Abstract. We extend the key notion of Martin-Löf randomness for infinite bit sequences to the quantum setting, where the sequences become states of an infinite dimensional system. We prove that our definition naturally extends the classical case. In analogy with the Levin-Schnorr theorem, we work towards characterising quantum ML-randomness of states by incompressibility (in the sense of quantum Turing machines) of all initial segments.

1. Introduction

Algorithmic theory of randomness in the classical setting. An infinite sequence of classical bits can be thought of as random if it satisfies no exceptional properties. Examples of exceptional property are that every other bit is 0, and that all initial segments have more 0s than 1s. An infinite sequences of fair coin tosses has neither of the two properties.

Infinite bit sequences form the so-called Cantor space $2^\mathbb{N}$, which is equipped with a natural compact topology, and the uniform measure which makes the infinitely many coin tosses independent and fair. Recall that a subset of $2^\mathbb{N}$ is defined to be null if it is contained in $\bigcap_m G_m$ for a sequence of open sets $G_m$ with measure tending to 0. An exceptional property then corresponds to a null set in $2^\mathbb{N}$.

Since no sequence can actually avoid all the null sets, one has to restrict the class of null sets that can be considered. One only allows null sets that are effective, i.e. can be described in an algorithmic way. The possible levels of effectiveness one can choose determine a hierarchy of formal randomness notions. Such notions are studied for instance in the books [9, 25]. In recent work, the algorithmic theory of randomness has been connected to mathematical fields such as ergodic theory and set theory [23, 15, 20, 21].

Martin-Löf (ML) randomness, introduced in [17], is a central algorithmic randomness notion. Roughly speaking, a bit sequence $Z$ is ML-random if it
is in no null set $\bigcap_{m \in \mathbb{N}} G_m$ where the $G_m$ are effectively open uniformly in $m$, and the uniform measure of $G_m$ is at most $2^{-m}$. This notion is central because there is a universal test, and because ML-randomness of an infinite bit sequence can be naturally characterised by an incompressibility condition on the initial segments of the sequence (Levin-Schnorr theorem). Detail will be given below.

The quantum setting. Our main goal is to develop an algorithmic theory of randomness for infinite sequences of quantum bits. This poses two challenges.

The first challenge is to provide a satisfying mathematical model for such sequences. This is not as straightforward as in the classical case: deleting one qubit from a system of finitely many entangled qubits (e.g. the EPR state, which describes two entangled photons) creates a mixed state, namely a statistical superposition of possibilities for the remaining qubits. So one actually studies states of a system that can be interpreted as statistical superpositions of infinite sequences of quantum bits (qubits). Such states have been considered in theoretical physics in the form of half-infinite spin chains (e.g. a linear arrangement of hydrogen atoms with the electron in the basic or the excited state).

The usual mathematical approach (e.g. [7, 6, 2]) to deal with such statistical superpositions is as follows. The sequences of qubits are modeled by coherent sequences $\langle \rho_n \rangle_{n \in \mathbb{N}}$ of density matrices. We have $\rho_n \in M_n$ where $M_n$ is the algebra of $2^n \times 2^n$ matrices over $\mathbb{C}$. The idea is that $\rho_n$ describes the first $n$ qubits. Infinite qubit sequences are states (that is, positive functionals of norm 1) of a certain C*-algebra $M_\infty$, the direct limit of the matrix algebras $M_n$.

The second challenge is the absence of measure in the quantum setting. We will use instead the unique tracial state $\tau$ on $M_\infty$ as a noncommutative analog of the uniform measure. For a projection $p \in M_n$ one has $\tau(p) = 2^{-n} \dim \text{rg}(p)$. The analog of an effectively open set in Cantor space is now a computable increasing sequence $G = \langle p_n \rangle_{n \in \mathbb{N}}$ of projections, $p_n \in M_n$, and one defines $\tau(G) = \sup_n \tau(p_n)$. Based on this we will introduce our main technical concept, a quantum version of ML-tests.

Overview of the paper. Section 2 provides the necessary preliminaries on finite sequences of qubits, as well as on density matrices, which describe statistical superpositions of qubit sequences of the same length. We also review the mathematical model for states that embody infinite sequences of qubits.

In Section 3 we introduce quantum Martin-Löf tests. We show that there is a universal such test. Every infinite sequence of classical bits can be seen as a state of the C*-algebra $M_\infty$. We show that for such a sequence, quantum ML-randomness coincides with the usual ML-randomness. So our notion naturally extends the classical one.

The Levin-Schnorr theorem (Levin [16], Schnorr [28]) characterises ML-randomness of a bit sequence $Z$ by the growth rate of the initial segment complexity $K(Z \mid n)$ (here $Z \mid n$ denotes the string consisting of the first $n$ bits, and $K$ denotes a version of Kolmogorov complexity where the set of descriptions that a universal machine can use as inputs has to be prefix
free). In Section 4 we work towards a potential quantum version of this important result. This would mean that quantum Martin-Löf random states are characterized by having initial segments of a fast growing quantum Kolmogorov complexity. The actual formulation of our result corresponds to the Gács-Miller-Yu theorem \[12, 18\] which uses plain Kolmogorov complexity \(C\), rather than the original Levin-Schnorr theorem, for reasons related to different properties of classical and quantum Turing machines [4].

We note that there has been an earlier application of notions from computability theory to spin chains. Wolf, Cubitt and Perez-Garcia [8] studied undecidability in the quantum setting. They constructed Hamiltonians on square lattices with associated ground states which radically change behaviour as the system size grows. For example, while being a product state for small system sizes, it becomes entangled for large sizes [1]. Furthermore, based only on initial segments of the sequence, it is computationally impossible to predict whether this effects happens. The states we consider here are defined on a spin chain rather than on a two-dimensional lattice, and are also not constrained to be ground states of local Hamiltonians. However, they share similar features in the sense of possessing unpredictable behaviour as the system size grows.

2. Preliminaries

2.1. Quantum bits. A classical bit can be in states 0, 1. A qubit is a physical system with two possible classical states: for instance, the polarisation of photon horizontal/vertical, an hydrogen atom in the ground or the first excited state. A qubit can be in a superposition of the two classical states: \(\alpha |0\rangle + \beta |1\rangle\), where \(\alpha, \beta \in \mathbb{C}\), \(|\alpha|^2 + |\beta|^2 = 1\). A measurement of a qubit w.r.t. the standard basis \(|0\rangle, |1\rangle\) yields 0 with probability \(|\alpha|^2\), and 1 with probability \(|\beta|^2\).

2.2. Finite sequences of quantum bits. The state of a physical system is represented by a vector in a finite dimensional Hilbert space \(A\). For vectors \(a, b \in A\), \(\langle a|b\rangle\) denotes the inner product of vectors \(a, b\), which is linear in the second component and antilinear in the first. For systems represented by Hilbert spaces \(A, B\), the tensor product \(A \otimes B\) is a Hilbert space that represents the combined system. One defines an inner product on \(A \otimes B\) by \(\langle a \otimes b|c \otimes d\rangle = \langle a|c\rangle \langle b|d\rangle\).

Mathematically, a qubit is simply a unit vector in \(\mathbb{C}^2\). The state of a system of \(n\) qubits is a unit vector in the tensor power 
\[\mathcal{H}_n := (\mathbb{C}^2)^\otimes n = \mathbb{C}^2 \otimes \ldots \otimes \mathbb{C}^2.\]

We denote the standard basis of \(\mathbb{C}^2\) by \(|0\rangle, |1\rangle\). The standard basis of \(\mathcal{H}_n\) consists of vectors 
\[|a_0 \ldots a_{n-1}\rangle := |a_0\rangle \otimes \ldots \otimes |a_{n-1}\rangle,\]
where \(\sigma = a_0 \ldots a_{n-1}\) is an \(n\)-bit string. While the usual notation for \(|a_0 \ldots a_{n-1}\rangle\) in quantum physics is \(|\sigma\rangle\), for brevity we will often write \(\sigma\).

The state of the system of \(n\) qubits is a unit vector \(\mathcal{H}_n\) and hence a certain linear superposition of these basis vectors. For example, for \(n = 2\), the EPR (or “maximally entangled”) state is \(\frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)\).
2.3. Mixed states and density operators. With each state \( |\psi\rangle \) (a unit vector in \( \mathcal{H}_n \)) we associate, and often identify, the linear form \( |\psi\rangle \langle \psi| \) on \( \mathcal{H}_n \) given by \( |\phi\rangle \mapsto |\psi\rangle \langle \psi| |\phi\rangle \). A mixed state is a convex linear combination \( \sum_{i=1}^{2^n} p_i |\psi_i\rangle \langle \psi_i| \) of pairwise orthogonal states \( \psi_i \). In this context a state \( |\psi\rangle \) (identified with \( |\psi\rangle \langle \psi| \)) is called pure.

Recall that for an operator \( S \) on a finite dimensional Hilbert space \( A \), the trace \( \text{Tr}(S) \) is the sum of the eigenvalues of \( S \) (counted with multiplicity). A Hermitian operator is called positive if all eigenvalues are non-negative. A mixed state corresponds to a positive operator \( S \) on \( \mathcal{H}_n \) with \( \text{Tr}(S) = 1 \), as one can see via the spectral decomposition of \( S \).

A \( C^* \)-algebra is a subalgebra of the bounded operators on some Hilbert space closed under taking the adjoint, and topologically closed in the operator norm. We let
\[
M_k = \text{Mat}_{2^k}(\mathbb{C})
\]
denote the \( C^* \)-algebra of \( 2^k \times 2^k \) matrices over \( \mathbb{C} \) (identified with operators on \( \mathbb{C}^{2^k} \)). A density operator (or density matrix) in \( M_k \) is a positive operator in \( M_k \) with trace 1. The states \( \rho \in S(M_k) \) can be identified with the density operators \( S \) on \( \mathcal{H}_k \): to a state \( \rho \) corresponds the unique density operator \( S \) such that
\[
\rho(X) = \text{Tr}(SX) \quad \text{for each} \quad X \in M_k.
\]

2.4. Embeddings between matrix algebras. We view \( \mathcal{H}_{n+1} \) as the tensor product \( \mathcal{H}_n \otimes \mathbb{C}^2 \). Then \( M_{2n+1} \) is naturally isomorphic to \( M_{2n} \otimes M_2 \). We view the indices of matrix entries as numbers written in “reverse binary”, i.e., with the most significant digit written on the right. Thus a matrix entry is indexed by a pair of strings \( \sigma, \tau \) of the same length, and a matrix in \( M_{2n+1} \) has the form
\[
A = \begin{pmatrix}
A_{00} & A_{01} \\
A_{10} & A_{11}
\end{pmatrix}
\]
where each \( A_{i,k} = (a_{\sigma_i,\tau_k})_{|\sigma| = |\tau| = n} \) is in \( M_{2^n} \). We have embeddings \( M_{2n} \to M_{2n+1} \) given by
\[
A \mapsto A \otimes I_2 = \begin{pmatrix}
A & 0 \\
0 & A
\end{pmatrix}.
\]
Note that the embeddings preserve the operator norm.

2.5. Partial trace operation. For each \( n \), there is a unique linear map \( T_n : M_{2n+1} \to M_{2^n} \), called the partial trace operation, such that \( T_n(R \otimes S) = R \cdot \text{Tr}(S) \) for each \( R \in M_{2^n} \) and \( S \in M_2 \). Intuitively, this operation corresponds to deleting the last qubit; for instance, \( T_1([10 \langle 10|]) = [1 \langle 1|] \).

Remark 2.1. Consider again the EPR state \( \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle) \), now viewed as the operator \( \beta = \frac{1}{2}(|00\rangle + |11\rangle)(|00\rangle + \langle 11|) \) in \( M_2 \). While this state is pure, \( T_1(\beta) = \frac{1}{2}(|0\rangle \langle 0| + |1\rangle \langle 1|) \) is a properly mixed state.

One can provide an explicit description of the partial trace operation \( T_n \) as follows. \( \mathcal{H}_{n+1} \) has as a base the \( |\sigma r\rangle \), \( \sigma \) a string of \( n \) bits, \( r \) a bit. For
a $2^{n+1} \times 2^{n+1}$ matrix $A = (a_{\sigma r, \tau s})_{|\sigma r|,|\tau s|=n, r, s \in \{0,1\}}$, $T_n(A)$ is given by the $2^n \times 2^n$ matrix

$$b_{\sigma, \tau} = a_{\sigma 0, \tau 0} + a_{\sigma 1, \tau 1}. \tag{3}$$

It is easy to check that if $A$ is a density matrix, then so is $T_n(A)$.

2.6. Direct limit of matrix algebras, and tracial states. The so-called CAR algebra $M_{2^\infty}$ is the direct limit of the $M_{2^k}$ under the norm-preserving embeddings in (2). Thus, $M_{2^\infty}$ is the norm completion of the union of the $M_{2^k}$, seen as a $*$-algebra. Clearly $M_{2^\infty}$ is a $C^*$-algebra. Note that it is more common to write $M_{2^\infty}$ for this algebra, and to denote our $M_k$’s by $M_{2^k}$, but we use the present notations for simplicity.

A state on a $C^*$-algebra $M$ is a positive linear functional $\rho : M \to \mathbb{C}$ that sends the unit element of $M$ to 1 (this implies that $\|\rho\| = 1$). To be positive means that $x \geq 0 \Rightarrow \rho(x) \geq 0$.

A state $\rho$ is called tracial if $\rho(ab) = \rho(ba)$ for each pair of operators $a, b$. On $M_{2^n}$ there is a unique tracial state $\tau_n$ given by $\tau_n(a) = 2^{-n} \text{Tr}(a) = 2^{-n} \sum_{|\sigma|=n} a_{\sigma, \sigma}$. The corresponding density matrix is $2^{-n} I_{2^n}$ (i.e., it has $2^{-n}$ on the diagonal and 0 elsewhere). Note that the states $\tau_n$ are compatible with the embeddings $M_n \to M_{n+1}$. This yields a tracial state $\tau$ on $M_{2^\infty}$, which is as well.

2.7. Quantum Cantor space. The quantum analog of Cantor space is $S(M_{2^\infty})$, the set of states of the $C^*$-algebra $M_{2^\infty}$. The space $S(M_{2^\infty})$ is endowed with a convex structure, and is compact in the weak * topology (the coarsest topology that makes the application maps $\rho \mapsto \rho(x)$ continuous) by the Banach-Alaoglu theorem. The following is well known but hard to reference in this form.

Fact 2.2. A state $\rho \in S(M_{2^\infty})$ corresponds to a sequence $(\rho_n)_{n \in \mathbb{N}}$, where $\rho_n$ is a density matrix in $M_{2^n}$, and which is coherent in the sense that taking the partial trace of $\rho_{n+1}$ yields $\rho_n$.

Proof. First let $\rho \in S(M_{2^\infty})$. Let $\rho_n$ be the state which is the restriction of $\rho$ to $M_{2^n}$, (later on we will use the notation $\rho|_n$). Let $S_n$ be the density matrix on $M_{2^n}$ corresponding to $\rho_n$ according to (1).

Claim 2.3. $T_n(\rho_{n+1}) = \rho_n$.

To see this note that a brief calculation using (3) shows that for each $A \in M_{2^n}$,

$$\text{Tr} \left( S_{n+1} \begin{bmatrix} A & 0 \\ 0 & A \end{bmatrix} \right) = \text{Tr} \left( T_n(S_{n+1})A \right).$$

We also have $\rho_{n+1}(A \otimes I_2) = \rho_n(A)$ by definition of the $\rho_n$. Therefore $T_n(S_{n+1}) = S_n$ by the uniqueness of the density matrix for $\rho_n$.

Conversely, given a sequence $(\rho_n)$ of states on $M_{2^n}$ such that $T_n(\rho_{n+1}) = \rho_n$, there is a unique $\rho \in S(M_{2^\infty})$ such that $\rho_n$ is the restriction of $\rho$ to $M_{2^n}$ for each $n$. To see this, first one defines a bounded functional $\tilde{\rho}$ on the *-algebra $\bigcup_n M_{2^n}$ that extends each $\rho_n$. Then one extends $\tilde{\rho}$ to a state $\rho$ on $M_{2^\infty}$ using that $\tilde{\rho}$ is continuous. \qed
Remark 2.4. Suppose that all the $\rho_n$ are in diagonal form, and hence the entries of the corresponding matrices are in $[0, 1]$. For each $\sigma$ we can interpret $a_{\sigma, \sigma}$ as the probability that $\sigma$ is an initial segment of a bit sequence: by (3) we have $a_{\sigma, \sigma} = a_{\sigma 0, \sigma 0} + a_{\sigma 1, \sigma 1}$. In other words, the $\rho \in S(M_{2^\infty})$ with all $\rho_n$ in diagonal form correspond to the probability measures on $2^\mathbb{N}$. The tracial state $\tau$ defined in Subsection 2.6 corresponds to the uniform measure.

One can now view an infinite sequence of classical bits $Z \in 2^\mathbb{N}$ as a state in $S(M_{2^\infty})$, which corresponds to the probability measure concentrating on $\{Z\}$. For more detail, recall that the Hilbert space $\mathcal{H}_n$ has as a base the vectors $|\sigma\rangle$, for a string $\sigma$ of $n$ classical bits. A classical bit sequence $Z$ corresponds to the state $(\rho_n)_{n \in \mathbb{N}}$, where the bit matrix $B = \rho_n \in M_{2^n}$ is given by $b_{\sigma, \sigma} = 1 \Leftrightarrow \sigma = \tau = Z |n\rangle$. For $\sigma = Z |n\rangle$, $\rho_n$ is the pure state $|\sigma\rangle\langle\sigma|$ on $M_n$.

Characterisation of quantum Cantor space. Cantor space can be characterised as the projective (or inverse) limit of the discrete topological spaces $X_n$ of $n$-bit strings with the maps $f_n: X_{n+1} \to X_n$ so that $f_n(\sigma\tau) = \sigma$, i.e., $f_n$ removes the last bit. We now show that quantum Cantor space is a projective limit of the state sets of the $M_{2^n}$.

By a convex (topological) space we mean a topological space $X$ with a continuous operation $F(\delta, a, b) = \delta a + (1 - \delta)b$, for $\delta \in [0, 1]$, $a, b \in X$, satisfying obvious arithmetical axioms such as $F(\delta, a, a) = a$. Clearly $S(M_{2^n})$ is a convex space. A map $g: X \to Y$ between convex spaces is called affine if $g(F(\delta, a, b)) = F(\delta, g(a), g(b))$ for each $a, b \in X$ and each $\delta$. The projective limit of a sequence $\langle X_n \rangle$ of convex spaces with continuous affine maps $T_n: X_{n+1} \to X_n$, $n \in \mathbb{N}$ (called a diagram), is the convex space $P$ of all $\rho \in \prod X_n$ such that $T_n(\rho(n+1)) = \rho(n)$ for each $n$ with the subspace topology and the canonical operation $F$.

Denote by $g_n: P \to X_n$ the map sending $\rho$ to $\rho(n)$. The projective limit $P$ is characterised up to affine homeomorphism by as a colimit from category theory: we have $T_n \circ g_{n+1} = g_n$ for each $n$, and for any convex space $A$ with continuous affine maps $f_n: A \to X_n$ such that $T_n \circ f_{n+1} = f_n$ for each $n$, there is a unique continuous affine map $f: A \to P$ such that $g_n \circ f = f_n$ for each $n$.

Proposition 2.5. Consider the diagram consisting of the $S(M_{2^n})$ together with the partial trace maps $T_n: S(M_{2^{n+1}}) \to S(M_{2^n})$. Seen as a convex space, $S(M_{2^\infty})$ is affinely homeomorphic to the projective limit of the $S(M_{2^n})$.

Proof. Define $\hat{g}_n: S(M_{2^n}) \to S(M_{2^n})$ by $\hat{g}_n(\rho) = \rho |M_{2^n}\rangle$. By Claim 2.3, $T_n \circ \hat{g}_{n+1} = \hat{g}_n$ for each $n$. It now suffices to verify the universal property for $S(M_{2^\infty})$ together with the maps $\hat{g}_n: S(M_{2^n}) \to S(M_{2^n})$. Suppose we
are given a convex space $A$ with continuous affine maps $f_n : A \to S(M_{2^n})$ such that $T_n \circ f_{n+1} = f_n$ for each $n$. Let $f : A \to S(M_{2^n})$ be the map such that $f(x) = \rho$ where $\rho$ is the state determined as above by the sequence $\rho_n \in S(M_{2^n})$ such that $\rho_n = f_n(x)$. Clearly $f$ is affine. We show that $f$ is continuous. A basic open set of $S(M_{2^n})$ with its weak-* topology has the form

$$U_{v,S} = \{ \rho : \rho(v) \in S \}$$

where $v \in M_{2^n}$ and $S \subseteq C$ is open. If $\rho \in U_{v,S}$ then there is $\varepsilon > 0$ such that the open ball $B_\varepsilon(\rho(v))$ is contained in $S$. Furthermore, there is $k \in \mathbb{N}$ and $w \in M_{2^k}$ such that $\| v - w \| < \varepsilon / 2$. Since states have operator norm 1, this implies $|\rho(w) - \rho(v)| < \varepsilon / 2$. Letting $S' = B_{\varepsilon/2}(\rho(v))$, we have $U_{v,S'} \subseteq U_{v,S}$.

So for continuity of $f$ it suffices to show that $f^{-1}(U_{w,S'})$ is open for any $k$, any $w \in M_{2^k}$ and open $S' \subseteq C$. By definition of $f$ we have $f^{-1}(U_{w,S'}) = f_k^{-1}(\{ \theta \in S(M_k) : \theta(w) \in U_{w,S'} \})$. Since $\rho(w) = \rho \downharpoonright_{M_k}(w)$, $f^{-1}(U_{w,S'})$ is open by the hypothesis that $f_k : A \to S(M_{2^k})$ is continuous. $\square$

3. Randomness for states of $M_{2^n}$

Our main purpose is to introduce and study a version of Martin-Löf’s randomness notion for states on $M_{2^n}$, Definition 3.3 below. We begin by recalling the definition of Martin-Löf tests, phrased in such a way that it can be easily lifted to the quantum setting. A clopen (i.e. closed and open) set $C$ in Cantor space can be described by a set $F$ of strings of the same length $k$ in the sense that $C = \bigcup_{\sigma \in F} \{ Z : Z \succeq \sigma \}$ (note that $k$ is not unique). A $\Sigma^0_1$ set $S$ (or effectively open set) is a subset of Cantor space $2^\mathbb{N}$ given in a computable way as an ascending union of clopen sets. In more detail, we have $S = \bigcup C_n$ where $C_n$ is clopen, $C_n \subseteq C_{n+1}$, and a finite description of $C_n$ can be computed from $n$. A Martin-Löf test is a uniformly computable sequence of $\Sigma^0_1$ sets $(G_m)_{m \in \mathbb{N}}$ (i.e., $G_m = \bigcup_k C^m_k$, where the map sending a pair $m,k$ to a description of the clopen set $C^m_k$ is computable) such that $\lambda G_m \leq 2^{-m}$. Here $\lambda$ denotes the uniform measure, which C. K. G. obtained by viewing the $k$-th bit as the result of the $k$-th toss of a fair coin, where all the coin tosses are independent.

A sequence $Z \in 2^\mathbb{N}$ is Martin-Löf random if it passes all such tests in the sense that $Z \notin \bigcap_m G_m$. By the 1973 Levin-Schnorr theorem (see e.g. [25, 3.2.9]), this is equivalent to the incompressibility condition on initial segments that for some constant $b$, for each $n$, the prefix free Kolmogorov complexity of the first $n$ bits of $Z$ is at least $n - b$.

As an aside, we add the restriction on tests that the measure of $G_m$ is a computable real uniformly in $m$, we obtain the weaker notion of Schnorr randomness, now frequently used in the effective study of theorems from analysis, e.g. [27]. This notion (as well as its variant, computable randomness) embody an alternative paradigm of randomness, namely that it is hard to predict the next bit from the previously seen ones.

In the following we will use letters $\rho, \eta$ for states on $M_{2^n}$. We write $\rho \downharpoonright_n$ for the restriction of $\rho$ to $M_{2^n}$, viewed either as a density matrix or a state of $M_{2^n}$. After introducing quantum ML-randomness in Definition 3.3, we will show that it ties in with the classical definition of ML-randomness as
mentioned above, any classical bit sequence defines a pure (product) quantum state of $M_{2^\infty}$, by mapping the bits to the corresponding basis elements in the computational basis. We then prove that for classical bit sequences, Martin-Löf randomness agrees with its quantum analog under this embedding. Even in the classical setting our notion is broader, because probability measures over infinite bit sequences can be viewed as states according to Remark 2.4. For instance, the uniform measure on $2^\mathbb{N}$, seen as the tracial state $\tau$, is quantum ML-random. So in the new setting, randomness of $\rho$ does not contradict that the function $n \to \rho |_n$ is computable. Philosophically there is some doubt whether these states should be called random at all; the term “unstructured” appears more apt, and only for classical bit sequences being unstructured actually implies being random. However, we prefer the term “random” here simply for practical reasons.

### 3.1. Quantum analog of Martin-Löf tests

Quite generally, a projection in a $C^*$ algebra is a self-adjoint positive operator $p$ such that $p^2 = p$. In the definition of ML-tests, we will replace a clopen set given by strings of length $n$ by a projection in $M_{2^n}$. However, we need to restrict its possible matrix entries to complex numbers that have a finite description. 

**Definition 3.1.** A complex number $z$ is called algebraic if it is the root of a polynomial with rational coefficients. Let $\mathbb{C}_{\text{alg}}$ denote the field of algebraic complex numbers. A matrix over $\mathbb{C}_{\text{alg}}$ will be called elementary.

Clearly such numbers are given by a finite amount of information, and in fact they are polynomial time computable: for each $n$ one can in time polynomial in $n$ compute a Gaussian rational within $2^{-n}$ of $z$. Note that if the matrix determining an operator on $\mathcal{H}_n$ consists of algebraic complex numbers, then its eigenvalues are in $\mathbb{C}_{\text{alg}}$ and its eigenvectors are vectors over $\mathbb{C}_{\text{alg}}$. We note that by a result of Rabin, $\mathbb{C}_{\text{alg}}$ has a computable presentation: there is a 1-1 function $f: \mathbb{C}_{\text{alg}} \to \mathbb{N}$ such that the image under $f$ of the field operations are partial computable functions with computable domains.

Suppose that a projection $p \in M_{2^n}$ is diagonal with respect to the standard basis. Since its only possible eigenvalues are 0, 1, the entries are 0 or 1. Thus, projections in $M_n$ with a diagonal matrix directly correspond to clopen sets in Cantor space.

For $u, v \in M_{2^n}$ one writes $u \leq v$ if $v - u$ is positive. Note that $p \leq q$ for projections $p, q \in M_{2^n}$ means that the range of $p$ is contained in the range of $q$. A projection $p \in M_n$ with matrix entries in $\mathbb{C}_{\text{alg}}$ will be called a special projection. Such a projection has a finite description, given by the size of its matrix and all the entries in its matrix.

**Definition 3.2.** A quantum $\Sigma_0^1$ set (or q-$\Sigma_0^1$ set for short) $G$ is a computable sequence of special projections $(p_i)_{i \in \mathbb{N}}$ such that $p_i \in M_2$, and $p_i \leq p_{i+1}$ for each $i$.

We note that the limit of an increasing sequence of projections $(p_i)_{i \in \mathbb{N}}$ does not necessarily exist in $M_{2^\infty}$. For, the limit would be a projection itself, and the projection lattice of $M_{2^\infty}$ is not complete. See e.g. [11] where it is shown that its completeness would yield an embedding of the nonseparable $C^*$-algebra $\ell^\infty(\mathbb{C})$ into $M_{2^\infty}$, which is not possible as the latter is separable.
Recall that for a state \( \rho \) and \( p \in M_{2^n} \), we have \( \rho(p) = \text{Tr}(\rho |_p p) \) by (1). We write \( \rho(G) = \sup, \rho(p_i) \). In particular we let \( \tau(G) = \sup, \tau(p_i) \), where \( \tau \) is the tracial state defined in Section 2.6. Note that \( \tau(G) = \) a real in \([0,1]\) that is the supremum of a computable sequence of rationals. Each \( \Sigma^0_1 \) set \( S \) in Cantor space is an effective union of clopen sets, and hence can be seen as a \( \Sigma^0_1 \) set. If the state \( \rho \) is a measure then \( \rho(S) \) yields the usual result: evaluating \( \rho \) on \( S \).

We chose the term “quantum \( \Sigma^0_1 \) set” by analogy with the notion of \( \Sigma^0_1 \) subsets of Cantor space; they are not actually sets. The physical intuition is that a projection \( p_i \in M_{2^n} \) describes a measurement of \( \rho |_{M_{2^n}} \), strictly speaking given by the pair of projections \( (p_i, I_{M_{2^n}} - p_i) \). Then \( \rho(p_i) = \text{Tr}(\rho |_{M_{2^n}} p_i) \) is the outcome of the measurement, the probability that the first alternative given by the measurement occurs, and \( \rho(G) \) is the overall outcome of measuring the state. So one could view \( G \) as a probabilistic set of states: for \( 0 \leq \delta \leq 1 \), \( \rho \) is in \( G \) with probability \( \delta \) if \( \rho(G) > \delta \). The “inclusion relation” is \( \text{G} \leq \text{H} \) if \( \rho(G) \leq \rho(H) \) for each state \( \rho \). We note that a “level set” of states \( \{ \rho: \rho(G) > \delta \} \) is open in \( S(M_{2^n}) \) with the weak * topology (Section 2.7).

For special projections \( p, q \in M_{2^n} \), we denote by \( p \lor q \) the projection in \( M_2 \) with range \( \text{rg}\ p + \text{rg}\ q \). We have \( \tau(p \lor q) \leq \tau(p) + \tau(q) \). For quantum \( \Sigma^0_1 \) sets \( G = \langle p_k \rangle_{k \in N} \) and \( H = \langle q_k \rangle_{k \in N} \) we define \( G \lor H \) to be \( \langle p_k \lor q_k \rangle_{k \in N} \). Note that again \( \tau(G \lor H) \leq \tau(G) + \tau(H) \). Inductively we then define \( G_1 \lor \ldots \lor G_r \) for \( r \geq 2 \).

**Definition 3.3** (Quantum Martin-Löf randomness). A quantum Martin-Löf test (qML-test) is an effective sequence \( \langle G_r \rangle_{r \in N} \) of quantum \( \Sigma^0_1 \) sets such that \( \tau(G_r) \leq 2^{-r} \) for each \( r \). For \( \delta \in (0,1) \), we say that \( \rho \) fails the qML test at order \( \delta \) if \( \rho(G_r) > \delta \) for each \( r \); otherwise \( \rho \) passes the qML test at order \( \delta \). We say that \( \rho \) is quantum ML-random if it passes each qML test \( \langle G_r \rangle_{r \in N} \) at each positive order, that is, \( \inf_r \rho(G_r) = 0 \).

**Proposition 3.4.** There is a qML-test \( \langle R_n \rangle \) such that for each qML test \( \langle G_k \rangle \) and each state \( \rho \), for each \( n \) there is \( k \) such that \( \rho(R_n) \geq \rho(G_k) \). In particular, the test is universal in the sense that \( \rho \) is qML random iff \( \rho \) passes this single test.

**Proof.** This follows the usual construction due to Martin-Löf; see e.g. [25, 3.2.4]. We may fix an effective listing \( \langle G^e_m \rangle_{m \in N} \) of all the quantum ML tests, where \( G^e_m = \langle p^e_{m,r} \rangle_{r \in N} \) for projections \( p^e_{m,r} \) in \( M_{2^n} \). Informally, we let

\[
R_n = \bigvee_e G^e_{e+n+1}.
\]

However, this infinite supremum of quantum \( \Sigma^0_1 \) sets is actually not defined. To interpret it, think of \( \bigvee_e G^e_{e+n+1} \) as \( \bigvee_e \bigvee_r p^e_{e+n+1,r} \) (which is still not defined). Now let

\[
q^e_k = \bigvee_{e+n+1 \leq k} p^e_{e+n+1,k}
\]

which is a finite supremum of projections. Clearly \( q^e_k \leq q^e_{k+1} \), and \( \tau(q^e_k) \leq \sum_e \tau(p^e_{e+n+1,k}) \leq 2^{-n} \). We let \( R_n = \langle q^e_k \rangle_{k \in N} \), so that \( \tau(R_n) \leq 2^{-n} \). Hence \( \langle R_n \rangle_{n \in N} \) is a quantum ML-test.
Fix $e$. For each $n$ we have
\begin{align*}
\rho(R_n) &= \sup_k \rho(q_k^e) \\
&\geq \sup_k \rho(p_{n+e+1,k}^e) \\
&= \rho(C_{n+e+1}^e).
\end{align*}

A basic property one expects of random bit sequences $Z$ is the law of large numbers, namely $\lim_{n \to \infty} \frac{1}{n} \sum_{i=0}^{n-1} Z(i) = 1/2$. This property holds for Martin-Löf (or even Schnorr) random bit sequences; see e.g. [25, 3.5.21]. The first author and Tomamichel have proved a version of the law of large numbers for qML-random states. For $i < n$ let $S_{n,i}$ be the subspace of $\mathbb{C}^{2^n}$ generated by those $\sigma$ with $\sigma_i = 1$. It is as usual identified with its orthogonal projection. So for any state $\rho$ on $M_{2^n}$, the real $\rho(S_{n,i}) = \text{Tr}(\rho|_n S_i^o)$ is the probability that a measurement of the $i$-th qubit of its initial segment $\rho|_n$ returns 1.

**Proposition 3.5** ([10], Section 6.6). Let $\rho$ be a qML-random state. We have
\begin{equation*}
\lim_n \frac{1}{n} \sum_{i<n} \rho(S_{n,i}) = 1/2.
\end{equation*}

Their argument is based on Chernoff bounds. It works in more generality for any computable bias $r$ in place of 1/2, and for states that are qML-random with respect to that bias, as detailed in [10], Section 6.6.

### 3.2. Comparison with ML-randomness for bit sequences.

Recall from Subsection 2.7 that each bit sequence $Z$ can be viewed as a state on $M_{2^n}$. In this section we show that $Z$ if ML-random iff $Z$ viewed as a state is qML-random (Thm. 3.9). Each classical ML-test can be viewed as quantum ML-test, so quantum ML-randomness implies ML-randomness for $Z$. For the converse implication, the idea is to turn a quantum ML-test that $Z$ fails at order $\delta$ into a classical test that $Z$ fails. We need a few preliminaries. We thank the anonymous referees for suggesting simplifications implemented in the argument below.

Recall that the vectors $\sigma$, for $n$-bit strings $\sigma$, form the standard basis of $\mathcal{H}_n$. Note that if $p \in M_{2^k}$ is a projection and $\eta$ is a bitstring of length $k$, then $\text{Tr}(|\eta\rangle\langle\eta| p) = ||p(\eta)||^2 = \langle \eta | p | \eta \rangle$. Given a bit sequence $Z$, letting $\eta = Z|_k$, we have $Z(p) = \text{Tr}(|\eta\rangle\langle\eta| p)$ (if $Z$ is viewed as a state then $Z|_k$ is viewed as the density matrix $|\eta\rangle\langle\eta|$ in Dirac notation).

**Definition 3.6.** Fix $k \in \mathbb{N}$, and let $p \in M_{2^k}$ be a projection. For $\delta > 0$ define
\begin{equation}
S = S_{p,\delta}^k = \{ \eta \in \{0,1\}^k : \delta \leq \text{Tr}(|\eta\rangle\langle\eta| p) \}.
\end{equation}

In the following we identify the set $S$ of strings of length $k$ in (4) with the corresponding diagonal projection in $M_{2^k}$. By $|S|$ we denote the size of the set $S$.

**Claim 3.7.** $\tau(S) \leq \tau(p)/\delta$.

**Proof.** $\delta|S| \leq \sum_{\eta \in S} \text{Tr}(|\eta\rangle\langle\eta| p) \leq \sum_{\eta} \text{Tr}(|\eta\rangle\langle\eta| p) = \text{Tr}(p),$ so $|S|2^{-k} \leq \text{Tr}(p)2^{-k}/\delta = \tau(q)/\delta$. \hfill $\square$
Claim 3.8. Suppose $p \in M_{2k}$ are as above. Then
\[ S_{p,\delta}^{k+1} = \{ \eta a : |\eta| = k, a = 0, 1 \land \eta \in S_{p,\delta}^k \}, \]
where $p'$ is the lifting of $p$ to $M_{2k+1}$.

Proof. For $\eta, a$ as above we have $p'(\eta a) = p(\eta) \otimes a$ and so $\text{Tr}(|\eta\rangle\langle\eta|p) = ||p(\eta)||^2 = ||p'(\eta a)||^2 = \text{Tr}(|\eta a\rangle\langle\eta a|p')$. \hfill \square

Theorem 3.9. Suppose $Z \in 2^N$. Then $Z$ is $\text{ML}$-random iff $Z$ viewed as an element of $S(M_{2^\infty})$ is $\text{qML}$-random.

Proof. Suppose $Z$ fails the $\text{qML}$-test $\langle G^r \rangle_{r \in \mathbb{N}}$ at order $\delta > 0$, where $G^r$ is given by the sequence $\langle p_k^r \rangle_{k \in \mathbb{N}}$. Thus $\forall r \exists k Z(p_k^r) > \delta$, and $\sup_k \tau(p_k^r) \leq 2^{-r}$. Uniformly in $r$ we will define a $\Sigma^0_r$ set $V_r \subseteq 2^N$ containing $Z$ and of measure at most $2^{-r/\delta}$. This will show that $Z$ is not $\text{ML}$-random.

We fix $r$ and suppress it from the notation for now. We may assume that $p_k \in M_{2k}$ for each $k$. Define $S_{p_k,\delta}^k$ as in (4). We let $V^r = V = \bigcup_k S_k$, where $S_k = [S_{p_k,\delta}^k]$. (here $[X]$ denotes the open set given by a set $X$ of strings).

Clearly $Z \in V$. It remains to verify that the uniform measure of $V$ is at most $2^{-r/\delta}$. By Claim 3.7, it suffices to show that $S_k \subseteq S_{k+1}$ for each $k$. By Claim 3.8 viewing $p_k \in M_{2k+1}$, we can evaluate (4) for $k + 1$ and obtain a set of strings generating the same clopen set $S_k$. Since $p_k \leq p_k+1$, this set of strings is contained in $S_{p_k+1,\delta}$.

The first author and Stephan have studied the case of states that can be seen as measures on Cantor space in a separate paper [26]. They call a measure $\rho$ Martin-Löf absolutely continuous if $\lim_m \rho(G_m) = 0$ for each $\text{ML}$-test $\langle G_m \rangle$. Tejas Bhojraj, a PhD student of Joseph Miller at UW Madison, has shown that this notion coincides with quantum ML-randomness for measures, generalising the result above.

3.3. Solovay tests in the quantum setting. We discuss some quantum analogs of Solovay tests, a test notion that is equivalent to $\text{ML}$-tests in the classical setting [25, Ch. 3]. Quantum Solovay tests will be used in the statement of Theorem 4.4.

Definition 3.10 (Quantum Solovay randomness).

- A quantum Solovay test is an effective sequence $\langle G_r \rangle_{r \in \mathbb{N}}$ of quantum $\Sigma^0_r$ sets such that $\sum_r \tau(G_r) < \infty$.
- We say that the test is strong if the $G_r$ are given as projections; that is, from $r$ we can compute $n_r$ and a matrix of algebraic numbers in $M_{nyr}$ describing $G_r = p_r$.
- For $\delta \in (0, 1)$, we say that $\rho$ fails the quantum Solovay test at order $\delta$ if $\rho(G_r) > \delta$ for infinitely many $r$; otherwise $\rho$ passes the qML test at order $\delta$.
- We say that $\rho$ is quantum Solovay-random if it passes each quantum Solovay test $\langle G_r \rangle_{r \in \mathbb{N}}$ at each positive order, that is, $\lim_r \rho(G_r) = 0$.

Tejas Bhojraj has shown that quantum Martin-Löf randomness implies quantum Solovay randomness; the converse implication is trivial. He converts a quantum Solovay test into a quantum Martin-Löf test, so that failing the former at level $\delta$ implies failing the latter at level $O(\delta^2)$.
4. Initial segment complexity

Our definition of quantum Martin-Löf randomness is by analogy with classical ML-randomness, but also based on the intuition that the properties of quantum Martin-Löf random states are hard to predict. So we expect that the complexity of their initial segments is high. In order to formalize this, we start off from a theorem of Gács and also Miller and Yu \[18\] that asserts that a sequence \(Z\) is ML-random iff all its initial segments are hard to compress, in the sense of plain descriptive string complexity. Our main result works towards an extension of this theorem to the quantum setting.

**Classical setting.** Let \(K(x)\) denote the prefix-free version of descriptive complexity of a bit string \(x\). (See [25, Ch. 2] for a brief overview of descriptive string complexity, also called Kolmogorov complexity.) The Levin-Schnorr theorem (see [9, Thm. 5.2.3] or [25, Thm. 3.2.9]) says that a bit sequence \(Z\) is ML-random if and only if each of its initial segments is incompressible in the sense that \(\exists b \in \mathbb{N} \forall n K(Z|_n) > n - b\). The Miller-Yu Theorem [18, Thm. 7.1] is a version of this in terms of plain, rather than prefix-free, descriptive string complexity, usually denoted by \(C(x)\). The constant \(b\) is replaced by a sufficiently fast growing computable function \(f(n)\). We will provide a quantum analog of the Miller-Yu theorem, thereby avoiding the obstacles to introducing prefix-free descriptive string complexity in the quantum setting.

A slight variant of the Miller-Yu Theorem was obtained by Bienvenu, Merkle and Shen [5]. Their version states that, for an appropriate computable function \(f\) such that \(\sum n 2^{-f(n)} < \infty\), \(Z\) is ML-random iff there is \(r\) such that for each \(n\) we have \(C(Z|_n) \geq n - f(n) - r\), where \(C(x|_n)\) is the plain Kolmogorov complexity of a string \(x\) given its length \(n\). Requiring \(\sum n 2^{-f(n)} < \infty\) of course means that \(f\) grows sufficiently fast; the borderline is between \(\log_2 n\) and \(2 \log_2 n\).

**Quantum setting.** Quantum Kolmogorov complexity is measured via quantum Turing machines [3, 30]. In the version due to Berthiaume, van Dam and Laplante [4, Def. 7], the compression of a state of \(M_{2^n}\) is via a state of \(M_{2^k}\), and only approximative in the sense that a state in \(M_{2^n}\) “nearby” the given state can actually be compressed. More detail on this was provided in Markus Müller’s thesis [22], which in particular contains a detailed discussion of how to define halting for a quantum Turing machine.

In order to avoid obscuring the arguments below by discussions of quantum Turing machines and universality, we will use a restricted machine model that is sufficient for a meaningful analog of the Gács-Miller-Yu Theorem. This machine model corresponds to uniformly generated circuit sequences. After proving our result, in Remark 4.7 we will discuss its relationship with quantum Kolmogorov complexity in the sense of [4].

**Convention 4.1.** In the following all qubit sequences and all states will be elementary. Thus, the relevant matrices only have entries from the field \(\mathbb{C}_{\text{alg}}\) of algebraic complex numbers.

**Definition 4.2.** A unitary machine \(L\) is given by computable sequence of unitary (elementary) matrices \(L_n \in M_{2^n}\). For an input \(z\) which is a density
matrix in $M_{2^n}$, its output is $L(z; n) := L_n z L_n$. Thus, if $z$ is a pure state $|\psi\rangle$, with the usual identifications the output is $L_n |\psi\rangle$.

Recall that the trace norm of an $n \times n$ matrix $A$ over $\mathbb{C}$ is defined by $\|A\|_{tr} = \sqrt{\text{tr}(AA^*)}$. The trace distance between two $n \times n$ matrices is $D(A, B) = \frac{1}{2} \|A - B\|_{tr}$.

**Definition 4.3.** Let $L$ be a unitary machine. The $L$-quantum Kolmogorov complexity $QC^L_n(x | n)$ of a (possibly mixed) state $x$ on $n$-qubits is the least natural number $k$ such that there exists a (mixed) state $y \in M_{2^k}$ with

$$D(x, L(y \otimes |0^{n-k}\rangle \langle 0^{n-k}|; n)) < \varepsilon.$$ 

That is, the output of $L$ on $y \otimes |0^{n-k}\rangle \langle 0^{n-k}|$ approximates $x$ to an accuracy of $\varepsilon$ in the trace distance.

We fix a computable listing $\langle \sigma_i \rangle_{i \in \mathbb{N}}$ of the elementary pure qubit strings so that $\ell(\sigma_i) \leq i$ for each $i$.

We now prove a weak quantum analog of the Gács-Miller-Yu theorem.

**Theorem 4.4.** Let $\rho$ be a state on $M_{2^\infty}$.

1. Let $L$ be a unitary machine. Let $1 > \varepsilon > 0$ and suppose $\rho$ passes each qML-test at order $1 - \varepsilon$. Then for each computable function $f$ satisfying $\sum_n 2^{-f(n)} < \infty$, for almost every $n$

$$QC^L_n(\rho | n) n - f(n).$$

2. For each strong quantum Solovay test $\langle p_r \rangle_{r \in \mathbb{N}}$, there exists a total computable function $f : \mathbb{N} \to \mathbb{N}$ with $\sum_n 2^{-f(n)} \leq 4$ and a unitary machine $L$ such that the following holds. If $\rho$ fails $\langle p_r \rangle$ at order $1 - \varepsilon$ where $1 > \varepsilon > 0$, then there are infinitely many $n$ such that

$$QC^L_n(\rho | n) n - f(n).$$

Note that this is not a full analog, because the second part can only be obtained under the hypothesis that $\rho$ fails a strong Solovay test (Def. 3.10). Bhojraj has announced an alternative version of Part 1 where the hypothesis is that $\rho$ pass all strong Solovay tests at order $1 - \varepsilon$.

**Proof.** Part 1: We may assume that $\sum_n 2^{-f(n)} \leq 1/4$, because we can replace $f$ by $f = f + C$ where $C$ is sufficiently large so that this condition is met.

Recall our fixed listing $\langle \sigma_i \rangle_{i \in \mathbb{N}}$ of the pure elementary quantum states of any length. For a given parameter $r \in \mathbb{N}$, and $t, n \in \mathbb{N}$, let $S_{r,t}(n)$ be the set of pure qubit strings $x = \sigma_i$, $i \leq t$, of length $n$ so that for some pure qubit string $y = \sigma_k$, $k \leq t$, we have

$$|y| \leq n - f(n) - r$$

and $L(y \otimes |0^{n-|y|}\rangle; n) = x$.

Note that $S_{r,t}(n)$ is computable in $r, t, n$ using Convention 4.1. Hence from $r, t, n$ we can compute an orthogonal projection $p_{r,t}(n)$ in $M_{2^n}$ onto the subspace generated by $S_{r,t}(n)$. Let $p_{r,t} = \sup_{n \leq t} p_{r,t}(n)$. Then $p_{r,t} \in M_{2^t}$ and $p_{r,t}$ is computable in $r, t$. Clearly $p_{r,t} \leq p_{r,t+1}$ for each $t$.

By definition of unitary machines the dimension of the range of $p_{r,t}(n)$ is bounded by $2^{n-f(n)-r+2}$. Hence $\tau(p_{r,t}(n)) \leq 2^{-f(n)-r+2}$, and then $\tau(p_{r,t}) \leq \sum_n 2^{-f(n)-r+2} \leq 2^{-r}$ by our hypothesis on $f$. 
Let $G_r$ be the quantum $\Sigma^0_1$ set given by the sequence $\langle p_{r,t} \rangle_{t \in \mathbb{N}}$. Then $\langle G_r \rangle_{r \in \mathbb{N}}$ is a quantum ML-test.

We show that there is $r$ such that for each $n$ we have $QC^\varepsilon_L(\rho \mid_n | n) \geq n - f(n) - r$. Since we can carry out the same argument with $\lfloor f \rfloor$ instead of $f$, and $f(n) \to \infty$, this will be sufficient.

We proceed by contraposition. Suppose that for arbitrary $r \in \mathbb{N}$ there is $n$ such that $QC^\varepsilon_L(\rho \mid_n | n) < n - f(n) - r$. This means that there is a state $y$ (possibly mixed) of length $k < n - f(n) - r$ such that $D(x, \rho \mid_n | n) < \varepsilon$ where $x = L(y \otimes |0^{n-k}\rangle \langle 0^{n-k}|, n)$. Let $y = \sum \alpha_i |y_i\rangle$ be the corresponding convex combination of pure states with $\alpha_i$ algebraic and $y_i$ of length $k$. We have $x = \sum_i \alpha_i |x_i\rangle \langle x_i|$ where $x_i = L(y_i \otimes |0^{n-k}\rangle, n)$. Then there is $t$ such that $x_i \in S_{r,t}(n)$ for each $i$, and hence $\text{Tr}[x_{r,t}(n)] = 1$. This implies that $\rho(p_{r,t}(n)) > 1 - \varepsilon$ and hence $\rho(G_r) > 1 - \varepsilon$. Since $r$ was arbitrary this shows that $\rho$ fails the test at order $1 - \varepsilon$.

Part 2: Let $\langle p_{r,t} \rangle_{r \in \mathbb{N}}$ be a strong quantum Solovay test. We may assume that $\sum_r \tau(p_r) \leq 1/2$, and that $p_r \in M_{2^n}$, where $n_r$ is computed from $r$ and $n_r < n_{r+1}$ for each $r$. The idea is as follows: suppose the range of $p_r$ has dimension $k < n_r$. Then $z'_n$, the projection of $\rho \mid_n$ to $p_r$, as defined below, can be directly described by a density matrix in $M_{2^k}$ if we define our unitary machine $L$ to compute an isometry between $H_k$ and the range of $p_r$. If $\rho(p_r) > 1 - \varepsilon$ we show that the trace distance from $z'_n$ to $\rho \mid_n$ is at most $\sqrt{\varepsilon}$. Therefore $QC^\varepsilon_L(\rho \mid_n | n) \leq k$. For a function $f$ as required, we can ensure $k < n - f(n_r)$ for each $r$.

For the details, let $f : \mathbb{N} \to \mathbb{N}$ be a computable function such that

$$2^{-f(n_r)} \geq \tau(p_r) > 2^{-f(n_r) - 1}$$

and $f(m) = m$ if $m$ is not of the form $n_r$. Note that $f$ is computable and satisfies $\sum_n 2^{-f(n)} \leq 4$. Let $g(n) = n - f(n)$.

To describe the unitary machine $L$ we need to provide a computable sequence of unitary matrices $\langle L_n \rangle_{n \in \mathbb{N}}$. For $n = n_r$, let $L_n$ be a unitary matrix in $M_{2^n}$ such that its restriction $L_n \mid H_{g(n)}$ is an isometry $H_{g(n)} \cong \mathbb{C}^r(p_r)$ (the range of $p_r$). By hypothesis on the sequence $\langle p_r \rangle$ this sequence of unitary matrices is computable.

For a projection operator $p$ in $M_{2^n}$ and a density matrix $s$ in $M_{2^n}$, we define the projection of $s$ by $p$ to be

$$\text{Proj}(s ; p) = \frac{1}{\text{Tr}[sp]} p sp$$

Note that this is again a density matrix, and each of its eigenvectors is in the range of $p$.

In the following fix an $r$ such that $\rho(p_r) > 1 - \varepsilon$. Write $n = n_r$ and $z_n = \rho \mid_n \in M_{2^n}$. So $\text{Tr}(z_n p_r) > 1 - \varepsilon$. Let

$$z'_n = \text{Proj}(z_n ; p_r)$$

Claim 4.5. $QC^\delta_L(z'_n \mid n) \leq g(n)$ for each $\delta > 0$.

Proof. Each eigenvector of $z'_n$ is in the range of $p_r$. So there is a density matrix $y \in M_{2^{g(n)}}$ such that $L_n(y \otimes |0^{g(n)}\rangle \langle 0^{g(n)}|) L_n^\dagger = z'_n$. □
We now argue that \( D(z'_n, z_n) < \sqrt{\varepsilon} \) (recall that \( D \) denotes the trace distance). We rely on the following.

**Proposition 4.6.** Let \( p \) be a projection in \( M_2^n \), and let \( \theta \) be a density matrix in \( M_2^n \). Write \( \alpha = \text{Tr}[\theta p] \). Let \( \theta' = \text{Proj}(\theta; p) \). Then \( D(\theta', \theta) \leq \sqrt{1 - \alpha} \).

**Proof.** Let \( |\psi_\theta\rangle \) be a purification of \( \theta \). Then \( \alpha - \frac{1}{2} p |\psi_\theta\rangle \) is a purification of \( \theta' \). Uhlmann’s theorem (e.g. [24, Thm. 9.4]) implies \( F(\theta', \theta) \geq \alpha - \frac{1}{2} \langle \psi_\theta | p | \psi_\theta \rangle = \alpha - \frac{1}{2} \), where \( F(\sigma, \tau) = \text{Tr} \sqrt{\sqrt{\sigma} \tau \sqrt{\sigma}} \) denotes fidelity. Now it suffices to recall from e.g. [24, Eqn. 9.110] that \( D(\theta', \theta) \leq \sqrt{1 - F(\theta', \theta)^2} \). \( \square \)

We apply Prop. 4.6 to \( p = p_r \) and \( \theta = z_n \) and \( \theta' = z'_n \), where as above \( n = n_r \). By hypothesis \( \alpha = \text{Tr}[z_n p_r] = \rho(p_r) > 1 - \varepsilon \) and hence \( \sqrt{1 - \alpha} < \sqrt{\varepsilon} \). Claim 4.5 now shows \( QC_{L}^z(z_n) \leq g(n) \). Since there are infinitely many \( r \) such that \( \rho(p_r) > 1 - \varepsilon \), we obtain Part 2 of Thm. 4.4. \( \square \)

**Remark 4.7.** In an important extended abstract, Yao [32] proved that the quantum Turing machines (QTM) of Bernstein and Vazirani [3] can be simulated by quantum circuits with only a polynomial overhead in time. For recent work on such a simulation see [19].

Yao also announced the converse direction: a QTM can simulate the input/output behaviour of a computable sequence of quantum circuits. The argument is briefly discussed after the statement of Theorem 3 in [32] (also see [31]). So with suitable input/output conventions, Definition 4.3 can be seen as a special case of the definition of \( QC_M^z \) for a quantum Turing machine \( M \) as in [4, Def. 7].

We ignore at present whether Part 1 can be strengthened to general quantum Turing machines. The input/output behaviour of such a machine is merely given by a quantum operation, for instance because at the end of a computation the state has to be discarded.

On the other hand, since a QTM \( M \) can simulate the effect of the sequence of quantum circuits \( \langle L_n \rangle \), and a universal QTM in the sense of [3] can simulate \( M \) with a small loss in accuracy, we obtain the following.

**Corollary 4.8.** In the setting of Part 2 of the theorem, we have \( QC_{L}^z(\rho \upharpoonright_n) < n - f(n) \) for infinitely many \( n \).

It would be interesting to find a version of Theorem 4.4 in terms of Gács’ version of quantum Kolmogorov complexity, which is based on semi-density matrices rather than machines [13].

5. **Outlook**

As mentioned, randomness via algorithmic tests has been related to effective dynamical systems in papers such as [23, 15]. For a promising connection with quantum information processing, recall that a spin chain can be seen as a quantum dynamical system with the shift operation [6], in analogy with the classical case with the shift operation on \( 2^N \) that deletes the first bit of a sequence. An interesting potential application of our randomness notion is
to obtain an effective quantum version of the Shannon-McMillan-Breiman (SMB) theorem from the 1950s (see e.g. [29]). That result is important in the area of data compression because it determines the asymptotic compression rate of sequences of symbols emitted by an ergodic source.

Let $A$ be a finite alphabet, and let $P$ be an ergodic probability measure on $A^\mathbb{N}$. Let $h(P)$ denote the entropy of $P$. The classical theorem states that for almost every $Z \in A^\mathbb{N}$, we have

\begin{equation}
(5) \quad h(P) = -\lim_{n \to \infty} \frac{1}{n} \log P[Z \mid n];
\end{equation}

informally, $h(P)$ can be obtained by looking at the asymptotic “empirical entropy” along a random sequence $Z$.

The Shannon-McMillan (SM) theorem is a slightly weaker, earlier version of the full SMB theorem based on the notion of convergence in probability. Breiman then phrased the Shannon-McMillan theorem as a property of almost every sequence in the sense of the given ergodic measure. Bija et al. [6] provided a quantum version of the SM-theorem. Their setting is the one of bi-infinite spin chains, or more generally, $d$-dimensional lattices; it can be easily adapted to the present setting.

Algorithmic versions of the SMB theorem [14, 15] show that Martin-Löf randomness of $Z$ relative to the computable ergodic measure is sufficient for (5) to hold. The question then is whether in the quantum setting, quantum ML-randomness relative to a computable shift-invariant ergodic state is sufficient.

The von Neumann entropy of a density matrix $S$ is defined by $H(S) = -\text{Tr}(S \log S)$. For a state $\psi$ on $M_2^\mathbb{N}$ we let $h(\psi) = \lim_n \frac{1}{n} H(\psi \mid M_2^n)$. For background and notions not defined here see [10], Section 6.

**Conjecture 5.1** (with M. Tomamichel). Let $\psi$ be an ergodic computable state on $M_2^\mathbb{N}$. Let $\rho$ be a state that is quantum ML-random with respect to $\psi$. Then $h(\psi) = -\lim_n \frac{1}{n} \text{Tr}(\rho \mid M_2^n \log(\psi \mid M_2^n))$.

Note that this reduces to the classical theorem in case $\psi$ is a probability measure and $\rho$ a bit sequence, because each matrix $\rho \mid M_n \log(\psi \mid M_n)$ is diagonal with at most one nonzero entry. Tomamichel and the first author have verified the conjecture in case $\mu$ is an i.i.d. state; see [10, Section 6]. The first author and Stephan [26, Thm. 23] have proved the conjecture in case that $\psi$ and $\rho$ are measures on Cantor space and the empirical entropy $-\frac{1}{n} \log \psi(x)$, for $x$ an $n$-bit string, is bounded above (this means that $\psi$ is close to the uniform measure).

**Acknowledgements.** We thank Tejas Bhojraj and Marco Tomamichel for corrections and helpful discussions, and the anonymous referee for many helpful suggestions, in particular on Theorem 4.4. We also thank Willem Fouché and Peter Gács for helpful comments.

VBS is grateful for the hospitality of the University of Auckland. This work was started while he was still with the Department of Physics at Ghent University, and supported by the EU through the ERC grant Qute. He also acknowledges support by the NCCR QSIT. AN is grateful for the hospitality of Ghent University and of the IMS at NUS, Singapore. He acknowledges support by the Marsden fund of New Zealand.
