteristics can be found in Martin et al. (2005) and Morrissey et al. (2005).

The present sample includes all Virgo cluster early-type systems detected in the NUV GALEX band (264 objects, 194 from the NGS); of these, 126 (of which 74 from the NGS) have been also detected in the FUV. The resulting sample is thus ideal for the proposed analysis as it provides us with the first large volume-limited sample of elliptical, lenticular and dwarf galaxies spanning 4 dex in luminosity with homogeneous data. Whenever available, we extracted fluxes from the deep NGS images, obtained with an average integration time of $\sim 1500$ sec, complete to $m_{AB} \sim 21.5$ in the NUV and FUV. Elsewhere UV fluxes have been extracted from the less deep
AIS images (∼ 70 sq. degrees), obtained with an average integration time of ∼ 100 sec, complete to $m_{AB} \sim 20$ in both the FUV and NUV bands. The resulting sample, although not complete in both UV bands, includes giants and dwarf systems: at a limiting magnitude of $M_B \leq -15$, 71% of the observed galaxies have been detected in the NUV, 46% in the FUV.

All UV images come from the GALEX IR1.0 release. UV fluxes were obtained by integrating GALEX images within elliptical annuli of increasing diameter up to the optical B band 25 mag arcsec$^{-2}$ isophotal radii consistently with the optical and near-IR images. Independent measurements of the same galaxies obtained in different exposures give consistent photometric results within 10% in the NUV and 15% in the FUV in the AIS, and about a factor of two better for bright (NUV ≤ 16) galaxies. The statistical uncertainty in the UV photometry is on average a factor of ∼ 2 better in the NGS than in the AIS especially for fainter objects.

UV data have been combined with multifrequency data taken from the GOMедьMine database (http://goldmine.mib.infn.it; Gavazzi et al. 2003). These are B and V imaging data, mostly from Gavazzi et al. (2005) and Boselli et al. (2003), and near-IR data from Gavazzi et al. (2000, 2001). Optical and near-IR data have on average a photometric precision of ∼ 10%. Spectroscopic metallicity index Mg$^2$ and velocity dispersion data come from GOMедьMine or from Golev & Prugniel (1998) and Bernardi et al. (2002). Unless specified, we adopt the homogeneous morphological classification of Binggeli et al. (1985) based on high quality photographic material.

Galaxies analyzed in this work are all bona-fide Virgo cluster members: given the 3-D structure of the cluster, distances have been assigned following the subcluster membership criteria of Gavazzi et al. (1999). Owing to the high galactic latitude of Virgo, no galactic extinction correction was applied ($A_B \leq 0.05$).

3. THE UV PROPERTIES OF EARLY-TYPE GALAXIES

Despite the complex 3-D structure of Virgo (Gavazzi et al. 1999), the uncertainty on the distance (hence on the luminosity) of the target galaxies, does not constitute a major source of dispersion in the determination of the color-magnitude (CMR) relation. Figure 1 shows various UV to optical and near-IR CMRs. Similar results are obtained if, instead of the mass-tracer H band luminosity (Zibetti et al. 2004), we use the B band absolute magnitude.

The NUV to optical (Fig. 1b) and near-IR (Fig. 1a) CMRs are well defined and are similar to optical or near-IR CMRs, with brighter galaxies having redder colors, independent of their morphological type: the color index (NUV − $V$) increases by ∼ 2 magnitudes from dwarfs ($L_H \sim 10^9 L_\odot$) to giants ($L_H \sim 10^{11.5} L_\odot$), while (NUV − $H$) changes by ∼ 3 mag. A weak flattening of the relation appears for $L_H \geq 10^{10} L_\odot$. This behavior confirms the one reported by Ferguson (1994) in the ($B − V$) vs. $M_B$ CMR.

On the contrary, the FUV to optical (Fig. 1d) and near-IR (Fig. 1c) CMRs differ systematically for dwarfs and giant systems: galaxies brighter than $L_H \sim 10^{9.5} L_\odot$ have similar red colors, while for $L_H \leq 10^{9.5} L_\odot$ colors become progressively bluer. Even if this trend can be due to a selection effect, (reddest dwarfs being undetectable in the FUV), it is indisputable that there exists a significant population of dEs with bluer colors than Es and S0s.

A similar pattern (systematic differences between massive and dwarf systems and between NUV and FUV to optical or near-IR color indices) is obtained using color-color diagrams (not shown).

The dichotomy between giants and dwarfs is even more apparent in the UV color index ($FUV − NUV$) (see Fig. 2). The ($FUV − NUV$) becomes redder with increasing luminosity for dwarf ellipticals while, on the contrary, it becomes bluer for giant ellipticals (Fig. 2a). The blueing relation is tight among ellipticals (see Table 1) and barely observed in lenticulars because of their higher dispersion.

| $x$ | $y$ | $a$ | $b$ | $R_{rms}$ |
|-----|-----|-----|-----|----------|
| Ellipticals$^1$ |
| $L_H$ | $FUV − NUV$ | $−0.30 \pm 0.14$ | $+4.52 \pm 1.52$ | $−0.47 \pm 0.31$ |
| $L_H$ | $FUV − H$ | $−0.22 \pm 0.19$ | $+10.55 \pm 2.10$ | $−0.28 \pm 0.43$ |
| $L_H$ | $NUV − H$ | $0.17 \pm 0.18$ | $+4.85 \pm 1.85$ | $0.22 \pm 0.47$ |
| $L_H$ | $FUV − V$ | $−0.15 \pm 0.18$ | $+8.38 \pm 1.88$ | $−0.21 \pm 0.38$ |
| $L_H$ | $NUV − V$ | $0.26 \pm 0.12$ | $+2.55 \pm 1.30$ | $0.45 \pm 0.31$ |
| $B − H$ | $FUV − NUV$ | $−0.84 \pm 0.45$ | $+3.22 \pm 0.98$ | $−0.43 \pm 0.32$ |
| $\sigma$ | $FUV − NUV$ | $−1.35 \pm 0.37$ | $+4.39 \pm 0.89$ | $−0.69 \pm 0.26$ |
| Lenticulars |
| $L_H$ | $FUV − NUV$ | $−0.28 \pm 0.15$ | $+4.40 \pm 1.62$ | $−0.31 \pm 0.45$ |
| $L_H$ | $FUV − H$ | $0.31 \pm 0.21$ | $+0.75 \pm 2.00$ | $0.27 \pm 0.58$ |
| $L_H$ | $NUV − H$ | $0.61 \pm 0.11$ | $+0.51 \pm 1.17$ | $0.65 \pm 0.36$ |
| $L_H$ | $FUV − V$ | $0.03 \pm 0.25$ | $+6.62 \pm 2.38$ | $0.03 \pm 0.59$ |
| $L_H$ | $NUV − V$ | $0.49 \pm 0.09$ | $+0.26 \pm 1.00$ | $0.68 \pm 0.25$ |
| $B − H$ | $FUV − NUV$ | $−1.00 \pm 0.32$ | $+3.70 \pm 0.70$ | $−0.49 \pm 0.42$ |
| $\sigma$ | $FUV − NUV$ | $−1.29 \pm 0.39$ | $+4.28 \pm 0.84$ | $−0.58 \pm 0.39$ |

Notes to Table: Col. 1 and 2: $x$ and $y$ variables; Col. 3 and 4: slope $a$ and intercept $b$ of the bisector linear fit with weighted variables; Col. 5: Pearson correlation coefficient; Col. 6: mean dispersion around the best fit; 1: excluding VCC 1499; *: uncertain values because of the UV detection limit.

$^1$ The scatter in the blueing relation among ellipticals decreases significantly (from 0.31 to 0.10) if we exclude the misclassified poststarburst dwarf VCC 1499 (Gavazzi et al. 2001; Deharveng et al. 2002), the radio galaxy M87, VCC 1297 (the highest surface brightness galaxy in the sample of Gavazzi et al. (2005)) and VCC 1146. Beside its extremely high surface brightness, making VCC 1297 a non standard object, we do not have any evidence indicating a peculiar star formation history or present nuclear activity in VCC 1297 and VCC 1146 that could justify their exclusion.
A similar behavior between ellipticals and lenticulars is observed in the \( (FUV - NUV) \) color relation (Fig. 2b): this mixed giant population becomes bluer in the UV with increasing reddening in the \( (B - H) \) color index. The behavior of dwarf ellipticals is different: although with a huge dispersion, the \( (FUV - NUV) \) color index reddens as the \( (B - H) \), \( (B - V) \) and \( (FUV - V) \) indices (the two last not shown). The dichotomy between dwarf and giant systems cannot be observed in the run of \( (FUV - NUV) \) vs. central velocity dispersion (which is directly related to the system total dynamical mass; Fig. 2c) nor as a function of the metallicity sensitive \( \text{Mg}_2 \) Lick index (Fig. 2d) because these two parameters are not available for dwarfs. In ellipticals and lenticulars the UV color index \( (FUV - NUV) \) depends on both the metallicity index \( \text{Mg}_2 \) and \( \sigma \) in a way opposite to the behavior at optical wavelengths, where galaxies are redder when having higher \( \text{Mg}_2 \) and velocity dispersions.

4. DISCUSSION AND CONCLUSION

For the first time the UV properties of early-type galaxies have been studied down to \( M_B \sim -15 \) mag. The comparison with previous studies is thus limited to the brightest objects. Our CMR can be compared with the one obtained by Yi et al. (2005) based on a complete sample of bright early-type objects \( (M_r \leq -20 \) mag) extracted from the Sloan Digital Sky Survey (SDSS) by Bernardi et al. (2003). The CMR presented by Yi et al. (2005, \( NUV - r \) vs. \( M_r \)) shows a significantly larger dispersion \( (\sigma \geq 1.5 \) mag) than the one found in Virgo (see Table 1). As discussed in Yi et al. (2005), the large dispersion in their CMR can be ascribed to galaxies with a mild or residual star formation activity included in the Bernardi et al. (2003) sample. If restricted to the "UV weak" sample, the dispersion in the Yi et al. relation drops to 0.58 mag, i.e. still larger than the one seen in the Virgo cluster in the same luminosity range. Despite possible larger distance uncertainties in the SDSS, the difference in the scatter between our and the Yi et al. (2005) CMR might arise from the classification in the SDSS that uses concentration indices and luminosity profiles in discriminating hot from rotating systems. It is in fact conceivable that the larger dispersion in the CMR of "UV weak" galaxies of Yi et al. (2005) comes from the contamination of quiescent, bulge-dominated Sa spiral disks, that have structural (concentration indices and light profiles) or population properties (colors and spectra) similar to ellipticals and lenticulars (Scodeglio et al. 2002; Gavazzi et al. 2002).

The monotonic increase of the \( (NUV - V) \) and \( (NUV - H) \) colors with luminosity, similar to the one observed in the visible bands by Ferguson (1994) and Ferguson & Binggeli (1994) strongly suggests that both in dwarfs and giant systems the NUV 2310 Å flux is dominated by the same stellar population emitting at longer wavelengths. The plateau and the higher dispersion observed in the FUV CMRs confirm that the UV upturn is observable only in the FUV GALEX band at 1530 Å, as already remarked by Dorman et al. (2003) and Rich et al. (2005).

The mild trend between the \( (FUV - NUV) \) color and the metallicity sensitive \( \text{Mg}_2 \) index, as seen in the present dataset, is predicted by models (Bressan et al. 1994; Yi et al. 1998). It is also in qualitative agreement with the early IUE result of Burstein et al.
Fig. 2.— The relationship between the UV color index \((F_{\text{UV}} - NUV)\) and a) the total H band luminosity, b) the B-H color index, c) the logarithm of the central velocity dispersion and d) the Mg\(_2\) index. Symbols are as in Fig. 1. Labeled points indicate objects having unusual radio or optical properties (see Sect. 3).

However, it should be noted that the Burstein (1988) dataset is systematically different from the GALEX dataset: Burstein et al. used a different color index, \((1550 \AA - V)\), which was computed inside a fixed IUE aperture. On the other hand, the trend noted here contrasts with the analysis of Rich et al. (2005) who recently reported the lack of a significant correlation between the \((F_{\text{UV}} - r)\) color index and Mg\(_2\), and the velocity dispersion \(\sigma\). They examined a large sample of SDSS early-type galaxies, also observed by GALEX. We can only speculate that the lack of correlation in the dataset may be the result of a relatively restricted dynamic range in the variables available to those authors at that time: only 2.1-2.4 km s\(^{-1}\) in Log \(\sigma\) and 0.18-0.30 in Mg\(_2\). Clearly the issue is not decided and would benefit from targetted new observations.

The newest result of the present paper, shown in Fig. 2, addresses the question raised by O'Connell (1999) concerning the dependence of the UV properties on galaxy morphology. We have shown that a dichotomy exists between giant and dwarf ellipticals and, to a lesser extent, between ellipticals and lenticulars. The blueing of the UV color index with luminosity, metallicity and velocity dispersion indicates that the UV upturn is more important in massive, metal rich systems.

The accurate morphological classification in our sample allow us to discriminate between E and SOs. The higher dispersion in the \((F_{\text{UV}} - NUV)\) vs. \(L_H\) relation observed for the lenticulars compared to the extremely tight one for ellipticals (see Table 1), bears witness to recent, minor episodes of star formations combined with an old stellar population, as determined also from kinematic and spectroscopic observations (Dressler & Sandage 1983; Neistein et al. 1999; Hinz et al. 2003). We have shown that the UV properties of ellipticals are different than those of lenticulars, suggesting a different evolution. The opposite behavior (reddening of the UV color index with luminosity) of dwarfs with respect to giants, similar to that observed for spirals, indicates that the UV spectra of low luminosity objects are shaped by the contribution of young stars, thus are more sensitive to the galaxy's star formation history than to the metallicity. Spectroscopy was recently obtained (unpublished) for the 7 bluest dEs \(((F_{\text{UV}} - NUV) \leq 1.4 \text{ mag})\) in our sample. Three out of seven show Balmer emission lines, another three strong H\(\delta\) in absorption (H\(\delta\)EW \(\geq 5 \AA\))
witnessing a present or recent star formation activity. This implies that the stellar population of dwarfs has been formed in discrete and relatively recent episodes, as observed in other nearby objects (Grebel 1999).

More evidences are building up that mass drives the star formation history in hot systems (Trager et al. 2000; Gavazzi et al. 2002; Caldwell et al. 2003; Poggianti 2004) as in rotating ones (Gavazzi et al. 1996, 2002; Boselli et al. 2001) and that the stellar population of massive ellipticals is on average older than that of dwarfs.

We thank an unknown referee for his/her criticism.

GALEX (Galaxy Evolution Explorer) is a NASA Small Explorer, launched in April 2003. We gratefully acknowledge NASA's support for construction, operation, and science analysis for the GALEX mission, developed in cooperation with the Centre National d'Etudes Spatiales of France and the Korean Ministry of Science and Technology. The authors would like to take this opportunity to thank the members of the GALEX SODA Team for their valiant efforts in the timely reduction of the complex observational dataset covering the full expanse of the Virgo cluster.
