Belief propagation (BP) is a message-passing heuristic for statistical inference in graphical models such as Bayesian networks and Markov random fields. BP is used to compute marginal distributions or maximum likelihood assignments and has applications in many areas, including machine learning, image processing, and computer vision. However, the theoretical understanding of the performance of BP is unsatisfactory.

Recently, BP has been applied to combinatorial optimization problems. It has been proved that BP can be used to compute maximum-weight matchings and minimum-cost flows for instances with a unique optimum. The number of iterations needed for this is pseudo-polynomial and hence BP is not efficient in general.

We study belief propagation in the framework of smoothed analysis and prove that with high probability the number of iterations needed to compute maximum-weight matchings and minimum-cost flows is bounded by a polynomial if the weights/costs of the edges are randomly perturbed. To prove our upper bounds, we use an isolation lemma by Beier and Vöcking (SIAM J. Comput. 2006) for matching and generalize an isolation lemma for min-cost flow by Gamarnik, Shah, and Wei (Operations Research, 2012). We also prove almost matching lower tail bounds for the number of iterations that BP needs to converge.

1 Belief Propagation

The belief propagation (BP) algorithm is a message-passing algorithm that is used for solving probabilistic inference problems on graphical models. It has been introduced by Pearl in 1988 \cite{Pearl88}. Typical graphical models to which BP is applied are Bayesian networks and Markov random fields. There are two variants of BP. The sum-product variant is used to compute marginal probabilities. The max-product or min-sum variant is used to compute maximum a posteriori (MAP) probability estimates.

\textsuperscript{*}This research was supported by ERC Starting Grant 306465 (BeyondWorstCase) and NWO grant 613.001.023 (Smoothed Analysis of Belief Propagation).
Recently, BP has experienced great popularity. It has been applied in a large number of fields, such as machine learning, image processing, computer vision, and statistics. For an introduction to BP and several applications, we refer to Yedidia et al. [17]. The are basically two main reasons for the popularity of BP. First of all, it is generally applicable and easy to implement because of its simple and iterative message-passing nature. In addition, it performs well in practice in numerous applications [15][16].

If the graphical model is tree-structured, BP computes exact marginals/MAP estimates. In case the graphical model contains cycles, convergence and correctness of BP have been shown only for specific classes of graphical models. To improve the general understanding of BP and to gain new insights about it, the performance of BP as either a heuristic or an exact algorithm for several combinatorial optimization problems has been studied. Amongst others it has been applied to the maximum-weight matching (MWM) problem, the minimum spanning tree (MST) problem, the minimum-cost flow (MCF) problem, and the maximum-weight independent set problem [12].

Bayati et al. [4] have shown that max-product BP correctly computes the MWM in bipartite graphs in pseudo-polynomial time if it is unique. For MST, it is known that BP converges to the correct optimal solution, if it converges at all (which is not guaranteed) [3]. Gamarnik et al. [6] have shown that the max-product BP algorithm computes the MCF in pseudo-polynomial time if it is unique.

1.1 Belief Propagation for Matching and Flow Problems

In this section we discuss the previous results about the BP algorithm for computing maximum-weight matchings and minimum-cost flows in more detail. Bayati et al. [4] have shown that the max-product BP algorithm correctly computes the maximum-weight matching in bipartite graphs if it is unique. Convergence of BP takes pseudo-polynomial time and depends linearly on the weight of the heaviest edge and on $1/\delta$, where $\delta$ is the difference in weight between the best and second-best matching. In Section 2.3 we describe the BP algorithm for MWM in detail.

Belief propagation has also been applied to finding maximum-weight perfect matchings in arbitrary graphs and to finding maximum-weight perfect $b$-matchings [2][11], where a perfect $b$-matching is a set of edges such that every vertex is incident to exactly $b$ edges in the set. For arbitrary graphs the BP algorithm for MWM does not necessarily converge [11]. However, Bayati et al. [2] and Sanghavi et al. [11] have shown that the BP algorithm converges to the optimal matching if the relaxation of the corresponding linear program has an optimal solution that is unique and integer. The number of iterations needed until convergence depends again linearly on the reciprocal of the parameter $\delta$. Bayati et al. [2] have also shown that the same result holds for the problem of finding maximum-weight $b$-matchings that do not need to be perfect.

It turns out that BP can, to some extent, solve the relaxation of the corresponding linear program for matching, even if it has a non-integral optimal solution. Bayati et al. [2] have shown that it is possible to solve the LP relaxation by considering so-called graph covers, in which they compute a bipartite matching. In case of an optimum that is unique and integer, the optimal solution in the graph cover corresponds to the optimal solution. In case of a unique but fractional optimal solution, the average of the estimates of two consecutive iterations (both of which are perfect matchings in the graph cover) yield a value of 0, 1/2, or 1 for any edge, which then equals its value in the optimal solution of the relaxed LP.
Sanghavi et al. [11] have shown that BP remains uninformativ e for some edges (and outputs “?” for those), but computes the correct values for all edges that have a fixed integral value in all optimal solutions.

Gamarnik et al. [6] have shown that BP can be used to find a minimum-cost flow, provided that the instance has a unique optimal solution. The number of iterations until convergence is pseudo-polynomial and depends again linearly on the reciprocal of the difference in cost between the best and second-best integer flow. In addition, they have proved a discrete isolation lemma [6, Theorem 8.1] that shows that the edge costs can be slightly randomly perturbed to ensure that, with probability at least 1/2, the perturbed MCF instance has a unique optimal solution. Using this result, they have constructed an FPRAS for MCF using BP.

1.2 Smoothed Analysis

Smoothed analysis has been introduced by Spielman and Teng [13] in order to explain the performance of the simplex method for linear programming. It is a hybrid of worst-case and average-case analysis and an alternative to both: An adversary specifies an instance, and this instance is then slightly randomly perturbed. The perturbation can, for instance, model noise from measurement. Since its invention in 2001, smoothed analysis has been applied in a variety of contexts. We refer to two recent surveys [7, 14] for a broader picture.

We apply smoothed analysis to belief propagation for min-cost flow and maximum-weight matching. To do this, we consider the following general probabilistic model.

- The adversary specifies the graph $G = (V, E)$ and, in case of min-cost flow, the integer capacities of the edges and the integer budgets (both are not required to be polynomially bounded). Additionally the adversary specifies a probability density function $f_e : [0, 1] \rightarrow [0, \phi]$ for every edge $e$.

- The costs (for min-cost flow) or weights (for matching) of the edges are then drawn independently according to their respective density function.

The parameter $\phi$ controls the adversary’s power: If $\phi = 1$, then we have the average case. The larger $\phi$, the more powerful the adversary. The role of $\phi$ is the same as the role of $1/\sigma$ in the classical model of smoothed analysis, where instances are perturbed by independent Gaussian noise with standard deviation $\sigma$. In that model the maximum density $\phi$ is proportional to $1/\sigma$.

1.3 Our Results

We prove upper and lower tail bounds for the number of iterations that BP needs to solve maximum-weight matching problems and min-cost flow problems. Our bounds match up to a small polynomial factor.

We prove that the probability that BP needs more than $t$ iterations is bounded by $O(n^2m\phi/t)$ for the min-cost flow problem and $O(nm\phi/t)$ for various matching problems, where $n$ and $m$ are the number of nodes and edges of the input graph, respectively (Sections 3 and 4). The upper bound for matching problems holds for the variants of BP for the maximum-weight matching problem in bipartite graphs [4] as well as for the maximum-weight (perfect) $b$-matching problem in general graphs [2, 11]. For the latter it is required that the polytope corresponding to the relaxation of the matching LP is integral. If this is not the case, we can still solve the relaxation of the matching LP with a slightly modified BP algorithm [2] (using graph covers,
see Remark 4.3). To prove the upper tail bound for BP for MCF we use a continuous isolation lemma that is similar to the discrete isolation lemma by Gamarnik et al. [6, Theorem 8.1]. We need the continuous version since we not only want to have that a unique optimal solution, but we also need to quantify the gap between the best and the second-best solution.

These upper tail bounds are not strong enough to yield any bound on the expected number of iterations. Indeed we show that this expectation is not finite by providing a lower tail bound of \( \Omega(n \phi / t) \) for the probability that \( t \) iterations do not suffice to find a maximum-weight matching in bipartite graphs. This lower bound even holds in the average case, i.e., if \( \phi = 1 \) (Section 5.2), and it carries over to the variants of BP for the min-cost flow problem and the minimum/maximum-weight (perfect) \( b \)-matching problem in general graphs mentioned above [2, 4, 6, 11]. The lower bound matches the upper bound up to a factor of \( O(m) \) for matching and up to a factor of \( O(nm) \) for min-cost flow (Section 5.3). The smoother lower bound even holds for complete (i.e., non-adversarial) bipartite graphs.

Note that our lower bound on the number of iterations until convergence does not contradict the results by Salez and Shah [10]. Roughly speaking, they have proved that BP for matching requires expected time \( O(n^2) \). However, they allow that a small number of nodes are matched to incorrect nodes. It might even be the case that multiple nodes are matched to the same node. In our analysis we require convergence of the BP algorithm, i.e., each node should be matched to the unique node to which it is matched in the optimal matching.

Finally, let us remark that, for the min-cost flow problem, we bound only the number of iterations that BP needs until convergence. The messages might be super-polynomially long. For all matching problems, however, the length of the messages is always bounded by a small polynomial.

2 Definitions and Problem Statement

In this section we define the maximum-weight matching problems that we consider and the min-cost flow problem. We also describe the BP algorithms that we apply.

2.1 Maximum-Weight Matching and Minimum-Cost Flow

First we define the maximum-weight matching problem on bipartite graphs. For this consider an undirected weighted bipartite graph \( G = (U \cup V, E) \) with \( U = \{u_1, \ldots, u_n\} \), \( V = \{v_1, \ldots, v_n\} \), and \( E \subseteq \{(u_i, v_j) = e_{ij}, 1 \leq i, j \leq n\} \). Each edge \( e_{ij} \) has weight \( w_{ij} \in \mathbb{R}^+ \). A collection of edges \( M \subseteq E \) is called a matching if each node of \( G \) is incident to at most one edge in \( M \). We define the weight of a matching \( M \) by

\[
    w(M) = \sum_{e_{ij} \in M} w_{ij}.
\]

The maximum-weight matching \( M^* \) of \( G \) is defined as

\[
    M^* = \arg\max\{w(M) \mid M \text{ is a matching of } G\}.
\]

A \( b \)-matching \( M \subseteq E \) in an arbitrary graph \( G = (V, E) \) is a set of edges such that every node from \( V \) is incident to at most \( b \) edges from \( M \). A \( b \)-matching is called perfect if every node from \( V \) is incident to exactly \( b \) edges from \( M \). Also for these problems we assume that each edge \( e \in E \) has a certain weight \( w_e \) and we define the weight of a \( b \)-matching \( M \) accordingly.
2.2 Min-Cost Flow Problem

In the min-cost flow problem (MCF) the goal is to find a cheapest flow that satisfies all capacity and budget constraints. We are given a graph \( G = (V, E) \) with \( V = \{v_1, \ldots, v_n\} \). In principle we allow multiple edges between a pair of nodes, but for ease of notation we consider simple directed graphs. Each node \( v \) has a budget \( b_v \in \mathbb{Z} \). Each directed edge \( e = e_{ij} \) from \( v_i \) to \( v_j \) has capacity \( u_e \in \mathbb{N}_0 \) and cost \( c_e \in \mathbb{R}^+ \). For each node \( v \in V \), we define \( E_v \) as the set of edges incident to \( v \). For each edge \( e \in E \), we define \( \Delta(v, e) = 1 \) if \( e \) is an out-going edge of \( v \) and \( \Delta(v, e) = -1 \) if \( e \) is an in-going edge of \( v \). In the MCF one needs to assign a flow \( f_e \) to each edge \( e \) such that the total cost \( \sum_{e \in E} c_e f_e \) is minimized and the flow constraints

\[
0 \leq f_e \leq u_e \quad \text{for all } e \in E,
\]

and budget constraints

\[
\sum_{e \in E_v} \Delta(v, e) f_e = b_v \quad \text{for all } v \in V
\]

are satisfied. We refer to Ahuja et al. [1] for more details about MCF.

Let us remark that we could have allowed also rational values for the budgets and capacities. As our results do not depend on these values, they are not affected by scaling all capacities and budgets by the smallest common denominator.

Note that finding a perfect minimum-weight matching in a bipartite graph \( G = (U \cup V, E) \) is a special case of the min-cost flow problem, see Ahuja et al. [1] for details.

2.3 Belief Propagation

For convenience, we describe the BP algorithm used by Bayati et al. [4]. For the details of the other versions of BP for the (perfect) maximum-weight \( b \)-matching problem and the min-cost flow problem we refer to the original works [2][6][11]. When necessary, we discuss the differences between the different versions of BP in Sections 4 and 5.

The BP algorithm used by Bayati et al. [4] is an iterative message-passing algorithm for computing maximum-weight matchings (MWM). Bayati et al. define their algorithm for complete bipartite graphs \( G = (U \cup V, E) \) with \( |U| = |V| = n \). In each iteration \( t \), each node \( u_i \) sends a message vector

\[
\tilde{M}_ij^t = [\tilde{m}_{ij}^t(1), \tilde{m}_{ij}^t(2), \ldots, \tilde{m}_{ij}^t(n)]
\]

to each of its neighbors \( v_j \). The messages can be interpreted as how ‘likely’ the sending node thinks it is that the receiving node should be matched to a particular node in the MWM. The greater the value of the message \( \tilde{m}_{ij}^t(r) \), the more likely it is according to node \( u_i \) in iteration \( t \) that node \( v_j \) should be matched to node \( u_r \). Similarly, each node \( v_j \) sends a message vector \( \tilde{M}_{ji}^t \) to each of its neighbors \( u_i \). The messages are initialized as

\[
\tilde{m}_{ij}^0(r) = \begin{cases} w_{ij} & \text{if } r = i, \\ 0 & \text{otherwise and} \end{cases}
\]

\[
\tilde{m}_{ji}^0(r) = \begin{cases} w_{ij} & \text{if } r = j, \\ 0 & \text{otherwise}. \end{cases}
\]
The messages in iterations $t \geq 1$ are computed from the messages in the previous iteration as follows:

\[
\tilde{m}_{ij}^t(r) = \begin{cases} 
  w_{ij} + \sum_{k \neq j} \tilde{m}_{ki}^{t-1}(j) & \text{if } r = i, \\
  \max_{q \neq j} \left[ w_{iq} + \sum_{k \neq j} \tilde{m}_{ki}^{t-1}(q) \right] & \text{otherwise and} \\
  w_{ij} + \sum_{k \neq i} \tilde{m}_{ki}^{t-1}(i) & \text{if } r = j, \\
  \max_{q \neq i} \left[ w_{qj} + \sum_{k \neq i} \tilde{m}_{kj}^{t-1}(q) \right] & \text{otherwise.}
\end{cases}
\]

The beliefs of nodes $u_i$ and $v_j$ in iteration $t$ are defined as

\[
b_{u_i}^t(r) = w_{ir} + \sum_k \tilde{m}_{ki}^t(r), \\
b_{v_j}^t(r) = w_{rj} + \sum_k \tilde{m}_{kj}^t(r).
\]

The beliefs can be interpreted as the 'likelihood' that a node should be matched to a particular neighbor. The greater the value of $b_{u_i}^t(r)$, the more likely it is that node $u_i$ should be matched to node $v_j$. We denote the estimated MWM in iteration $t$ by $\hat{M}^t$. The estimated matching $\hat{M}^t$ matches each node $u_i$ to node $v_j$, where $j = \arg\max_{1 \leq r \leq n} \{ b_{u_i}^t(r) \}$. Note that $\hat{M}^t$ does not always define a matching, since multiple nodes may be matched to the same node. However, Bayati et al. [4] have shown that if the MWM is unique, then for $t$ large enough, $\hat{M}^t$ is a matching and equal to the MWM.

### 3 Isolation Lemma for Maximum-Weight Matchings and Min-Cost Flows

Before we turn to proving the upper tail bounds for the number of iterations of the BP algorithm in Section 4, we take a closer look at the quantity $\delta$, which we defined above as the difference in weight or cost between the best and second-best matching or integer flow, respectively. The previous results discussed in Section 1.1 indicate that in order for the BP algorithm to be efficient $\delta$ must not be too small. While $\delta$ can be arbitrarily small for weights or costs that are chosen by an adversary, it is a well-known phenomenon that $\delta$ is with high probability not too small when the weights or costs are drawn randomly.

#### 3.1 Maximum-Weight Matchings

Beier and Vöcking [5] have considered a general scenario in which an arbitrary set $S \subseteq \{0,1\}^m$ of feasible solutions is given and to every $x = (x_1, \ldots, x_m) \in S$ a weight $w \cdot x = w_1 x_1 + \ldots + w_m x_m$ is assigned by a linear objective function. As in our model they assume that every coefficient $w_i$ is drawn independently according to an adversarial density function $f_i : [0,1] \to [0,\phi]$ and they define $\delta$ as the difference in weight between the best and the second-best feasible
solution from \( S \), i.e., \( \delta = w \cdot x^* - w \cdot \hat{x} \) where \( x^* = \arg\max_{x \in S} w \cdot x \) and \( \hat{x} = \arg\max_{x \in S \setminus \{x^*\}} w \cdot x \).

They prove a strong isolation lemma that, regardless of the adversarial choices of \( S \) and the density functions \( f_i \), the probability of the event \( \delta \leq \varepsilon \) is bounded from above by \( 2\varepsilon \phi m \) for any \( \varepsilon \geq 0 \).

If we choose \( S \) as the set of incidence vectors of all matchings or (perfect) \( b \)-matchings in a given graph, Beier and Vöcking’s results yield for every \( \varepsilon \geq 0 \) an upper bound on the probability that the difference in weight \( \delta \) between the best and second-best matching or the best and second-best (perfect) \( b \)-matching is at most \( \varepsilon \). Combined with the results in Section 1.1 this can immediately be used to obtain an upper tail bound on the number of iterations of the BP algorithm for these problems.

### 3.2 Min-Cost Flows

The situation for the min-cost flow problem is significantly more difficult because the set \( S \) of feasible integer flows cannot naturally be expressed with binary variables. If one introduce a variables for each edge corresponding to the flow on that edge, then \( S \subseteq \{0, 1, 2, \ldots, u_{\text{max}}\}^m \) where \( u_{\text{max}} = \max_{e \in E} u_e \). Röglin and Vöcking [9] have extended the isolation lemma to the setting of integer, instead of binary, vectors. However, their result is not strong enough for our purposes as it bounds the probability of the event \( \delta \leq \varepsilon \) by \( \varepsilon \phi m (u_{\text{max}} + 1)^2 \) from above for any \( \varepsilon \geq 0 \). As this bound depends on \( u_{\text{max}} \) it would only lead to a pseudo-polynomial upper tail bound on the number of iterations of the BP algorithm when combined with the results of [6]. Our goal is, however, to obtain a polynomial tail bound that does not depend on the capacities. In the remainder of this section, we prove that the isolation lemma from [9] can be significantly strengthened when structural properties of the min-cost flow problem are exploited.

In the following we consider the residual network for a flow \( f \). For each edge \( e_{ij} \) in the original network that has less flow than its capacity \( u_{ij} \), we include an edge \( e_{ij} \) with capacity \( u_{ij} - f_{ij} \) in the residual network. Similarly, for each edge \( e_{ij} \) that has flow greater than zero, we include the backwards edge \( e_{ji} \) with capacity \( f_{ij} \) in the residual network. We refer to Ahuja et al. [1] for a more details about residual networks.

As all capacities and budgets are integers, there is always a min-cost flow that is integral. An additional property of our probabilistic model is that with probability one there do not exist two different integer flows with exactly the same costs. This follows directly from the fact that all costs are continuous random variables. Hence, without loss of generality we restrict our presentation in the following to the situation that the min-cost flow is unique.

In fact, Gamarnik et al. [6] have not used \( \delta \), the difference in cost between the best and second-best integer flow, to bound the number of iterations needed for BP to find the unique optimal solution of MCF, but they have used another quantity \( \Delta \). They have defined \( \Delta \) as the length of the cheapest cycle in the residual network of the min-cost flow \( f^* \). Note that \( \Delta \) is always non-negative. Otherwise, we could send one unit of flow along a cheapest cycle. This would result in a feasible integral flow with lower cost. With the same argument we can argue that \( \Delta \) must be at least as large as \( \delta \) because sending one unit of flow along a cheapest cycle results in a feasible integral flow different from \( f^* \) whose costs exceed the costs of \( f^* \) by exactly \( \Delta \). Hence any lower bound for \( \delta \) is also a lower bound for \( \Delta \) and so it suffices for our purposes to bound the probability of the event \( \delta \leq \varepsilon \) from above.

The isolation lemma we prove is based on ideas that Gamarnik et al. [6, Theorem 8.1] have developed to prove that the optimal solution of a min-cost flow problem is unique with high
probability if the costs are randomly drawn integers from a sufficiently large set. We provide
a continuous counterpart of this lemma, where we bound the probability that the second-best
integer flow is close in cost to the optimal integer flow.

**Lemma 3.1.** The probability that the cost of the optimal and the second-best integer flow
differs by at most $\varepsilon \geq 0$ is bounded from above by $2\varepsilon \varphi m$.

**Proof.** Consider any fixed edge $\tilde{e}$, and let the costs of all other edges be fixed by an adversary.
The cost $c_\tilde{e}$ is drawn according to its probability distribution, whose density is bounded
by $\varphi$.

For $e \in E$, let $E_e^\varepsilon$ be the event that there exist two different integer flows $f^*$ and $\hat{f}$ with the
following properties:

(i) $f^*$ is optimal.

(ii) $c \cdot f^*$ and $c \cdot \hat{f}$ differ by at most $\varepsilon$, i.e., $c \cdot \hat{f} \leq c \cdot f^* + \varepsilon$.

(iii) $f_e^* = 0$ and $\hat{f}_e > 0$.

Let $\tilde{E}_e^\varepsilon$ be analogously defined, except for Condition (iii) being replaced by $f_e^* = u_e$ and $\hat{f}_e < u_e$.

**Claim 3.2.** Let $e \in E$ be arbitrary. Assume that all costs except for $c_e$ are fixed. Let $I \subseteq [0, 1]$ be the set of real numbers such that $I = \{c_e \mid E_e^\varepsilon\}$. Then $I$ is a subset of an interval of length at most $\varepsilon$.

**Proof.** If $I \neq \emptyset$, let $\alpha = \min(I)$ and let $f^*$ be an optimal integer flow for $c_e = \alpha$ with $f_e^* = 0$.

Due to the choice of $\alpha$ it is clear that $I \subseteq [\alpha, \infty)$ We claim that $I \subseteq [\alpha, \alpha + \varepsilon]$. If $c_e = \alpha + \eta$ for some $\eta > 0$, then $f^*$ stays optimal, and, for any feasible integer solution $f$ with $f_e > 0$, we have

$$
c \cdot f = \sum_{\tilde{e} \neq e} c_{\tilde{e}} f_{\tilde{e}} + (\alpha + \eta) f_e \geq \sum_{\tilde{e} \neq e} c_{\tilde{e}} f_{\tilde{e}} + \alpha f_e + \eta
$$

as $f_e \geq 1$

$$
\geq c \cdot f^* + \eta
$$

as $f_e^* = 0$ and $f^*$ is optimal.

Thus, for $\eta > \varepsilon$, the event $E_e^\varepsilon$ does not occur.

The proof of the following claim is omitted as it is completely analogous to the proof of the previous claim.

**Claim 3.3.** Let $e \in E$ be arbitrary. Assume that all costs except for $c_e$ are fixed. Let $I \subseteq [0, 1]$ be the set of real numbers such that $I = \{c_e \mid \tilde{E}_e^\varepsilon\}$. Then $I$ is a subset of an interval of length at most $\varepsilon$.

The following claim shows that, provided no event $E_e^\varepsilon$ or $\tilde{E}_e^\varepsilon$ occurs, the second-best integer
flow is more expensive than the best integer flow by at least an amount of $\varepsilon$.

**Claim 3.4.** Assume that for every edge $e \in E$ neither $E_e^\varepsilon$ nor $\tilde{E}_e^\varepsilon$ occurs. Let $f^*$ be a min-cost flow and let $\hat{f} \neq f^*$ be a min-cost integer flow that differs from $f^*$, i.e., a second-best integer flow. Then $c \cdot \hat{f} \geq c \cdot f^* + \varepsilon$. 

8
Proof. First we prove that under our assumption that the min-cost flow is unique some edge \(e\) exists such that \(f^*_e \in \{0, u_e\}\) and \(\hat{f}_e \neq f^*_e\). Suppose that no such edge \(e\) exists and let \(d = f^* - \hat{f}\). Then \(d_e > 0\) only if \(f^*_e < u_e\) and \(d_e < 0\) only if \(f^*_e > 0\) because otherwise there is an edge \(e\) with \(f^*_e \in \{0, u_e\}\) and \(\hat{f}_e \neq f^*_e\). From this, we can conclude that there exists a \(\lambda > 0\) such that \(f^* + \lambda d\) is a feasible flow. Let \(\lambda_0 = \max\{\lambda \mid f^* + \lambda d\text{ is feasible}\}\) and \(\hat{f} = f^* + \lambda_0 d\). From the assumption that the min-cost flow is unique it follows that \(c \cdot d = c \cdot f^* - c \cdot \hat{f} < 0\). Hence, \(c \cdot \hat{f} < c \cdot f^*\), contradicting the choice of \(f^*\) as min-cost flow.

This argument shows that there always exists an edge \(e\) such that \(f^*_e \in \{0, u_e\}\) and \(\hat{f}_e \neq f^*_e\). As none of the events \(\mathbb{E}^e_\varepsilon\) and \(\mathbb{E}_\varepsilon\) occurs for this edge \(e\), it follows that \(c \cdot \hat{f} \geq c \cdot f^* + \varepsilon\). \(\square\)

From Claims 3.2 and 3.3 we obtain \(\mathbb{P}(\mathbb{E}^e_\varepsilon) \leq \varepsilon\phi\) and \(\mathbb{P}(\mathbb{E}_\varepsilon) \leq \varepsilon\phi\): We fix all edge costs except for \(c_e\) and then \(\mathbb{E}^e_\varepsilon\) can only occur if \(c_e\) falls into an interval of length at most \(\varepsilon\). Since the density function of \(c_e\) is bounded from above by \(\phi\), this happens with a probability of at most \(\varepsilon\phi\). The same holds for any \(\mathbb{E}_\varepsilon\). Thus, the lemma follows by a union bound over all \(2m\) events \(\mathbb{E}^e_\varepsilon\) and \(\mathbb{E}_\varepsilon\). \(\square\)

The isolation lemma (Lemma 3.1) together with the discussion about the relation between \(\delta\), the difference in cost between the best and second-best integer flow, and \(\Delta\), the length of the cheapest cycle in the residual network of the min-cost flow \(f^*\), immediately imply the following upper bound for the probability that \(\Delta\) is small.

Corollary 3.5. For any \(\varepsilon > 0\), we have \(\mathbb{P}(\Delta \leq \varepsilon) \leq 2\varepsilon m\).

4 Upper Tail Bounds

4.1 Maximum-Weight Matching

We first consider the BP algorithm of Bayati et al. \cite{4}, which computes maximum-weight matchings in complete bipartite graphs \(G\) in \(O(nw^*/\delta)\) iterations on all instances with a unique optimum. Here \(w^*\) denotes the weight of the heaviest edge and \(\delta\) denotes the difference in weight between the best and the second-best matching. Even though it is assumed that \(G\) is a complete bipartite graph, this is not strictly necessary. If a non-complete graph is given, missing edges can just be interpreted as edges of weight 0.

With Beier and V"ocking’s isolation lemma (cf. Section 3.1) we obtain the following tail bound for the number of iterations needed until convergence when computing maximum-weight perfect matchings in bipartite graphs using BP.

Theorem 4.1. Let \(\tau\) be the number of iterations until Bayati et al.’s BP \cite{4} for maximum-weight perfect bipartite matching converges. Then \(\mathbb{P}(\tau \geq t) = O(nm\phi/t)\).

Proof. The number of iterations until BP converges is bounded from above by \(O(nw^*/\delta)\) \cite{4}. The weight of each edge is at most 1, so \(w^* \leq 1\). The upper bound exceeds \(t\) only if \(\delta \leq O(n/t)\). By Beier and V"ocking’s isolation lemma, we have \(\mathbb{P}(\delta \leq O(n/t)) \leq O(nm\phi/t)\), which yields the bound claimed. \(\square\)

This tail bound is not strong enough to yield any bound on the expected running-time of BP for bipartite matchings. But it is strong enough to show that BP has smoothed polynomial running-time with respect to the relaxed definition adapted from average-case complexity \cite{5}, where it is required that the expectation of the running-time to some power \(a > 0\) is at most...
linear. However, a bound on the expected number of iterations is impossible, and the tail bound proved above is tight up to a factor of \(O(m)\) (Section 5).

As discussed in Section 1.1, BP has also been applied to finding maximum-weight (perfect) \(b\)-matchings in arbitrary graphs [2,11]. The result is basically that BP converges to the optimal matching if the optimal solution of the relaxation of the corresponding linear program is unique and integer. The number of iterations needed until convergence depends again on “how unique” the optimal solution is. For Bayati et al.’s variant [2], the number of iterations until convergence depends on \(1/\delta\), where \(\delta\) is again the difference in weight between the best and the second-best matching. For Sanghavi et al.’s variant [11], the number of iterations until convergence depends on \(1/c\), where \(c\) is the smallest rate by which the objective value will decrease if we move away from the optimum solution.

However, the technical problem in transferring the upper bound for bipartite graphs to arbitrary graphs is that the adversary can achieve that, with high probability or even with a probability of 1 (for larger \(\phi\)), the optimal solution of the LP relaxation is not integral. Already in the average-case, i.e., for \(\phi = 1\), where the adversary has no power at all, the optimal solution of the LP relaxation has some fractional variables with high probability.

Still, we can transfer the results for bipartite matching to both algorithms for arbitrary matching if we restrict the input graphs to be bipartite, since in this case the constraint matrix of the associated LP is totally unimodular.

**Theorem 4.2.** Let \(\tau\) be the number of iterations until Bayati et al.’s [2] or Sanghavi et al.’s [11] BP for general matching, restricted to bipartite graphs as input, converges. Then \(\mathbb{P}(\tau \geq t) = O\left(\frac{nm\phi}{t}\right)\).

**Proof.** For Bayati et al.’s BP algorithm, this follows in the same way as Theorem 4.1 from their bound on the number of iterations until convergence, which is \(O(n/\delta)\) [2, Theorem 1].

Sanghavi et al. prove that their variant of BP for general graphs converges after \(O\left(\frac{1}{c}\right)\) iterations, provided that the LP relaxation has no fractional optimal solutions. Here, \(c\) is defined as

\[
c = \min_{\hat{x} \neq x^* \text{ is a vertex of } P} \frac{w \cdot (x^* - \hat{x})}{\|x^* - \hat{x}\|_1},
\]

where \(x^*\) is the (unique) optimal solution to the relaxation and \(P\) is the matching polytope [11, Remark 2].

For any \(\hat{x} \neq x^*\), we have \(\|x^* - \hat{x}\|_1 \leq n\). Furthermore, \(w \cdot (x^* - \hat{x})\) is just the difference in weights between \(x^*\) and \(\hat{x}\). Since the input graph is bipartite, all vertices of \(P\) are integral. Thus, \(w \cdot (x^* - \hat{x}) \geq \delta\), where (again) \(\delta\) is the difference in weight between the best and the second-best matching. Thus, \(c \geq \delta/n\), which proves the theorem. \(\square\)

**Remark 4.3.** Bayati et al. [2] and Sanghavi et al. [11] have also shown how to compute \(b\)-matchings with BP. If \(b\) is even, then the unique optimum to the LP relaxation is integral. Thus, we circumvent the problem that the optimal solution might be fractional. Hence, following the same reasoning as above, the probability that BP for \(b\)-matching for even \(b\) runs for more than \(t\) iterations until convergence is also bounded by \(O\left(\frac{nm\phi}{t}\right)\).

Furthermore, Bayati et al. [2, Section 4] have shown how to compute the optimal solution of the relaxation of the matching LP with graph covers. They obtain the same \(O(n/\delta)\) bound for the number of iterations until convergence as for ordinary matching. However, since we are no longer talking about integer solutions, we cannot directly apply the isolation lemma of Beier and Vöcking [2]. To see that \(\delta\) is still unlikely to be small in the same way (with a
slightly worse constant), we can apply the isolation lemma of Röglin and Vöcking \[9\] since the matching polytope is half-integral. Thus, if we scale the right-hand side with a factor of 2, then we obtain a $0/1/2$ integer program. Because of this, we obtain the same $O(mn\phi/t)$ tail bound for the probability that the number of iterations until convergence exceeds $t$.

### 4.2 Min-Cost Flow

The bound for the probability that $\Delta$ is small (Corollary 3.5) plus the pseudo-polynomial bound by Gamarnik et al. \[6\] yields a tail bound for the number of iterations that BP needs until convergence.

**Theorem 4.4.** Let $\tau$ be the number of iterations until BP for min-cost flow \[6\] converges. Then $\mathbb{P}(\tau \geq t) = O(n^2 m\phi/t)$.

**Proof.** The number of iterations until BP for min-cost flow converges is bounded from above by $cLn/\Delta$ for some constant $c$, where $L$ is the maximum cost of a simple directed path in the residual network for the optimal flow \[6, Theorem 4.1\]. The cost of each edge is at most 1, so $L \leq n$. The upper bound exceeds $t$ only if $\Delta \leq cn^2/t$. By Corollary 3.5, we have $\mathbb{P}(\Delta \leq cn^2/t) \leq 2cn^2 m\phi/t$, which yields the bound claimed.

### 5 Lower Tail Bounds

We show that the expected number of iterations necessary for convergence of BP for maximum-weight matching (MWM) is unbounded. To do this, we prove a lower tail bound on the number of iterations that matches the upper tail bound from Section 4. The lower bound holds even for a two by two complete bipartite graph with edge weights drawn independently and uniformly from the interval $[0, 1]$. In the following analysis, we consider the BP variant introduced by Bayati et al \[4\]. Our results can be extended to other versions of BP for matching and min-cost flow \[2, 6, 11\] in a straightforward way. We discuss these extensions in Section 5.4.

We first discuss the average case, i.e., $\phi = 1$, for which we obtain a lower tail bound of $\Omega(n/t)$ for the probability that more than $t$ iterations are needed for convergence (Section 5.2). For this lower bound, we use a simple adversarial graph. We leave it as an open problem whether the lower bound also holds for the complete bipartite graph on $n$ vertices. After that, we consider complete bipartite graphs with smoothed weights and prove a lower bound of $\Omega(n\phi/t)$ for the probability that more than $t$ iterations are needed for convergence (Section 5.3). We conclude this section with a discussion on how to transfer our results to the other variants of BP for matching and min-cost flow.

#### 5.1 Computation Tree

For proving the lower bounds, we need the notion of a *computation tree*, which we define analogously to Bayati et al. \[4\].

Let $G = (U \cup V, E)$ be a bipartite graph with $U = \{u_1, \ldots, u_n\}$ and $V = \{v_1, \ldots, v_n\}$. We denote the level-$k$ computation tree with the root labeled $x \in U \cup V$ by $T^k(x)$. The tree $T^k(x)$ is a weighted rooted tree of height $k + 1$. The root node in $T^0(x)$ has label $x$, its degree is the degree of $x$ in $G$, and its children are labeled with the adjacent nodes of $x$ in $G$. $T^{k+1}(x)$ is obtained recursively from $T^k(x)$ by attaching children to every leaf node in $T^k(x)$. Each child of a former leaf node labeled $y$ is assigned one vertex adjacent to $y$ in $G$ as a label, but the
label of the former leaf node’s parent is not used. (Thus, the number of children is the degree of \( y \) minus 1.) Edges between nodes with label \( u_i \) and label \( v_j \) in the computation tree have a weight of \( w_{ij} \).

We call a collection \( \Lambda \) of edges in the computation tree \( T^k(x) \) a \textit{T-matching} if no two edges of \( \Lambda \) are adjacent in \( T^k(x) \) and each non-leaf node of \( T^k(x) \) is the endpoint of exactly one edge from \( \Lambda \). Leaves can be the endpoint of either one or zero edges from \( \Lambda \). Let \( t^k(u_i; r) \) be the weight of a maximum weight \( T \)-matching in \( T^k(u_i) \) that uses the edge \((u_i, v_r)\) at the root.

### 5.2 Average-Case Analysis

Consider the undirected weighted complete bipartite graph \( K_{2,2} = (U \cup V, E) \), where \( U = \{u_1, u_2\} \), \( V = \{v_1, v_2\} \), and \((u_i, v_j) \in E \) for \( 1 \leq i, j \leq 2 \). Each edge \((u_i, v_j) = e_{ij}\) has weight \( w_{ij} \) drawn independently and uniformly from \([0, 1]\). We define the event \( E_\varepsilon \) for \( 0 < \varepsilon \leq \frac{1}{8} \) as the event that \( w_{11} \in \left[\frac{8}{9}, 1\right] \), \( w_{12} \in \left(\frac{1}{8}, \frac{5}{8}\right] \), \( w_{21} \in \left(\frac{5}{8}, \frac{3}{4}\right] \), and \( w_{22} \in \left[w_{12} + w_{21} - w_{11} - \varepsilon, w_{12} + w_{21} - w_{11}\right) \). Consider the two possible matchings \( M_1 = \{e_{11}, e_{22}\} \) and \( M_2 = \{e_{12}, e_{21}\} \). If event \( E_\varepsilon \) occurs, then the weight of \( M_2 \) is greater than the weight of \( M_1 \) and the weight difference is at most \( \varepsilon \). In addition, \( w_{11} \) is greater than \( w_{12} \) and the weight difference is at least \( 1/4 \). See Figure 1 for a graphical illustration.

![Figure 1](image-url)

**Figure 1:** If event \( E_\varepsilon \) occurs, then the weight of the dashed matching \( M_2 = \{e_{12}, e_{21}\} \) is greater than the weight of the solid matching \( M_1 = \{e_{11}, e_{22}\} \) and the weight difference is at most \( \varepsilon \). In addition \( w_{11} \) is greater than \( w_{12} \) and the weight difference is at least \( 1/4 \).

**Lemma 5.1.** The probability of event \( E_\varepsilon \) is \( \varepsilon/8^3 \).

**Proof.** The intervals in which \( w_{11}, w_{12}, \) and \( w_{21} \) have to assume values in order for event \( E_\varepsilon \) to occur all have a length of \( 1/8 \). The interval in which \( w_{22} \) has to take a value in order for event \( E_\varepsilon \) to occur, has a length of \( \varepsilon \). It is contained completely in the interval \( \left(0, \frac{1}{2}\right] \), since

\[
w_{12} + w_{21} - w_{11} - \varepsilon > \frac{1}{2} + \frac{5}{8} - \frac{1}{8} = 0
\]

and

\[
w_{12} + w_{21} - w_{11} \leq \frac{5}{8} + \frac{3}{4} - \frac{7}{8} = \frac{1}{2}.
\]

Now the probability that \( w_{11}, w_{12}, w_{21} \), and \( w_{22} \) all take values in the interval necessary for event \( E_\varepsilon \) to occur is \( \varepsilon/8^3 \). \( \square \)

**Lemma 5.2.** If event \( E_\varepsilon \) occurs, then the belief of node \( u_1 \) of \( K_{2,2} \) at the end of the \( 4k \)-th iteration is incorrect for all integers \( k \leq \frac{1}{8\varepsilon} - 1 \).
Proof. Consider the computation tree $T^{4k}(u_1)$ (see Figure 2). According to Bayati et al. [4, Lemma 1], the belief of node $u_1$ of $K_{2,2}$ after $4k$ iterations is given by the two-dimensional vector $b^{4k}_{u_1} = \left[ 2t^{4k}(u_1;1) \ 2t^{4k}(u_1;2) \right]^T$. This means that, after $4k$ iterations, the belief of node $u_1$ that it should be matched to $v_1$ is equal to twice the weight of the maximum-weight $T$-matching of $T^{4k}(u_1)$ that selects edge $(u_1, v_1)$ at the root. Analogously, after $4k$ iterations, the belief of node $u_1$ that it should be matched to $v_2$ is equal to twice the weight of the maximum-weight $T$-matching of $T^{4k}(u_1)$ that selects edge $(u_1, v_2)$ at the root. The maximum-weight $T$-matching $\hat{\Lambda}$ that matches the root node to its child labeled $v_2$, matches each node labeled $u_1$ to a node labeled $v_2$ and each node labeled $u_2$ to a node labeled $v_1$, since this is the only possible $T$-matching that matches the root node to its child labeled $v_2$. Define $\Lambda^*$ as the $T$-matching that matches each node labeled $u_1$ to a node labeled $v_1$ and each node labeled $u_2$ to a node labeled $v_2$. We show that $\Lambda^*$ has larger weight than $\hat{\Lambda}$, which implies that the belief at node $u_1$ after $4k$ iterations is incorrect. We have

$$w(\Lambda^*) - w(\hat{\Lambda}) = (2k + 1)w_{11} + 2kw_{22} - (2k + 1)w_{12} - 2kw_{21} = 2k(w_{11} + w_{22} - w_{12} - w_{21}) + w_{11} - w_{12} \geq -2\varepsilon + 1/4.$$ 

Now $-2\varepsilon + 1/4$ is greater than zero if $k \leq \frac{1}{8\varepsilon} - 1$. \hfill $\square$

**Theorem 5.3.** The probability that BP for MWM needs at least $t$ iterations to converge for $K_{2,2}$ with edge weights drawn independently and uniformly from $[0,1]$ is at least $\frac{1}{ct}$ for some constant $c > 0$.

**Proof.** We denote the number of iterations necessary for convergence of BP for MWM by $\tau$. Using Lemma 5.1 and Lemma 5.2 we have

$$P(\tau \geq t) \geq P(\tau \geq 4\lceil t/4 \rceil) \geq P\left( E \frac{1}{\theta(\lceil t/4 \rceil + 1)} \right) = \frac{1}{8^4(\lceil t/4 \rceil + 1)} \geq \frac{1}{ct}$$

13
for some constant $c > 0$.

**Corollary 5.4.** There exist bipartite graphs on $n \geq 4$ nodes, where $n$ is a multiple of 4, with edge weights drawn independently and uniformly from $[0, 1]$, for which the probability that BP for MWM needs at least $t$ iterations to converge is $\Omega\left(\frac{n}{c^2}\right)$ for $t \geq \frac{n}{c} + 1$ for some constant $c > 0$.

**Proof.** The bipartite graph consists of $n/4$ copies of $K_{2,2}$ and there are no edges between nodes in different copies of $K_{2,2}$. If BP does not converge in less than $t$ iterations for at least one of the $n/4$ copies of $K_{2,2}$, then BP does not converge in less than $t$ iterations. This holds since a run of BP on this bipartite graph corresponds to $n/4$ parallel runs of BP on the $n/4$ copies of $K_{2,2}$. Using Theorem 5.3, we have that a constant $c > 0$ exists such that

$$P(\tau < t) = (1 - P(BP \text{ needs at least } t \text{ iterations for a particular copy of } K_{2,2}))^{n/4} \leq \left(1 - \frac{1}{ct}\right)^{n/4} \leq \exp\left(-\frac{n}{4ct}\right) \leq 1 - \frac{n}{8ct},$$

where the second inequality follows from $1 - x \leq \exp(-x)$ and the last inequality follows from $\exp(-x) \leq 1 - \frac{x}{2}$ for $x \in [0,1]$ and from $\frac{1}{4ct} \leq 1$ which holds if $t \geq \frac{n}{4c}$. \qed

### 5.3 Smoothed Analysis

In this section we consider complete bipartite graphs $K_{n,n}$ in the smoothed setting. We denote by $X \sim U[a, b]$ that random variable $X$ is uniformly distributed on interval $[a, b]$. In the following we assume that $\phi \geq 26$ and $n \geq 2$ and even. Similarly to the average case (Section 5.2), we define the event $E^\phi$ for $K_{2,2}$ and for $0 < \varepsilon \leq 1/\phi$ as the event that $w_{11} \in [1 - \frac{1}{\phi}, 1]$, $w_{12} \in [\frac{23}{26}, \frac{23}{26} + \frac{1}{\phi}]$, $w_{21} \in [\frac{23}{26}, \frac{23}{26} + \frac{1}{\phi}]$, and $w_{22} \in [w_{12} + w_{21} - w_{11} - \varepsilon, w_{12} + w_{21} - w_{11}]$. Consider the two possible matchings $M_1 = \{e_{11}, e_{22}\}$ and $M_2 = \{e_{12}, e_{21}\}$. If event $E^\phi$ occurs, then the weight of $M_2$ is greater than the weight of $M_1$ and the weight difference is at most $\varepsilon$. In addition $w_{11}$ is greater than $w_{12}$ and the weight difference is at least $\frac{3}{26} - \frac{2}{\phi}$.

**Lemma 5.5.** There exist probability distributions on $[0, 1]$ for the weights of the edges, whose densities are bounded by $\phi$, such that the probability of event $E^\phi$ is at least $\varepsilon\phi/4$.

**Proof.** The intervals in which $w_{11}$, $w_{12}$, and $w_{21}$ have to assume values in order for event $E^\phi$ to occur all have a length of $\frac{1}{\phi}$. We choose the corresponding probability distributions such that they have density $\phi$ on the corresponding interval and density 0 elsewhere. The interval in which $w_{22}$ has to assume a value in order for event $E^\phi$ to occur has a length of $\varepsilon$. It is contained completely in the interval $[\frac{20}{26} - \frac{1}{\phi}, \frac{23}{26} + \frac{3}{\phi}]$, since

$$w_{12} + w_{21} - w_{11} - \varepsilon > \frac{23}{26} + \frac{23}{26} - 1 - \frac{1}{\phi} = \frac{20}{26} - \frac{1}{\phi},$$

and

$$w_{12} + w_{21} - w_{11} \leq \left(\frac{23}{26} + \frac{1}{\phi}\right) + \left(\frac{23}{26} + \frac{1}{\phi}\right) - \left(1 - \frac{1}{\phi}\right) = \frac{20}{26} + \frac{3}{\phi}.$$

We choose the probability distribution for $w_{22}$ such that it has density $\frac{\phi}{4}$ on the interval $[\frac{20}{26} - \frac{1}{\phi}, \frac{20}{26} + \frac{3}{\phi}]$ and 0 elsewhere. Now the probability that $w_{11}$, $w_{12}$, and $w_{21}$ take values in the interval necessary for event $E^\phi$ to occur is 1. For $w_{22}$, this probability is $\varepsilon\phi/4$. This completes the proof of Lemma 5.5. \qed
Lemma 5.6. If event $E^2_k$ occurs, then the belief of node $u_1$ at the end of the $4k$-th iteration is incorrect for all integers $k \leq \frac{1}{26} - 1$.

Proof. As in Lemma 5.2, a maximum-weight $T$-matching that selects the edge labeled $(u_1, v_1)$ at the root has greater weight than a maximum-weight $T$-matching that selects the edge labeled $(u_1, v_2)$ at the root for these values of $k$.

Analogously to the proof of Theorem 5.3, Lemmas 5.5 and 5.6 above immediately yield a lower bound of $\Omega(\varphi/t)$ for the probability that BP runs for at least $t$ iterations.

Lemma 5.7. Let $\Lambda^*$ be the maximum-weight $T$-matching on the computation tree $T^k(u_i)$. Then $\Lambda^*$ does not contain any light edges.

Proof. Assume to the contrary that $\Lambda^*$ contains a light edge $(x, y)$. In that case $x$ and $y$ are in different subgraphs. The idea of the proof is to construct a path $P$ from one leaf of the computation tree to another leaf that includes edge $(x, y)$. Path $P$ alternately consists of edges that are in $\Lambda^*$ and edges that are not. We show that a new $T$-matching of greater weight can be constructed by removing from $\Lambda^*$ the edges in $P \cap \Lambda^*$ and adding the edges in $P \setminus \Lambda^*$.

We include the edge labeled $(x, y)$ in $P$ and extend $P$ on both sides: We start with node $z_0 = x$ and node $z_0 = y$, respectively, and construct the corresponding part of $P$ as follows:

1. for $i = 1, 3, 5, \ldots$ do
2. if $z_{i-1}$ is a leaf node then terminate.
3. Let $H^k$ be the subgraph that $z_{i-1}$ belongs to.
4. Let $e_i = (z_{i-1}, z_i)$ be the edge incident to $z_{i-1}$ that belongs to $H^k$ that remains. There are at most $|I|$ such subpaths in $P \cap \Lambda^*$.
5. Add $e_i$ to $P$.
6. if $z_i$ is a leaf node then terminate.
7. Let $e_{i+1} = (z_i, z_{i+1})$ be the (unique) edge incident to $z_i$ that belongs to $\Lambda^*$.
8. Add $e_{i+1}$ to $P$.

It is clear that the procedure can only terminate if it finds a leaf. Moreover, the constructed sequence is alternating. Now we can show that no node will be visited twice: Otherwise there was an index $i$ such that $z_{i-1} = z_{i+1}$ since we are moving in a tree. This can not happen, however, as the sequence is alternating. Hence, the procedure terminates. With the previous properties we also obtain that both paths constructed starting with $z_0 = x$ and $z_0 = y$, respectively, are disjoint since $z_1 \notin \{x, y\}$ in both cases. Consequently, we obtain one simple path $P$ connecting two distinct leaf nodes and containing edge $(x, y)$.

We now show that the weight of the edges in $P \setminus \Lambda^*$ is strictly larger than the weight of the edges in $P \cap \Lambda^*$. For this, let $P$ be of the form $P = (p_0, \ldots, p_{\ell})$, where $\ell$ is even and where $(p_0, p_{\ell}) \in \Lambda^*$. Let $I \subseteq \{1, \ldots, \ell\}$ be the set of indices $i$ for which $(p_{i-1}, p_i)$ is a light edge. Clearly, $(p_{i-1}, p_i) \in \Lambda^*$ for each $i \in I$ by construction (see Line 4). Since the light edge $(x, y)$ belongs to $P$ we have $I \neq \emptyset$. For $i \in I$ let $P_i = (p_{i-1}, p_i, p_{i+1})$ be the subpath of $P$ of length 2 starting at node $p_{i-1}$. As $(p_i, p_{i+1})$ is a heavy edge, $w_{p_{i-1}p_i} - w_{p_{i-1}p_{i+1}} \geq \frac{20}{26} - \frac{1}{\phi} = \frac{20 - 2}{26}$. Hence, the difference in weight between the edge of $P_i$ that belongs to $\Lambda^*$ and the other one is significant.

Now remove all paths $P_i$ from $P$ and consider the subpaths of $P$ (connected components) that remain. There are at most $|I| + 1$ such subpaths $P'$, each has even length, and they only consist of heavy edges, i.e., all their edges lie in one subgraph $H^k$ where $k$ depends on $P'$. Consider such a subpath $P'$ and partition it into subpaths $P_j$ of length 4 and, if the length of $P'$ is no multiple of 4, into one subpath $P$ of length 2. The $\Lambda^*$-edges of $P_j$ form the non-optimal matching on $H^k$, whereas the other two edges form the optimal matching on $H^k$. Hence, the total weight of $P_j \cap \Lambda^*$ is at most the total weight of $P_j \setminus \Lambda^*$. Only for $P$ we might have the case that the weight of $P \cap \Lambda^*$ is larger than the weight of $P \setminus \Lambda^*$, but since both edges are heavy, the difference is at most $1 - \left(\frac{20}{26} - \frac{1}{\phi}\right) = \frac{26 - 2}{26}$. Hence, the difference between the total weight of $P \setminus \Lambda^*$ and the total weight of $P \cap \Lambda^*$ is at least

$$|I| \cdot \left(\frac{20}{26} - \frac{2}{\phi}\right) - (|I| + 1) \cdot \left(\frac{6}{26} + \frac{1}{\phi}\right) = |I| \cdot \left(\frac{14}{26} - \frac{3}{\phi}\right) - \left(\frac{6}{26} + \frac{1}{\phi}\right) \geq \frac{4}{26} > 0$$

since $|I| \geq 1$ and $\phi \geq 26$.

We can now construct a $T$-matching with heavier weight than $\Lambda^*$ by removing the edges in $P \cap \Lambda^*$ from $\Lambda^*$ and adding the edges in $P \setminus \Lambda^*$. This contradicts the assumption that the maximum weight $T$-matching includes a light edge and proves the lemma.

**Theorem 5.8.** There exist probability distributions on $[0, 1]$ for the weights of the edges, whose densities are bounded by $\phi$, such that the probability that BP for MWM needs at least $t$ iterations to converge for $K_{n,n}$ is $\Omega(n\phi/t)$ for $t \geq n\phi/c$ for some constant $c > 0$.  

16
Proof. We choose the probability distributions for the edge weights according to (1). Let \( \varepsilon = \frac{1}{52(k+1)} \) for \( k = 4t/4 \) and assume that event \( E_\phi \) occurs for subgraph \( H^j \). In this case the weight of matching \( M_2 = \{e_{12}'', e_{21}'\} \) is larger than matching \( M_1 = \{e_{11}', e_{22}'\} \), but at most by the small amount of \( \varepsilon \). Consider the computation tree \( T^{4k}(u_i) \). As in the proof of Lemma 5.2 we know that if the maximum weight \( T \)-matching \( \Lambda^* \) on \( T^{4k}(u_i) \) does not include the edge labeled \( e_{12}' \) at the root, then BP has not yet converged within the first \( 4k \geq t \) iterations (see Bayati et al. [4, Lemma 1]).

We show that \( \Lambda^* \) does not include edge \( e_{12}' \). Assume to the contrary that it does. We know from Lemma 5.7 that \( \Lambda^* \) does not contain light edges. Now we use the same procedure to create a path \( P \) from one leaf of \( T^{4k}(u_i) \) to another leaf that contains edge \( e_{12}' \) and alternates between edges from \( \Lambda^* \) and edges from \( T^{4k}(u_i) \setminus \Lambda^* \). Since \( T^{4k}(u_i) \) has height \( 4k + 1 \) and since \( u_i \) is the root of \( T^{4k}(u_i) \), path \( P \) contains exactly \( 8k + 2 \) edges, \( 2k + 1 \) of which are edges \( e_{12}' \), \( 2k + 1 \) of which are edges \( e_{11}' \), \( 2k \) of which are edges \( e_{12}' \), and \( 2k \) of which are edges \( e_{22}' \). The edges \( e_{12}' \) and \( e_{11}' \) are exactly the edges of \( P \cap \Lambda^* \). As in Lemma 5.2 the difference of weight between edges from \( P \setminus \Lambda^* \) and \( P \cap \Lambda^* \) is at least

\[
 w_{11}' - w_{12}' - 2k \varepsilon \geq \left( 1 - \frac{1}{\phi} \right) - \left( \frac{23}{26} + \frac{1}{\phi} \right) - \frac{2k}{52(k+1)}
\]

\[
 > \frac{3}{26} - \frac{2}{\phi} - \frac{1}{26} \geq 0
\]

since \( \phi \geq 26 \). This contradicts the fact that \( \Lambda^* \) is optimal since removing from \( \Lambda^* \) the edges in \( P \cap \Lambda^* \) and adding the edges in \( P \setminus \Lambda^* \) yields a \( T \)-matching of heavier weight for \( T^{4k}(u_i) \).

We have shown that BP does not converge within the first \( t \) iterations if event \( E_\phi \) occurs for some subgraph \( H^j \). Since there are \( n/2 \) such subgraphs, we get that the probability that BP for MWM needs at least \( t \) iterations to converge for \( K_{n,n} \) is \( \Omega \left( \frac{n}{2^t} \right) \) since

\[
 P(\tau \leq t) \leq P \left( E_\phi \text{ does not occur for any subgraph } H^j \right)
\]

\[
 \leq \left( 1 - \frac{\varepsilon \phi}{4} \right)^{n/2} \leq \exp \left( -\frac{\varepsilon \phi}{8} \right) = \exp \left( -\frac{n \phi}{8 \cdot 52 \cdot (4 \cdot \left\lceil t/4 \right\rceil + 1)} \right)
\]

\[
 \leq 1 - \frac{n \phi}{2 \cdot 8 \cdot 52 \cdot (4 \cdot \left\lceil t/4 \right\rceil + 1)}
\]

where the second inequality follows from Lemma 5.3. The third inequality is due to the fact that \( 1 - x \leq \exp(-x) \), whereas the last inequality stems from \( \exp(-x) \leq 1 - \frac{x}{2} \) for \( x \in [0,1] \). If \( x = \frac{n \phi}{8 \cdot 52 \cdot (4 \cdot \left\lceil t/4 \right\rceil + 1)} \) is at most 1, which holds for \( t \geq \frac{n \phi}{8 \cdot 52} \), then the correctness follows. 

Note that the lower bound on the probability that BP for MWM converges within \( t \) iterations only differs a factor \( O(m) \) from the upper bound from Section 4.1.

5.4 Other Variants of Belief Propagation

The results of Sections 5.2 and 5.3 also hold for other versions of belief propagation for minimum/maximum-weight (perfect) b-matching and min-cost flow [2, 4, 11] applied to the matching problem on bipartite graphs. The difference in the number of iterations until convergence differs no more than a constant factor. We omit the technical details but provide some comments on how the proofs need to be adjusted.
Some of the versions of BP consider minimum-weight perfect matching \cite{Bayati} or min-cost flow \cite{Gamarnik} instead of maximum-weight perfect matching. For these versions we get the same results if we have edge weights \( \tilde{w}_e = 1 - w_e \) for all edges \( e \).

For some of the versions of BP \cite{Gamarnik, Sanghavi} the root of the computation tree is an edge instead of a node. If we choose the root of this tree suitably, then we have that the difference in weight between the two matchings \( M_1 \) and \( M_2 \) of at most \( \varepsilon \) not only has to 'compensate' the weight difference \( \Delta w(e_1, e_2) \) between an edge \( e_1 \) in \( M_1 \) and an edge \( e_2 \) in \( M_2 \), but the entire weight \( w_e \) of an edge \( e \) in \( M_1 \) or \( M_2 \). However, the probability distributions for the edge weights in Sections 5.2 and 5.3 are chosen such that \( \Delta w(e_1, e_2) \) and \( w_e \) do not differ more than a constant factor.
