On a Partition LP Relaxation for Min-Cost 2-Node Connected Spanning Subgraphs

Logan Grout*   Joseph Cheriyan†   Bundit Laekhanukit‡

Abstract

Our motivation is to improve on the best approximation guarantee known for the problem of finding a minimum-cost 2-node connected spanning subgraph of a given undirected graph with nonnegative edge costs. We present an LP (Linear Programming) relaxation based on partition constraints.

The special case where the input contains a spanning tree of zero cost is called 2NC-TAP. We present a greedy algorithm for 2NC-TAP, and we analyze it via dual-fitting for our partition LP relaxation.

Keywords: 2-node connected graphs, approximation algorithms, connectivity augmentation, greedy algorithm, network design, partition relaxation

1 Introduction

Two of the key problems in the area of approximation algorithms for network design are the min-cost 2ECSS (2-edge connected spanning subgraph) problem, and the the min-cost 2NCSS (2-node connected spanning subgraph) problem. The latter problem is as follows: Given an undirected graph $G = (V, E)$ and nonnegative costs on the edges, denoted by either $cost \in \mathbb{R}_{+}^E$ or $c \in \mathbb{R}_{+}^E$, find a minimum-cost spanning subgraph that is 2-node connected. Throughout, we use $n := |V|$ to denote the number of nodes of $G$. Recall that a graph is 2-node connected if it has $\geq 3$ nodes, it is connected, and the deletion of any one node leaves a connected graph. This problem is NP-hard, see [10].

Approximation algorithms for the min-cost 2NCSS problem have been studied for several decades, see [8, 9, 14]. The best approximation guarantee known is 2 (see [13, 6], though there are earlier references). Most of these algorithms are based on LP relaxations, and the analysis of the approximation guarantee shows that the integrality ratio of the standard LP relaxation, the so-called set-pairs LP, is $\approx 2$ (see [6]). The set-pairs LP (for the min-cost 2NCSS problem) can be

viewed as a generalization of the cut LP relaxation of the min-cost 2ECSS problem. Recall that
the cut LP relaxation of the min-cost 2ECSS problem is:

\[
(P_{\text{cut}}) \min \left\{ \sum_{e \in E} cost(e)x_e : x(\delta(S)) \geq 2, \ \forall \emptyset \subsetneq S \subsetneq V; \ 0 \leq x \leq 1 \right\}.
\]

(See Section 2 for definitions and notation.) The set-pairs LP is obtained from the LP \((P_{\text{cut}})\) by
adding the following family of constraints for each node \(w \in V\):

\[
\sum_{e \in E} x_e : e = uv \in E, u \in S, v \in (V - w) - S \geq 1, \ \forall \emptyset \subsetneq S \subsetneq V - w.
\]

Informally speaking, the additional constraints require that
the deletion of any node \(w\) results in a subgraph that is “fractionally connected”. An interesting
special case of the problem is the Tree Augmentation Problem for 2-node connectivity (2NC-TAP),
where the instance \((G, c)\) contains a spanning tree of zero cost; thus, \((V, \{e \in E : cost(e) = 0\})\)
contains a spanning tree, denoted by \(T\). The edges of \(E(G) - T\) are called links.

Recent research in the area has focused on the design and analysis of approximation algorithms
that beat the “natural threshold” of 2 for the approximation guarantee. The Weighted Tree Aug-
mentation Problem (WTAP) is a special case of the min-cost 2ECSS problem where the instance
\((G, c)\) contains a spanning tree of zero cost. Cohen and Nutov [3] designed an approximation
algorithm for a special case of WTAP with a guarantee of \((1 + \ln 2) < 1.7\), based on earlier work
by Zelikovsky on the Steiner Tree problem [19]. Recently, Traub and Zenklusen [17] presented an
approximation algorithm for WTAP with guarantee \(1 + (\ln 2) + \epsilon < 1.7\), via a so-called relative
greedy algorithm. Subsequently, they improved on the approximation guarantee for WTAP via
local search, see [18].

Nutov [15] recently presented a 1.91-approximation algorithm for unweighted 2NC-TAP, thus
beating the threshold of 2; this result does not use any LP relaxation.

One obstacle for beating the approximation threshold of 2 for the min-cost 2NCSS problem and
for (weighted) 2NC-TAP is that the set-pairs LP relaxation has integrality ratio \(\geq 2 - \epsilon\). There
is a simple family of examples of (unweighted) 2NC-TAP such that the integrality ratio of the
set-pairs LP relaxation is \(\geq 2 - \epsilon\) (where \(\epsilon\) is a small positive number), see Proposition 4.1.

One of the main contributions of this paper is a stronger LP relaxation for the min-cost 2NCSS
problem, that we call the partition LP relaxation. The partition LP relaxation \((P)\) of the min-cost
2NCSS problem is obtained from the cut LP relaxation of the min-cost 2ECSS problem by adding
the family of constraints

\[
\sum_{e \in E_{G - w}(P)} x_e \geq |P| - 1, \ \forall P \in \hat{\Pi}(\text{Comp}(G^0 - w))
\]

for each node \(w \in V\), where \(G^0\) denotes \((V, \{e \in E : cost(e) = 0\})\), and \(P\) denotes a partition of
\(V - w\) such that (the node-set of) each connected component of \(G^0 - w\) is contained in one of the
sets of \(P\).

Moreover, based on our partition LP relaxation, we design a simple greedy algorithm for
(weighted) 2NC-TAP that achieves approximation guarantee \(H(\lambda - 1)\), where \(\lambda\) denotes the maxi-
mum length over all the tree-paths \(T(\ell)\) of the links \(\ell\) of the instance, and \(H(k)\) denotes the \(k\)-th
harmonic number. For example, our algorithm achieves an approximation guarantee of \(H(3) = 11\)
for instances of 2NC-TAP such that each link \(\ell\) induces a tree-path \(T(\ell)\) of length \(\leq 4\), regardless
of the diameter of the initial tree. (See Figure 2 for an example of such an instance.) Fredrickson
and JáJá [8] showed that such instances of 2NC-TAP are NP-hard. Our algorithm and analysis are
based on two well-known results: (1) the greedy algorithm for SCP (the Set Covering Problem) and its analysis via “dual fitting” (i.e., charging the cost incurred by the greedy algorithm to a feasible solution of the dual of the standard LP relaxation), and (2) the analysis of the greedy algorithm for the minimum spanning tree (MST) problem via “dual fitting” with respect to the well-known partition LP formulation of MST, see [2], [12, Sec. 2].

Recall that the input to SCP consists of a set \( U \) of \( m \) points \( p_1, \ldots, p_m \), \( n \) subsets \( S_1, \ldots, S_n \) of \( U \), and a non-negative weight \( \text{cost}(S_j) \) for each subset \( S_j \), \( j = 1, \ldots, n \). The goal is to find a minimum weight collection of the subsets \( S_j \) that contains \( U \). The standard LP relaxation has a variable \( x_j \) for each subset \( S_j \), and a linear constraint for each point \( p_i \): \( \min \{ \sum \text{cost}(S_j) x_j : \sum_{S_j : S_j \ni p_i} x_j \geq 1, \forall p_i \in U; x \geq 0 \} \). The dual LP has a non-negative variable \( y_i \) for each point \( p_i \in U \): \( \max \{ \sum_{p_i \in U} y_i : \sum_{p_i \in S_j} y_i \leq \text{cost}(S_j), j = 1, \ldots, n; y \geq 0 \} \). The greedy algorithm iteratively picks a subset of the minimum cost-coverage ratio, where the cost-coverage ratio of a set \( S_j \) (at any time \( t \) in the execution) is \( \text{cost}(S_j)/|S_j^{(t)}| \), where \( |S_j^{(t)}| \) denotes the number of as-yet-uncovered points in \( S_j \). It is well known that if each set \( S_j \) in an instance of SCP contains \( k \) points, then the greedy algorithm for SCP achieves an approximation guarantee of \( H(k) \).

We note that the connection to SCP is obvious for the well-known (weighted) Tree Augmentation Problem for 2-edge connectivity (WTAP). The input for WTAP is the same as for 2NC-TAP, namely, \( G, c, T \) (where \( T \) is a spanning tree of \( G \) of cost zero), and the goal is to find a set of links \( F \) of minimum cost such that \( T \cup F \) is 2-edge connected. To view a TAP instance as an SCP instance, let \( U = T \), thus, the points of the SCP instance correspond to the edges of \( T \), and let the subsets \( S_j \) of the SCP instance correspond to the tree-paths \( T(\ell) \) of the links \( \ell \) of the TAP instance. For example, consider a TAP instance on \( K_4 \) (the complete graph on four nodes) where \( T \) is a claw (the star \( K_{1,3} \) with three leaves). The SCP instance has three points (that map to the three edges of the claw), and it has three subsets \( S_j \) of size two each (corresponding to the three links of \( E(K_4) - T \)). Clearly, the greedy algorithm for SCP gives an approximation algorithm for WTAP with a guarantee of \( H(\lambda) \). Based on this mapping between WTAP and SCP, Cohen and Nutov [3] designed an approximation algorithm for a special case of WTAP with a guarantee of \( (1 + \ln 2) < 1.7 \). The major component of their algorithm is a local improvement algorithm for SCP whose running time depends on the structure of the instance, and, an initial feasible solution. Their analysis of the running time of their algorithm relies on some key properties of WTAP that do not apply to 2NC-TAP. Cohen and Nutov start by rooting the tree \( T \) at an arbitrary node, and then, in polynomial time, they find a 2-approximate feasible solution to WTAP that consists only of so-called up-links; a link \( \ell \) of a rooted tree is called an up-link if it connects a node and its ancestor. Such feasible solutions do not exist for 2NC-TAP. (To illustrate this point, consider the above example on \( K_4 \), and suppose that the root \( r \) of the claw is the non-leaf node; to ensure that \( K_4 - \{ r \} \) is connected, the solution has to pick two links that are not up-links.) Secondly, for any feasible solution \( F \) of WTAP, Cohen and Nutov show (via the so-called shadow-complete assumption) that there is an equivalent feasible solution \( F' \) such that the family of tree-paths \( \{ T(\ell) : \ell \in F' \} \) is pair-wise (edge) disjoint; that is, every edge of the tree \( T \) is contained in exactly one of the tree-paths \( T(\ell) \), \( \ell \in F' \). Clearly, this property does not apply to 2NC-TAP. (To illustrate this point, again consider the above example on \( K_4 \), and let \( r \) be the non-leaf node of the claw; to ensure that \( K_4 - \{ r \} \) is connected, any solution \( F \) has to pick at least two links, hence, one of the edges of the claw \( T \) is contained in two of the tree-paths \( T(\ell) \), \( \ell \in F \).)

Some of the high-level ideas behind our analysis of the greedy algorithm for 2NC-TAP are as follows. We map an instance of 2NC-TAP to an instance of SCP by mapping the relevant partitions
\( \mathcal{P} \) (such that our partition LP has a constraint for \( \mathcal{P} \)) to the points \( p_i \) of SCP, and mapping the links to the subsets \( S_i \) of SCP. If every link covers \( \leq k \) relevant partitions, then the approximation guarantee of \( H(k) \) would follow immediately (from the analysis of the greedy algorithm for SCP). But, a link \( \ell \) could be incident to many relevant partitions (since the variable \( x_{\ell} \) could occur in \( 2^{|\mathcal{P}|} \) partition constraints). Informally speaking, we bypass this difficulty as follows: we maintain a current partition \( \mathcal{P}_{u}^{i} \) for each iteration \( i \) and each non-leaf node \( u \) of \( T \), and we fix the “scaled” dual variable \( y_{\delta_{u}} \) of the partition \( \mathcal{P}_{u}^{i} \) to be the difference between the cost-coverage ratio of the link that covers \( \mathcal{P}_{u}^{i} \) (for the first time in the execution) and the cost-coverage ratio of the link that covers the “previous” partition \( \mathcal{P}_{u}^{(i-1)} \) (for the first time in the execution). To derive the approximation guarantee, we need to show that the dual solution is feasible, and it “recovers” the cost of the links picked by the greedy algorithm (up to a factor of \( H(k) \)). This follows because (1) the cost-coverage ratios of the links are non-decreasing over the execution, (2) for any “picked link” \( \ell \), and any non-leaf node \( u \) (of \( T \)) such that \( \ell \) covers the current partition \( \mathcal{P}_{u}^{i} \), the sum of the “scaled” dual variables of the sequence of partitions \( \mathcal{P}_{u}^{1}, \ldots, \mathcal{P}_{u}^{i} \) “telescopes” to the cost-coverage ratio of \( \ell \), and (3) the “scaled” dual objective value \( \sum_{P}(|P| - 1) y_{P} \) is equal to the sum of the costs of the links picked by the greedy algorithm.

For example, suppose that \( T \) is a star; thus, \( \lambda = \max\{|T(\ell)| : \ell \text{ is a link} \} = 2 \). Then, our greedy algorithm for 2NC-TAP is the same as Kruskal’s MST (minimum spanning tree) algorithm applied to the subgraph induced on the leaves of \( T \), and the dual solution found by our algorithm is the same as the dual solution found by the algorithms of \cite{2}, \cite[Sec. 2]{12}.

We mention that some of the results and constructions of this paper have appeared in preliminary form in the thesis of the first author, see \cite{11}.

2 Preliminaries

This section has definitions and preliminary results. Our notation and terms are consistent with \cite{1} or \cite{7}, and readers are referred to those texts for further information.

For a positive integer \( k \), we use \( [k] \) to denote the set \( \{1, \ldots, k\} \). We denote the \( k \)-th harmonic number by \( H(k) \).

Let \( G = (V,E) \) be a (loop-free, simple) graph with non-negative costs on the edges. We take \( G \) to be the input graph, and we use \( n \) to denote \( |V(G)| \). We denote the cost of an edge \( e \) of \( G \) by \( \text{cost}(e) \). For a set of edges \( F \subseteq E(G) \), \( \text{cost}(F) := \sum_{e \in F} \text{cost}(e) \), and for a subgraph \( G' \) of \( G \), \( \text{cost}(G') := \sum_{e \in E(G')} \text{cost}(e) \).

A multi-graph \( H \) is called \( k \)-edge connected if \( |V(H)| \geq 2 \) and for every \( F \subseteq E(H) \) of size \( < k \), \( H - F \) is connected. A multi-graph \( H \) is called \( k \)-node connected if \( |V(H)| > k \) and for every \( S \subseteq V(H) \) of size \( < k \), \( H - S \) is connected. We use the abbreviations \( 2EC \) for “2-edge connected,” and \( 2NC \) for “2-node connected.”

We use the standard notion of contraction of an edge, see \cite[p.25]{16}: Given a multi-graph \( H \) and an edge \( e = vw \), the contraction of \( e \) results in the multi-graph \( H/(vw) \) obtained from \( H \) by deleting \( e \) and its parallel copies and identifying the nodes \( v \) and \( w \). (Thus, every edge of \( H \) except for \( vw \) and its parallel copies is present in \( H/(vw) \); we disallow loops in \( H/(vw) \).)

For a graph \( H \) and a set of nodes \( S \subseteq V(H) \), \( \delta_{H}(S) \) denotes the set of edges that have one end node in \( S \) and one end node in \( V(H) - S \). (We omit subscripts such as \( H \), when there is no danger of ambiguity.) Moreover, \( H[S] \) denotes the subgraph of \( H \) induced by \( S \), and \( H - S \) denotes the subgraph of \( H \) induced by \( V(H) - S \). For a graph \( H \) and a set of edges \( F \subseteq E(H) \), \( H - F \)
denotes the graph \( (V(H), E(H) - F) \). We may use relaxed notation for singleton sets, e.g., we may use \( H - v \) instead of \( H - \{v\} \). We may not distinguish between a subgraph and its node set; for example, given a graph \( H \) and a set \( S \) of its nodes, we use \( E(S) \) to denote the edge set of the subgraph of \( H \) induced by \( S \).

For a spanning tree \( T \) and a link \( \ell \), we use \( T(\ell) \) to denote the path of \( T \) between the two end nodes of \( \ell \).

### 2.1 The min-cost 2NCSS problem

Given an undirected graph \( G \) and nonnegative edge costs \( c \in \mathbb{R}_+^E \), the algorithmic goal in the min-cost 2NCSS problem is to find a 2NC spanning subgraph of minimum cost. (For notational convenience, we may denote an instance by \( G \) instead of \((G, c)\).) This problem is NP-hard. We assume that the input graph \( G \) is 2NC. For any instance \( H \), we denote the minimum cost of a 2-NCSS of \( H \) by \( opt(H) \). When there is no danger of ambiguity, we use \( opt \) rather than \( opt(H) \).

### 2.2 Partitions

A partition \( P \) of a ground set \( W \) is a family of sets of \( W \) such that each element of \( W \) belongs to exactly one set of \( P \). The number of sets in \( P \) is denoted by \(|P|\).

A partition is called proper if it consists of non-empty sets. A partition is called trivial if it consists of a single set, namely, \( W \). A partition that consists of singleton sets is called a point partition of \( W \). For example, if \( W = \{4\} \), then \( P = \{\{1\}, \{2\}, \{3\}, \{4\}\} \) is a point partition of \( W \). Let \( H = (W, E) \) be a graph, and let \( P \) be a partition of \( W \). An edge \( e \) of \( H \) is said to cross \( P \) if the two end nodes of \( e \) are in different sets of \( P \). We use \( e_H(P) \) to denote the set of edges of \( H \) that cross \( P \). For example, if \( H = K_4 \) and \( P \) is the point partition of \( V(H) \), then \( e_H(P) = E(H) \); if \( H = K_6 \) and \( P \) is a partition of \( V(H) \) into two sets of size 3, then \( e_H(P) \) consists of 9 edges.

Let \( T \) be a tree, and let \( u \) be a non-leaf node of \( T \). Let \( \pi(\text{Comp}(T - u)) \) denote the partition of \( V(T) - u \) induced by the connected components of \( T - u \); thus, for each connected component \( C \) of \( T - u \), there is a set \( V(C) \) in \( \pi(\text{Comp}(T - u)) \). Let \( \text{Comp}(T - u) \) denote the set of partitions \( P \) of \( V(T) - u \) such that \( \pi(\text{Comp}(T - u)) \) is a refinement of \( P \); thus, any partition that can be obtained by “merging” some of the sets of \( \pi(\text{Comp}(T - u)) \) is an element of the set \( \text{Comp}(T - u) \). For example, suppose that \( T \) is a tree with three leaves \( v_1, v_2, v_3 \) and one non-leaf node \( u \) (of degree three). Then, \( \pi(\text{Comp}(T - u)) = \{\{v_1\}, \{v_2\}, \{v_3\}\}, \{\{v_1, v_2, v_3\}\} \), and the set \( \text{Comp}(T - u) \) consists of the five partitions \( \pi(\text{Comp}(T - u)) \), \{\{v_1\}, \{v_2, v_3\}\}, \{\{v_2\}, \{v_1, v_3\}\}, \{\{v_3\}, \{v_1, v_2\}\}, \{\{v_1, v_2, v_3\}\} \).

### 2.3 A partition LP relaxation for the min-cost 2-NCSS problem

The partition LP relaxation \((P)\) of the min-cost 2NCSS problem has been presented in Section [I] and we recall it here for convenience. \((P)\) is obtained from the cut LP relaxation of the min-cost 2ECSS problem by adding the family of constraints

\[
\sum_{e \in e_{G^0 - w}(P)} x_e \geq |P| - 1, \forall P \in \text{Comp}(G^0 - w)
\]

for each node \( w \in V \), where \( G^0 \) denotes \( (V, \{e \in E : cost(e) = 0\}) \), and \( P \) denotes a partition of \( V - w \) such that (the node-set of) each connected component of \( G^0 - w \) is contained in one of the sets of \( P \).
2.4 Polynomial-time computations

There are well-known polynomial time algorithms for implementing all of the basic computations in this paper, see [16]. We state this explicitly in all relevant results, but we do not elaborate on this elsewhere.

3 A greedy algorithm for min-cost 2NC-TAP

We present a greedy algorithm for 2NC-TAP that achieves an approximation guarantee of \( H(\lambda - 1) \), where \( \lambda \) denotes the maximum length over all the tree-paths \( T(\ell) \) of the links \( \ell \) of the instance.

3.1 A primal and dual LP relaxation for 2NC-TAP

We start by presenting the partition LP relaxation for 2NC-TAP. This LP has a non-negative variable \( x_\ell \) for each link \( \ell \) of the instance \( G \). We denote the set of links of \( G \) by \( L(G) \). For each non-leaf node \( u \) of the given spanning tree \( T \), we have a family of partition constraints for the graph \( G \). We denote the set of non-leaf nodes of \( T \) by \( \Psi(T) \). The family of partition constraints for \( u \) is similar to the family of partition constraints for the partition LP for MST, and is as follows:

\[
\text{for each partition } \mathcal{P} \in \tilde{\Pi}(\text{Comp}(T - u)), \text{ there is a constraint } x(e_{G - u}(\mathcal{P})) \geq |\mathcal{P}| - 1 \text{ (i.e., the sum of the } x\text{-values of the links crossing } \mathcal{P} \text{ is required to be at least } |\mathcal{P}| - 1 \).
\]

The partition LP for 2NC-TAP, \((P)\), and the dual of this LP, \((D)\), are stated below.

\[
(P) \begin{align*}
\min \quad & \sum_{\ell \in L(G)} \text{cost}(\ell) x_\ell \\
\text{s.t.} \quad & \sum_{\ell \in L(G) \cap e_{G - u}(\mathcal{P})} x_\ell \geq |\mathcal{P}| - 1 \quad \forall u \in \Psi(T), \\
& x_\ell \geq 0 \quad \forall \ell \in L(G).
\end{align*}
\]

\[
(D) \begin{align*}
\max \quad & \sum_{u \in \Psi(T)} \sum_{\mathcal{P} \in \tilde{\Pi}(\text{Comp}(T - u))} y_{\mathcal{P}} \\
\text{s.t.} \quad & \sum_{u \in \Psi(T)} \sum_{\mathcal{P} \in \tilde{\Pi}(\text{Comp}(T - u))} y_{\mathcal{P}} \leq \text{cost}(\ell) \quad \forall \ell \in L(G) \\
& y \geq 0.
\end{align*}
\]

Remark: Let \( x \in \mathbb{R}^{L(G)}_{+} \) be a feasible solution of \((P)\). Let \( \tilde{x} \in \mathbb{R}^{E(G)}_{+} \) be the vector such that \( \tilde{x}_e = x_\ell \) for each link \( \ell \in L(G) \), and \( \tilde{x}_e = 1 \) for each edge \( e \in T \). Then, \( \tilde{x} \) satisfies the cut constraints for 2-edge connectivity. To see this, consider any nonempty, proper set of nodes \( S \subseteq V \). Clearly, \(|T \cap \delta(S)| \geq 1\), since \( T \) is a spanning tree. If \(|T \cap \delta(S)| \geq 2\), then \( \tilde{x}(\delta(S)) \geq |T \cap \delta(S)| \geq 2 \). Now, suppose that \(|T \cap \delta(S)| = 1\). Let \( vu \) be the unique edge in \( \delta_T(S) \). At least one of \( v \) or \( u \) must be a non-leaf node. We may assume that \( u \) is a non-leaf node and \( u \notin S \). Observe that \( S \) is (the node-set of) a connected component of \( T - vu \), hence, \( S \) is (the node-set of) a connected component of \( T - u \). Thus, the partition \( \{S, (V - S) - \{u\}\} \) is in \( \tilde{\Pi}(\text{Comp}(T - u)) \), and, moreover, \( x \) satisfies the constraint \( \sum_{\ell \in L(G) \cap e_{G - u}(\{S, (V - S) - \{u\}\})} x_\ell \geq 1 \). Hence, we have

\[
\tilde{x}(\delta(S)) \geq \tilde{x}_{uv} + x(e_{G - u}(\{S, (V - S) - \{u\}\})) \geq 2.
\]

The following result shows that the constraints \( x \leq 1 \) are redundant, whenever \((P)\) has an optimal solution.
Proposition 3.1. The extreme points of \((P)\) are contained in \([0,1]^E\).

Proof. Suppose there exists an extreme point \(x\) such that for some \(\hat{\ell} \in \mathcal{L}(G)\), \(x_{\hat{\ell}} = 1 + \epsilon\) for some \(\epsilon > 0\). Let \(\chi_{\hat{\ell}}\) be the standard basis vector corresponding to \(\hat{\ell}\), let \(x' = x - \epsilon \chi_{\hat{\ell}}\), and let \(x'' = x + \epsilon \chi_{\hat{\ell}}\). Clearly, \(x''\) is feasible for \((P)\). But \(x'\) is not feasible for \((P)\) (otherwise, \(x\) would not be an extreme point). Thus, there exists \(u \in V\) and \(P \in \Pi(C_{\text{Comp}}(T - u))\) such that \(\hat{\ell} \in e_{G - u}(P)\) and

\[
\sum_{\ell \in \mathcal{L}(G) \cap e_G(P)} x'\ell < |P| - 1 \leq \sum_{\ell \in \mathcal{L}(G) \cap e_G(P)} x_\ell.
\]

Note that \(|P| \geq 3\). (Otherwise, if \(|P| = 2\), then \(\sum_{\ell \in \mathcal{L}(G) \cap e_G(P)} x'\ell \geq x'_\ell \geq 1 = |P| - 1\).) Let \(v\) and \(w\) be the end nodes of \(\hat{\ell}\), let \(S_v\) and \(S_w\) be the sets of \(P\) that contain \(v\) and \(w\), respectively, and let \(P_{(vw)}\) be obtained from \(P\) by replacing \(S_v\) and \(S_w\) by the union \(S_v \cup S_w\). Clearly, \(|P_{(vw)}| = |P| - 1\).

Finally, note that

\[
\sum_{\ell \in \mathcal{L}(G) \cap e_G(P_{(vw)})} x_\ell \leq \left( \sum_{\ell \in \mathcal{L}(G) \cap e_G(P)} x_\ell \right) - x_{\hat{\ell}} = \left( \sum_{\ell \in \mathcal{L}(G) \cap e_G(P)} x'_\ell \right) + \epsilon - x_{\hat{\ell}} < (|P| - 1) - (x_{\hat{\ell}} - \epsilon) = (|P| - 1) - 1 = |P_{(vw)}| - 1.
\]

Thus, \(x\) violates the constraint of \(P_{(vw)}\), and this contradicts the assumption that \(x\) is feasible for \((P)\). \qed

### 3.2 A greedy algorithm for 2NC-TAP

The algorithm applies a number of iterations, and constructs a set \(F\) of chosen links; initially, \(F\) is the empty set. Each iteration picks one link according to a greedy rule and adds it to \(F\). The algorithm stops when \(T \cup F\) induces a 2-NCSS of \(G\). Moreover, the algorithm assigns a non-negative number, denoted \(\text{wgt}\), to each partition in \(\bigcup\{\Pi(C_{\text{Comp}}(T - u)) : u \in \Psi(T)\}\); initially, \(\text{wgt}(P) = 0\) for each of these partitions \(P\).

For each iteration \(i = 1, 2, \ldots\), let \(F^i\) denote the set of links picked by the previous iterations \(1, 2, \ldots, i - 1\); thus, \(|F^i| = i - 1\). At (the start of) each iteration \(i = 1, 2, \ldots\), for each non-leaf node \(u\) of the given spanning tree \(T\), the algorithm maintains the so-called current partition \(P^i_u \in \Pi(C_{\text{Comp}}(T - u))\); this partition corresponds to the connected components of \((T \cup F^i) - u\) (i.e., the sets of \(P^i_u\) correspond to the node-sets of the connected components of \((T \cup F^i) - u\).

Informally speaking, the working of the first iteration is the same as the first iteration of the greedy algorithm for the following SCP instance: there are \(|\Psi(T)|\) points \(p_1, p_2, \ldots, p_j, \ldots\) corresponding to the partitions \(P^i_u, u \in \Psi(T)\), and there are \(|\mathcal{L}(G)|\) sets \(S_1, S_2, \ldots, S_k, \ldots\) corresponding to the links \(\ell \in \mathcal{L}(G)\); moreover, the point \(p_j\) is in set \(S_k\) iff \(\ell_k \in e_G(P^i_u)\) where \(P^i_u\) denotes the partition corresponding to \(p_j\) and \(\ell_k\) denotes the link corresponding to \(S_k\).

Formally speaking, for each link \(\ell \in \mathcal{L}(G)\), let \(\text{inc}^i(\ell)\) denote the set of partitions \(P^i_u\) crossed by \(\ell\), that is, \(\text{inc}^i(\ell) = \{P^i_u : u \in \Psi(T), \ \ell \in e_G(P^i_u)\}\). The iteration picks a link \(\ell^*\) among the links \(\ell\) with \(\text{inc}^i(\ell) \neq \emptyset\) such that \(\frac{\text{cost}(\ell^*)}{|\text{inc}^i(\ell^*)|}\) is minimum. Moreover, the iteration assigns the weight \(\frac{\text{cost}(\ell^*)}{|\text{inc}^i(\ell^*)|}\)
to each of the partitions in \( \text{inc}^i(\ell) \); thus, \( \text{wgt}(P_u^i) = \frac{\text{cost}(\ell^*)}{|\text{inc}^i(\ell^*)|}, \forall u \in \Psi(T) : \ell^* \in e_G(P_u^i) \). Also, the iteration applies the required updates, namely, \( F^{i+1} := F^i \cup \{ \ell^* \} \), and for each node \( u \in \Psi(T) \), \( P_u^{i+1} \) is obtained from \( P_u^i \) by merging the two sets of \( P_u^i \) that each contain an end node of \( \ell^* \).

### 3.3 Analysis of the greedy algorithm for 2NC-TAP

Consider an arbitrary node \( u \in \Psi(T) \). Let \( \nu(u) \) denote the number of connected components of \( T - u \); clearly, \( \nu(u) = |\pi(\text{Comp}(T - u))| \), where \( \pi(\text{Comp}(T - u)) \) denotes the partition of \( V(T) - u \) induced by the connected components of \( T - u \). Observe that \( |P_u^i| = \nu(u) \) (since \( P_u^i = \pi(\text{Comp}(T - u)) \)), and after the \( i \)-th iteration of the greedy algorithm, either \( |P_u^{i+1}| = |P_u^i| \) or \( |P_u^{i+1}| = |P_u^i| - 1 \); moreover, if iteration \( i \) is the last iteration (that picks a link), then \( |P_u^{i+1}| = 1 \). Let \( P_u^{(1)}, P_u^{(2)}, \ldots, P_u^{(\nu(u)-1)} \) denote the sequence of partitions of \( \text{Comp}(T - u) \) that are assigned a positive weight during the running of the greedy algorithm, ordered according to the sequence in which the weights are assigned by the algorithm; thus, \( P_u^{(1)} \) is the first partition of \( \text{Comp}(T - u) \) (in the running of the greedy algorithm) that is crossed by the link picked in an iteration, \( P_u^{(2)} \) is the second partition of \( \text{Comp}(T - u) \) (in the running of the greedy algorithm) that is crossed by the link picked in an iteration, etc.

The dual solution (of the LP) corresponding to the run of the greedy algorithm is defined as follows. For each node \( u \in \Psi(T) \),

\[
\begin{align*}
y(P_u^{(1)}) &= \text{wgt}(P_u^{(1)}) \\
y(P_u^{(j)}) &= \text{wgt}(P_u^{(j)}) - \text{wgt}(P_u^{(j-1)}), \quad (j \in \{2, 3, \ldots, \nu(u) - 1\}) \\
y(P) &= 0 \quad \text{for all other partitions } P \in \text{Comp}(T - u) \end{align*}
\]

**Lemma 3.2.** For each node \( u \in \Psi(T) \) and each partition \( P_u \in \text{Comp}(T - u) \), we have \( y_{P_u} \geq 0 \).

**Proof.** Essentially, this follows from two facts: (1) suppose that at (the start of) the \( i \)-th iteration, the current partition \( P_u^i \) is crossed by a link \( \ell \); then \( \ell \) crosses \( P_u^h \) for all \( h < i \) (that is, if \( \ell \) is a “candidate link” w.r.t. the current partition of \( u \) in iteration \( i \), then in all previous iterations \( h = 1, \ldots, i - 1 \), \( \ell \) is a “candidate link” w.r.t. the partition \( P_u^h \) of that iteration); (2) the ratios \( \frac{\text{cost}(\ell^*)}{|\text{inc}^i(\ell^*)|} \) cannot decrease during the running of the greedy algorithm (that is, the ratio for an iteration is \( \geq \) the ratio for any previous iteration).

In more detail, for any \( j \in \{2, 3, \ldots, \nu(u) - 1\} \), we claim that \( \text{wgt}(P_u^{(j)}) \geq \text{wgt}(P_u^{(j-1)}) \). This can be seen as follows. Suppose that the greedy algorithm assigned the weight of the partition \( P_u^{(j-1)} \) in the \( i_{j-1} \)-th iteration, thus, \( P_u^{(j-1)} = P_u^{(j-1)} \); moreover, let \( \ell_{j-1} \) denote the link picked by that iteration. Similarly, suppose that the greedy algorithm assigned the weight of the partition \( P_u^{(j)} \) in the \( i_j \)-th iteration, and let \( \ell_{j} \) denote the link picked by that iteration.

Then \( \ell_{j} \in e_G(P_u^{(j-1)}) \); moreover, for each node \( w \in \Psi(T) \) such that \( P_u^{(j)} \in \text{inc}^{(j)}(\ell_{j}) \) denote that \( \ell_{j} \in e_G(P_u^{(j-1)}) \) (that is, if \( \ell_{j} \) crosses the partition \( P_u^{(j)} \) of a non-leaf node \( w \), then \( \ell_{j} \) crosses the partition \( P_u^{(j-1)} \)). Hence, the ratio for the link \( \ell_{j} \) in the \( i_{j-1} \)-th iteration, \( \frac{\text{cost}(\ell_{j})}{|\text{inc}^{(j-1)}(\ell_{j})|} \), is \( \leq \) the ratio for the link \( \ell_{j} \) in the \( i_{j} \)-th iteration. Since the greedy algorithm picked the link \( \ell_{j-1} \) (rather than \( \ell_{j} \)) in the \( i_{j-1} \)-th iteration, we have \( \frac{\text{cost}(\ell_{j})}{|\text{inc}^{(j-1)}(\ell_{j})|} \leq \frac{\text{cost}(\ell_{j})}{|\text{inc}^{(j-1)}(\ell_{j})|} \). Hence, the ratio for the \( i_{j-1} \)-th iteration is \( \leq \) the ratio for the \( i_{j} \)-th iteration, and hence, \( \text{wgt}(P_u^{(j)}) \geq \text{wgt}(P_u^{(j-1)}) \). \( \square \)
Lemma 3.3. \( \frac{1}{\mu(\lambda-1)} \) is a feasible solution to the dual LP (D).

Proof. Consider an arbitrary link \( \ell \in \mathcal{L}(G) \). Recall that \( T(\ell) \) denotes the path of \( T \) between the two end nodes of \( \ell \), and let \( Q \) denote the set of internal nodes of \( T(\ell) \). Note that this implies \(|Q| \leq \lambda \). We claim that

\[
\sum_{u \in \Psi(T)} \sum_{\{P \in \hat{T}( \text{Comp}(T-u)) : \ell \in \mathcal{E}(P) \}} y_P \leq H(|Q|) \text{cost}(\ell).
\]

First, consider any node \( u \in \Psi(T) - Q \); thus, \( u \) is not incident to \( T(\ell) \). For any partition \( P \in \hat{T}(\text{Comp}(T-u)) \), note that \( \ell \) does not cross \( P \), hence, \( \sum_{\{P \in \hat{T}(\text{Comp}(T-u)) : \ell \in \mathcal{E}(P) \}} y_P = 0 \).

Now, consider any node \( u \in Q \), and consider the partitions of \( \hat{T}(\text{Comp}(T-u)) \) that have positive weights, namely, \( P_u^{(1)}, P_u^{(2)}, \ldots, P_u^{(\nu(u)-1)} \). Observe that if \( \ell \) crosses \( P_u^{(j)} \), then \( \ell \) also crosses each of the partitions \( P_u^{(1)}, \ldots, P_u^{(j-1)} \). Let \( \eta_u \) denote the highest index \( j \) such that \( \ell \) crosses \( P_u^{(j)} \).

We have

\[
\sum_{\{P \in \hat{T}(\text{Comp}(T-u)) : \ell \in \mathcal{E}(P) \}} y_P = \sum_{j=1}^{\eta_u} y_{P_u^{(j)}} = \text{wgt}(P_u^{(\eta_u)}).
\]

Let \( u_1, u_2, \ldots, u_{|Q|} \) be an ordering of the nodes in \( Q \) according to the reverse of the order in which the greedy algorithm assigns weights to the partitions \( \{P_u^{(\eta_u)} : u \in Q\} \); that is, \( P_u^{(\eta_u_1)} \) is the last of these partitions to be assigned a weight, \( P_u^{(\eta_u_2)} \) is the second last of these partitions to be assigned a weight, etc. We have \( \text{wgt}(P_u^{(\eta_u_j)}) \leq \text{cost}(\ell)/j \), for each \( j = 1, \ldots, |Q| \), because at the iteration when the greedy algorithms assigns the weight of \( P_u^{(\eta_u_j)} \), the partitions \( P_u^{(\eta_u_1)}, \ldots, P_u^{(\eta_u_{j-1})}, P_u^{(\eta_u_j)} \) are crossed by \( \ell \), hence the weight assigned in that iteration cannot exceed \( \text{cost}(\ell)/j \). Hence, \( \sum_{u \in Q} \text{wgt}(P_u^{(\eta_u)}) \leq (1 + \frac{1}{2} + \cdots + \frac{1}{|Q|}) \text{cost}(\ell) \leq H(|Q|) \text{cost}(\ell) \). Therefore,

\[
\sum_{u \in \Psi(T)} \sum_{\{P \in \hat{T}(\text{Comp}(T-u)) : \ell \in \mathcal{E}(P) \}} y_P = \sum_{u \in \Psi(T)} \sum_{\{P \in \hat{T}(\text{Comp}(T-u)) : \ell \in \mathcal{E}(P) \}} \text{wgt}(P_u^{(\eta_u)}) \leq H(|Q|) \text{cost}(\ell).
\]

\[\square\]

Theorem 3.4. The cost of the set of links \( \hat{F} \) returned by the greedy algorithm, \( \text{cost}(\hat{F}) \), is \( \leq H(\lambda - 1) \text{opt}(P) \), where \( \text{opt}(P) \) denotes the optimal value of the LP (P).

Proof. The description of the greedy algorithm and the definition of the weights of the partitions imply that for each iteration \( i \) and the link \( \ell \) picked in that iteration,

\[
\text{cost}(\ell) = \sum\{\text{wgt}(P_u^i) : u \text{ is an internal node of } T(\ell) \text{ and } P_u^i \in \text{inc}(\ell)\};
\]

Furthermore, if \( \text{wgt}(P_u^i) > 0 \) then \( P_u^{i+1} \neq P_u^i \) because, in the \( i \)-th iteration, the end nodes of \( \ell \) are in different sets of \( P_u^i \), whereas, in the \( (i + 1) \)-th iteration, the end nodes of \( \ell \) are in the same set of \( P_u^{i+1} \). Hence, we have \( \text{cost}(\hat{F}) = \sum_{i=1}^{\hat{F}} \sum_{u \in \Psi(T)} \text{wgt}(P_u^i) \).
By the previous lemma, \( \frac{1}{\Pi(\lambda-1)} y \) is a feasible solution of the dual LP \( (D) \), hence, the objective value of this feasible solution is \( \leq \text{opt}(P) \). We rewrite this objective value:

\[
\frac{1}{\Pi(\lambda-1)} \sum_{u \in \Psi(T)} \sum_{P \in \Pi(\text{Comp}(T-u))} (|P| - 1) y_P
= \frac{1}{\Pi(\lambda-1)} \sum_{u \in \Psi(T)} \left( \sum_{j=1}^{\nu(u)-1} \text{wgt}(P_u^{(j)}) \right)
= \frac{1}{\Pi(\lambda-1)} \sum_{u \in \Psi(T)} \sum_{i=1}^{|F|} \text{wgt}(P_u^i)
= \frac{1}{\Pi(\lambda-1)} \text{cost}(\hat{F}).
\]

To derive the first two equations, consider any non-leaf node \( u \), and note that

\[
\sum_{P \in \Pi(\text{Comp}(T-u))} (|P| - 1) y_P = \sum_{j=1}^{\nu(u)-1} (\nu(u) - j) y_{P_u^{(j)}}
= \sum_{j=1}^{\nu(u)-1} (\nu(u) - j) \text{wgt}(P_u^{(j)})
- \sum_{j=1}^{\nu(u)-1} (\nu(u) - j - 1) \text{wgt}(P_u^{(j)})
= \sum_{j=1}^{\nu(u)-1} \text{wgt}(P_u^{(j)})
= \sum_{i=1}^{|F|} \text{wgt}(P_u^i).
\]

Therefore, \( \text{cost}(\hat{F}) \leq H(\lambda - 1) \text{opt}(P) \).

\[\square\]

### 3.4 A tight example for the greedy algorithm for 2NC-TAP

The example of Figure 1 shows that our analysis of the greedy algorithm (in Theorem 3.4) is tight when \( \lambda = 4 \). This can be generalized to any positive integer \( \lambda \geq 2 \) as follows. The problem instance has \( T \) being a path with vertex set \( [\lambda + 1] \) and edge set \( \{\{k, k + 1\} : k \in [\lambda]\} \). For \( k \in [\lambda - 1] \) let \( \ell_k = \{k, k + 2\} \) and \( \ell = \{1, \lambda + 1\} \). The link set is \( \{\ell_k : k \in [\lambda - 1]\} \cup \{\ell\} \). Finally, let the cost of the links be given by \( \text{cost}(\ell_k) = \frac{1}{k} \) for \( k \in [\lambda - 1] \) and \( \text{cost}(\ell) = 1 + \epsilon \). For each non-leaf node \( u \), note that \( T - u \) has two connected components; hence, the LP has a unique constraint of the form \( \sum_{\ell \in \mathcal{E}(G) \cap \Psi(\mathcal{P}_u)} x_{\ell} \geq |\mathcal{P}_u| - 1 \), where \( \mathcal{P}_u \) is a partition of \( V - u \) with \( |\mathcal{P}_u| = 2 \). For each \( k \in [\lambda - 1] \), note that \( \ell_k \) crosses \( \mathcal{P}_{k+1} \). Moreover, the link \( \ell \) crosses each of these \( \lambda - 1 \) partitions. At the start of the \( i \)-th iteration, the ratio \( \frac{\text{cost}(\ell)}{\text{inc}(\ell)} = \frac{1+\epsilon}{\lambda - 1 - (i-1)} \). However, even after picking the first \( i - 1 \) links, there is still a link of cost \( \frac{1}{\lambda - 1 - (i-1)} < \frac{1}{\lambda - 1 - (i-1)} \), namely, \( \ell_{\lambda - 1 - (i-1)} \), so the greedy algorithm will pick that link. Thus, the greedy algorithm finds a solution of cost

\[
\sum_{i=1}^{\lambda - 1} \frac{1}{\lambda - 1 - (i-1)} = \sum_{i=1}^{\lambda - 1} \frac{1}{i} = H(\lambda - 1).
\]

Observe that an optimal solution has cost \( 1 + \epsilon \) and consists of the link \( \ell \).

Using links of cost 0, one can easily string together multiple copies of this example to obtain a graph of arbitrary diameter, as shown in Figure 2. In particular, for \( \lambda \geq 3 \), if we have \( k \) copies of the above example, and the \( i \)-th copy has vertex set \( v_1^{(i)}, \ldots, v_{\lambda+1}^{(i)} \), then adding tree edges \( v_1^{(i)} v_{\lambda+1}^{(i+1)} \) and links \( v_2^{(i)} v_2^{(i+1)} \) of cost 0, for \( i \in [k-1] \), results in an instance that has diameter \( \geq k + 1 \); note that \( \lambda \) is still the maximum of the lengths of the tree paths \( T(\ell) \) defined by the links \( \ell \).

### 4 The integrality ratio of the partition LP relaxation of 2NCSS

In this section, we focus on the integrality ratio of the partition LP relaxation of 2NCSS. We show that the integrality ratio is \( \leq 2 \); this holds because the well-know set-pairs LP for 2NCSS has
Figure 1: An instance of 2NC-TAP such that the greedy algorithm returns a solution of cost $\frac{11}{6}$ times the optimal cost. Edges indicated by solid lines have cost 0 and edges indicated by dashed lines are labelled with their costs.

The integrality ratio $\approx 2$, and the set-pairs LP is a relaxation of the partition LP. Next, we show (via a simple construction) that the integrality ratio of the partition LP relaxation of 2NCSS is $\geq$ the integrality ratio of the well-known cut LP relaxation of 2ECSS. The latter LP is known to have integrality ratio $\geq \frac{3}{2}$ [1] (in fact, the ratio $\frac{3}{2}$ is achieved on a family of instances of TAP, the tree augmentation problem).

The instance of unweighted 2NC-TAP in Figure 3 shows that the partition LP for 2NC-TAP has integrality ratio $\geq \frac{4}{3}$; an optimal solution of the instance has cost 4, whereas the partition LP has a (fractional) solution of cost 3. This example has $\lambda = 4$. Theorem 3.4 gives an upper-bound of $H(\lambda - 1) = H(3) = \frac{11}{6}$ on the integrality ratio of any instance of 2NC-TAP with $\lambda = 4$. Possibly, the analysis of Theorem 3.4 could be improved for some special cases; it is not clear whether an approximation ratio of $\frac{4}{3}$ can be proved for instances of unweighted 2NC-TAP with $\lambda = 4$, see [5]. (Duh and Fürer [5] presented a $\frac{4}{3}$-approximation algorithm for unweighted 3-SCP via semi-local optimization; 3-SCP is the special case of the Set Covering Problem where $|S_j| \leq 3$ for each of the sets $S_j$ of the instance.)

**Proposition 4.1.** The set-pairs LP relaxation for the min-cost 2NCSS problem has integrality ratio $\approx 2$.

**Proof.** The upper-bound of 2 on the integrality ratio (for the set-pairs LP) follows from the analysis of the 2-approximation guarantee for the min-cost 2NCSS problem relative to the set-pairs LP by Fleischer et al., see [6, Theorems 3.13, 3.14]. (In fact, Fleischer et al. prove the 2-approximation guarantee for a more general problem, namely, VC-SNDP with requirements of $\{0, 1, 2\}$ openly-disjoint paths between pairs of nodes; the min-cost 2NCSS problem is a special case of VC-SNDP.)

A lower-bound of $2 - \frac{\Theta(1)}{n}$ is implied by the following well-known example: Consider an instance of unweighted 2NC-TAP that consists of the spanning tree $T = K_{1,n-1}$ (thus, $T$ is a star), and $n-1$ (unit-cost) links that form a cycle on the leaves of $T$. Any integer solution picks $n-2$ links, and has cost $n-2$. There is a (fractional) solution $\hat{x}$ to the set-pairs LP of cost $(n-1)/2$ that fixes $\hat{x}_\ell = \frac{1}{2}$ for each link $\ell$. 

### 4.1 A transformation from 2ECSS to 2NCSS

In this subsection, we show that the integrality ratio of our partition LP relaxation is $\geq 1.5$ by giving a transformation from TAP (the Tree Augmentation Problem for 2-edge connectivity) to the
Figure 2: An instance of 2NC-TAP with diameter \( \geq k + 1 \) (shown with \( \lambda = 4 \) and \( k = 3 \)). Edges indicated by solid lines have cost 0 and edges indicated by dashed lines are labelled with their costs. An optimal solution uses the links of cost 0 and the links of cost \( 6 + \epsilon \). The greedy algorithm returns a solution that uses all of the links except those of cost \( 6 + \epsilon \).

min-cost 2NCSS problem that preserves the integrality ratio. There is a well-known construction for TAP that has integrality ratio 1.5, see [1]. In this subsection, we denote the cost of an edge \( e \) by \( c_e \) or \( c'_e \).

Let \( G = (V,E) \) be a graph, and let each edge \( e \) have a cost \( c_e \in \mathbb{R} \). Let \( P_{EC}(G) \) denote the feasible region of the cut LP relaxation of the min-cost 2ECS problem:

\[
\min \left\{ \sum_{e \in E} c_e x_e : x(\delta(S)) \geq 2, \forall \emptyset \subsetneq S \subsetneq V; \ 0 \leq x \leq 1 \right\}.
\]

Let \( P_{NC}(G) \) denote the feasible region of the partition LP relaxation (\( P \)) of the min-cost 2NCSS problem, see Section 2.3.

The following well-known construction (inflation) maps an instance \((G, c)\) of the min-cost 2ECS problem to an instance \((G', c')\) of the min-cost 2NCSS problem. Each node \( u \) of \( G \) maps to a distinct clique \( C'_u \) on \( \deg_G(u) \) nodes of \( G' \) (that is, \( C'_u \) is a complete graph on \( \deg_G(u) \) nodes and \( C'_u, C'_w \) are node-disjoint for any two nodes \( u, w \in V(G), u \neq w \)), and each edge \( vw \) of \( G \) maps to an edge \( v'w' \) of \( G' \) that has one end node \( v' \) in \( C'_u \) and has the other end node \( w' \) in \( C'_w \) such that each node of a clique \( C'_u \) of \( G' \) is incident to exactly one inter-clique edge; moreover, \( c'_{v'w'} = c_{vw}, \forall vw \in E \), and for each edge \( e' \) of a clique \( C'_u \) of \( G' \), the cost \( c'_e \) is zero. Let \( F' = \bigcup_{u \in V(G)} E(C'_u) \); thus, \( F' \) consists of the edges of \( G' \) that have both end nodes in the same clique \( C'_u \) of \( G' \), \( u \in V(G) \). Figure 4 illustrates this construction on an instance of TAP (note that the Tree Augmentation Problem is a special case of the min-cost 2ECS problem).
**Proposition 4.2.** Let \((G = (V, E), c \in \mathbb{R}^E)\) be an instance of the min-cost 2ECSS problem, and let \((G' = (V', E'), c' \in \mathbb{R}^{E'})\) denote the instance of the min-cost 2NCSS problem that is obtained from \((G, c)\) by the above construction. The integrality ratio of the cut LP for \((G, c)\) is the same as the integrality ratio of the partition LP for \((G', c')\).

**Proof.** Our proof is based on two claims.

**Claim 4.3.** For \(x \in P_{EC}(G)\), define \(x' \in \mathbb{R}^{E'}\) as follows:

\[
x'_{vw} = \begin{cases} x_{vw} & \text{if } e' \in E' - F' \text{ and } e' = v'w' \\ 1 & \text{if } e' \in F' \end{cases}
\]

Then \(x' \in P_{NC}(G')\) and \(c^\top x' = c^\top x\).

**Claim 4.4.** Let \(x' \in P_{NC}(G')\) and define \(x \in \mathbb{R}^E\) as \(x_{vw} = x'_{v'w'}\) \(\forall vw \in E\). Then \(x \in P_{EC}(G)\) and \(c^\top x = c^\top x'\).

Let \(\hat{P}_{NC}(G') = \{x \in P_{NC}(G'): x_e = 1, \forall e \in F'\}\). Note that, if the partition LP for \(G'\) has an optimal solution, then there exists an optimal solution in \(\hat{P}_{NC}(G')\); this holds because \(c'_e = 0, \forall e \in F'\). Claims 4.3 and 4.4 give us a bijection \(\varphi: P_{EC}(G) \rightarrow \hat{P}_{NC}(G')\) such that \(c^\top x = c^\top \varphi(x)\) for all \(x \in P_{EC}(G)\). Furthermore, \(\varphi\) maps integral vectors to integral vectors.

Let \(x_*\) be an optimal (fractional) solution of the cut LP relaxation of the min-cost 2ECSS instance \((G, c)\), and let \(z_*\) be an optimal integral solution of the same LP (thus, \(z_*\) is a min-cost 2ECSS of \((G, c)\)). Similarly, let \(x'_*\) be an optimal (fractional) solution of the partition LP relaxation of the min-cost 2NCSS instance \((G', c')\), and let \(z'_*\) be an optimal integral solution of the same LP (thus, \(z'_*\) is a min-cost 2NCSS of \((G', c')\)). Thus, we have \(c^\top x_* = c^\top x'_*\), because \((c^\top x_* = c^\top \varphi(x_*) \geq c^\top x'_*)\) and \((c^\top x_* \leq c^\top \varphi^{-1}(x'_*) = c^\top x'_*)\). Similarly, we have \(c^\top z_* = c^\top z'_*\).

Therefore, \(c^\top x_* = c^\top z_* = c^\top x'_* = c^\top z'_*\). Hence, the two instances \((G, c)\) and \((G', c')\) have the same integrality ratios with respect to their LP relaxations (namely, the cut LP and the partition LP).

Figure 4 illustrates Proposition 4.2 and our construction. Figure 4 (a) shows a TAP instance from the family of TAP instances with integrality ratios converging to \(\frac{3}{2}\), see \(\S\). The application of our construction to this TAP instance results in the instance of the min-cost 2NCSS problem in Figure 4 (b). Moreover, the integrality ratio of this particular TAP instance for the cut LP relaxation is the same as the integrality ratio of the instance of the min-cost 2NCSS problem for the partition LP relaxation.
Figure 3: An instance of 2NC-TAP such that the integrality ratio of the partition LP is \( \frac{4}{3} \). Edges indicated by solid lines have cost 0 and edges indicated by dashed lines have cost 1. An optimal integer solution picks two of the three unit-cost links from each of the cycles \( p_1, p_2, p_3, p_1 \) and \( q_1, q_2, q_3, q_1 \). An LP solution \( \hat{x} \) of cost 3 has \( \hat{x}_\ell = \frac{1}{2} \) for each of the six unit-cost links \( \ell \).

Figure 4: (a) An instance of TAP with integrality ratio \( \frac{3k+3}{2k+3} \) \((k = 3)\) for the cut LP relaxation. Edges indicated by solid lines have cost 0 and x-value 1. Edges indicated by dashed lines have cost 1 and are labelled with their x-values.

(b) An instance of min-cost 2NCSS with integrality ratio \( \frac{3k+3}{2k+3} \) \((k = 3)\) for the partition LP relaxation. Edges indicated by solid lines or dotted lines have cost 0 and x-value 1. Edges indicated by dashed lines have cost 1 and are labelled with their x-values.
