See Morris and Weil (doi:10.1093/brain/awz014) for a scientific commentary on this article.

Idiopathic REM sleep behaviour disorder (iRBD) is a powerful early sign of Parkinson’s disease, dementia with Lewy bodies, and multiple system atrophy. This provides an unprecedented opportunity to directly observe prodromal neurodegenerative states, and potentially intervene with neuroprotective therapy. For future neuroprotective trials, it is essential to accurately estimate phenocconversion rate and identify potential predictors of phenocversion. This study assessed the neurodegenerative disease risk and predictors of neurodegeneration in a large multicentre cohort of iRBD. We combined prospective follow-up data from 24 centres of the International RBD Study Group. At baseline, patients with polysomnographically-confirmed iRBD without parkinsonism or dementia underwent sleep, motor, cognitive, autonomic and special sensory testing. Patients were then prospectively followed, during which risk of dementia and parkinsonism were assessed. The risk of dementia and parkinsonism was estimated with Kaplan-Meier analysis. Predictors of phenocconversion were assessed with Cox proportional hazards analysis, adjusting for age, sex, and centre. Sample size estimates for disease-modifying trials were calculated using a time-to-event analysis. Overall, 1280 patients were recruited. The average age was 66.3 ± 8.4 and 82.5% were male. Average follow-up was 4.6 years (range = 1–19 years). The overall conversion rate from iRBD to an overt neurodegenerative syndrome was 6.3% per year, with 73.5% converting after 12-year follow-up. The rate of phenocconversion was significantly increased with abnormal quantitative motor testing [hazard ratio (HR) = 3.16], objective motor examination (HR = 3.03), olfactory deficit (HR = 2.62), mild cognitive impairment (HR = 1.91–2.37), erectile dysfunction (HR = 2.13), motor symptoms (HR = 2.11), an abnormal DAT scan (HR = 1.98), colour vision abnormalities (HR = 1.69), constipation (HR = 1.67), REM atonia loss (HR = 1.54), and age (HR = 1.54). There was no significant predictive value of sex, daytime somnolence, insomnia, restless legs syndrome, sleep apnoea, urinary dysfunction, orthostatic symptoms, depression, anxiety, or hyperechogenicity on substantia nigra ultrasound. Among predictive markers, only cognitive...
variables were different at baseline between those converting to primary dementia versus parkinsonism. Sample size estimates for definitive neuroprotective trials ranged from 142 to 366 patients per arm. This large multicentre study documents the high phenoconversion rate from iRBD to an overt neurodegenerative syndrome. Our findings provide estimates of the relative predictive value of prodromal markers, which can be used to stratify patients for neuroprotective trials.

Introduction

The neurodegenerative synuclein aggregation disorders, namely Parkinson’s disease, dementia with Lewy bodies, and multiple system atrophy (MSA), all have a prodromal interval; that is, a period during which neurodegenerative symptoms/signs are present, but full clinical disease has not yet developed (Berg et al., 2015). In the synucleinopathies,
this interval is notably long, often exceeding a decade (Berg et al., 2015). This provides an unprecedented opportunity to provide potential neuroprotective therapy early, perhaps even preventing the development of parkinsonism and dementia.

Unlike many neurological diseases, whose prodromal states are predominantly identified by abnormalities in the same domain [e.g. mild cognitive impairment (MCI) is the primary prodromal marker of Alzheimer’s disease], prodromal synucleinopathy markers are notably diverse. In addition to subtle motor signs, the potential prodromal markers include autonomic abnormalities, olfactory loss, cognitive changes, depression, anxiety, etc. (Goldman and Postuma, 2014). Most are relatively non-specific, such that the large majority of marker-positive subjects will not develop disease. However, a notable exception is idiopathic REM sleep behaviour disorder (iRBD).

RBD is a parasomnia in which the normal paralysis of REM sleep is lost, such that patients ‘act out’ their dreams (Schenck et al., 2013b; Hogl et al., 2018). Idiopathic RBD [alternatively termed ‘isolated’ (Hogl et al., 2018) or ‘cryptogenic’ RBD] has a prevalence of ~1% over age 60 (Kang et al., 2013; Haba-Rubio et al., 2018; Pujol et al., 2017), although most do not present to medical attention. Observational studies, generally from single centres, have suggested that most patients with iRBD will eventually develop a defined neurodegenerative disease, almost always diagnosed as synucleinopathy (Wing et al., 2012; Schenck et al., 2013a; Ianzo et al., 2014; Arnulf et al., 2015; Mahlknecht et al., 2015; Postuma et al., 2015a, d; Li et al., 2017). In this context, RBD is likely related to neurodegeneration in the pontine or medullary areas associated with control of REM atonia (Valencia Garcia et al., 2018). The latency from symptom onset to disease phenoconversion (i.e. conversion from iRBD to defined dementia with Lewy bodies, Parkinson’s disease, or MSA) averages over 10 years (Schenck et al., 2013b). Therefore, this implies that 1% of the elderly population have a readily-diagnosable but often-undetected early-stage neurodegenerative syndrome.

So far, most studies of phenoconversion risk and predictors came from single centres, so whether this is seen across different countries and different contexts remains unclear. In this study, we combined the prospective experience of 24 centres from the International RBD Study Group, to quantify the risk of phenoconversion to defined parkinsonism/dementia and to test 21 potential predictors of phenoconversion.

Materials and methods

Subjects

For inclusion, all subjects had to have iRBD confirmed on polysomnogram according to American Academy of Sleep Medicine Criteria (American Academy of Sleep Medicine and Hauri, 2007), and be free of parkinsonism or dementia on baseline neurological examination. Each patient had at least one follow-up examination during which systematic assessment for parkinsonism and dementia was performed. All patients gave written informed consent according to the Declaration of Helsinki, and ethics approval was obtained from the local institutional boards.

Baseline variables

Centres collected all available information on baseline variables, then followed patients prospectively. We did not require that each variable be tested in each patient; rather, centres sent results for all those variables that they systematically assessed. Neither did we require that all variables be assessed with the same technique, as centres had different testing protocols for prodromal markers. For the analyses of hazard ratio (HR) in with tests were categorized as abnormal or normal, each centre defined each variable as abnormal/normal according to their own testing protocols, unless otherwise stated below. Detailed numbers of patients assessed with each variable is provided in Supplementary Table 1. Variables of interest and the assessment methods used included:

(i) Standardized motor examination: tested with the Movement Disorders Society Unified Parkinson Disease Rating Scale (MDS-UPDRS) (Goetz et al., 2008). Either the 1987 UPDRS or 2008 MDS-UPDRS version could be used. For stratification purposes, the cut-off score was >3 excluding action tremor (Postuma et al., 2012).

(ii) Standardized motor symptoms: UPDRS/MDS-UPDRS Part II (Fahn et al., 1987; Goetz et al., 2008).

(iii) Quantitative motor testing: tests included the alternate-tap test (Nutt et al., 2000; Postuma et al., 2015c), Purdue PegBoard (Desrosiers et al., 1995; Postuma et al., 2015c), 3-Metre Timed-Up-and-Go (Podsiadlo and Richardson, 1991; Postuma et al., 2015c), or Flamingo balance test (Barber et al., 2017). If multiple tests were conducted in one centre, the majority had to be abnormal to classify the testing as abnormal.

(iv) Olfaction: 12- or 40-item University of Pennsylvania Smell Identification Test (Doty et al., 1984) or Sniffin Sticks (Hummel et al., 1997; Mahlknecht et al., 2015).

(v) Colour vision: Farnsworth-Munsell 100-Hue test (Farnsworth, 1943).

(vi) Physician-documented insomnia: Insomnia Severity Index (Bastien et al., 2001), Athens Insomnia Scale (Soldatos et al., 2000), or clinical interview.

(vii) Excessive daytime somnolence: Epworth Sleepiness scale (Johns, 1991; Valencia Garcia et al., 2018) or clinical interview.

(viii) Restless legs syndrome: diagnosed using clinical interview.

(ix) Sleep apnoea: apnoea-hypopnoea index cut-off >15/h (secondary analysis was also performed using cut-off >5/h).

(x) REM sleep without atonia: scored as % tonic and phasic chin REM on the polysomnographic trace, using either Montreal scoring (Montplaisir et al., 2010), or % ‘any’ tone using SINBAR scoring, chin ≥ arm (Frautschy et al., 2012). For combined stratification, we divided each individual’s score by the mean estimate from their centre.

(xi) Constipation: Unified MSA Rating Scale (UMSARS) (Wenning et al., 2004), SCOPA-AUT (Visser et al., 2004), Rome Criteria (Higgins and Johanson, 2004), or clinical interview.

(xii) Urinary symptoms: UMSARS, SCOPA-AUT, or clinical interview.
(xiii) Erectile dysfunction: UMSARS, SCOPA-AUT, or clinical interview.
(xiv) Orthostatic symptoms: UMSARS, SCOPA-AUT, PD-NMS-Quest (Chaudhuri et al., 2006), or clinical interview.
(xv) Orthostatic blood pressure: assessed lying and after 1–3 min standing. For illustration/stratification purposes only, a cut-off systolic drop of >10 mmHg was used.
(xvi) Cognition, neuropsychological testing: MCI/neuropsychological disorder diagnosed as abnormal neuropsychological testing (generally two or more tests abnormal in one or more domain, adjusted for age and education), plus subjective cognitive complaint, and preserved activities of daily living. We also assessed predictive value of abnormal cognitive testing, regardless of reported cognitive symptoms.
(xvii) Cognition, office-based diagnosis: Folstein Mini-Mental State Examination (MMSE) (Folstein et al., 1975) or Montreal Cognitive Assessment (MoCA) (Nasreddine et al., 2005). For stratification, an education-adjusted MoCA < 26 and MMSE < 28 were defined as abnormal (for combined analysis, MoCA given priority, as it has a validated MCI cut-off) (Nasreddine et al., 2005). For definition of office-based possible MCI, we also required cognitive complaint/symptoms.
(xviii) Depression: Beck Depression Inventory (Beck et al., 1961), Geriatric Depression Scale (Yesavage et al., 1982), Patient Health Questionnaire-9 (Kroenke et al., 2001) or clinical interview.
(xix) Anxiety: Beck Anxiety Inventory (Beck et al., 1988), Neuropsychiatric Inventory (Cummings et al., 1994), State- Trait Anxiety Inventory (Gaudry et al., 1975), Hospital Anxiety and Depression scale (Zigmond and Snaith, 1983), Leeds Anxiety Scale (Snaith et al., 1976), and NMS-Quest (Chaudhuri et al., 2006), Generalized Anxiety Disorder-7 (Spitzer et al., 2006).
(xx) Dopamine-transporter single photon emission tomography (DAT-SPECT), focusing on the putamen as region of interest.
(xxi) Substantia nigra pars compacta hyperechogenicity measured by transcranial ultrasound.

Follow-up and disease conversion

All centres prospectively followed patients in-person evaluation to diagnose phenocconversion to defined parkinsonism [defined as bradykinesia plus at least one of rigidity or rest tremor (Postuma et al., 2015b)] or dementia [defined as cognitive impairment on standardized testing with functional impairment (Dubois et al., 2007)]. For patients with parkinsonism as the primary disease manifestation, the primary diagnosis (Parkinson’s disease/MSA) was made according to the treating neurologist. This differential diagnosis incorporated all available follow-up information (i.e. any patient who was initially diagnosed with Parkinson’s disease at phenoconversion but who was subsequently found to have MSA would be included as MSA). For dementia conversions, all patients had polysomno-gram-diagnosed RBD; therefore, they met 2017 criteria for probable dementia with Lewy bodies with a clinical core symptom plus biomarker loss of REM atonia (McKeith et al., 2017). One centre (Barcelona) excluded patients with MCI from their cohort at baseline and delineated de novo MCI as a phenoconversion. To prevent any resulting bias in conversion risk estimates, we delineated phenocconversion as new parkinsonism or neuropsychological-examination-diagnosed MCI for this centre only (and also conducted sensitivity analysis removing that centre). Survival analysis was done using Kaplan-Meier analysis to estimate disease risk. For overall analysis, time = 0 was the first baseline in-person evaluation. In analysis of individual variables, not all variables might have been measured at the same baseline visit. Therefore, we calculated the interval for each individual variable (i.e. time = 0 was the first evaluation of that specific variable). For the stratification analysis (and for illustration in figures), we defined predictive markers binarily (normal/abnormal). For those variables without definable cut-offs for abnormality within RBD (e.g. REM atonia, age), we stratified as above versus below mean values (Table 2). For testing potential prodromal markers, the primary analysis was Cox proportional hazards analysis adjusting for baseline age, sex, andcentre. Each prodromal marker was analysed both as continuous and categorical variables. To facilitate comparison between variables, we present the categorical analysis (stratified as discussed above); note that in all cases, statistical significance (P < 0.05 threshold) was the same for continuous and categorical analyses. Finally, we assessed the predictive value of selected markers in combination. To increase precision and reliability only combinations that could be tested in at least three centres, with >50 patients in each possible combination (i.e. none, one, or both variables present) were eligible for combined analysis.

On secondary analysis, among convertors who were diagnosed with Lewy body disease (i.e. excluding MSA), we compared those who developed dementia as the first disease manifestation versus parkinsonism-first conversions (if both were diagnosed on the same visit, the patient was classified as dementia-first). Finally, we estimated sample size requirements for a future neuroprotective trial. This assumed a categorical definitive end-point (defined disease phenoconversion), with two groups (placebo versus a single-dose of active treatment), two-sided alpha = 0.05, and 80% power. We used time-to-event analysis (http://www.quesgen.com/SSSurvival.php), for a 2-year trial, assuming an agent that reduces phenoconversion with HR = 0.5. We calculated sample size for the population as a whole, and using stratification by prodromal marker testing, using directly-observed conversion rates, and also by using the hazard ratio from the current study estimates (i.e. adjusting for centre effects by recalculating the conversion rate in each single analysis to equal the median conversion rate in the entire group). For assessment of MDS prodromal criteria, we included only patients who had sufficient testing to reasonably estimate their % probability, which was defined as four or more prodromal variables including at least one of the three highest-specificity variables (olfaction, objective motor examination/quantitative testing, DAT-SPECT); for all calculations, the likelihood ratio of RBD (130) was included.

Continuous variables are presented as mean ± standard deviation (n). To allow direct comparisons between markers, all continuous variables are stratified to normal versus abnormal; for values with no defined abnormal cut-off above (e.g. age) results were stratified as above or below mean values. Hazard ratios are presented according to Cox proportional hazards analysis performed with logistic regression adjusting for age, sex, and centre.

Each result is stratified to above or below mean values for that centre. The combined analysis combines tonic/phasic/any tone. Measures for which the confidence intervals do not cross one (i.e. P < 0.05) are highlighted in bold.

*Reference group is normal cognitive testing (regardless of complaint). Diagnosis of MDS prodromal criteria includes the likelihood ratio of RBD.

AhI = Apnoea–Hypopnea Index; MoCA = Montreal Cognitive Assessment; MMSE = Mini Mental State Examination; MTL = Montreal; SINBAR = Sleep Innsbruck Barcelona.

Overall outcome

During follow-up, 352 (28%) converted to an overt neurodegenerative syndrome (Fig. 1). The mean interval between baseline evaluation and phenoconversion was 4.6 ± 3.5 years. The median time to phenoconversion was 8.0 years,
with an overall phenoconversion rate of 6.25% per year. The risk of phenoconversion on Kaplan-Meier analysis was 10.6% after 2 years, 17.9% after 3 years, 31.3% after 5 years, 51.4% after 8 years, 60.2% after 10 years, and 73.5% after 12 years. With regards to disease classifications, 199 (56.5%) developed parkinsonism as the first disease manifestation [of whom 16 (4.5%) were diagnosed with probable MSA], and 153 (43.5%) developed dementia first.

Predictors of outcome

Kaplan-Meier analysis of selected predictors is illustrated on Fig. 2. On Cox proportional hazards analysis, adjusting for age, sex, and centre, numerous measures significantly predicted outcome (Table 2 and Figs 2–4). These included: (i) quantitative motor testing (HR = 3.16); (ii) standardized motor examination [HR = 3.03 overall, higher for MDS-UPDRS (3.77) than UPDRS-III (2.75)]; (iii) olfaction (HR = 2.62). Predictive value also improved when excluding MSA patients (HR = 2.91); (iv) MCI, with better prediction using neuropsychological examination (HR = 2.37) than with office-based testing (HR = 1.91); (v) erectile dysfunction (HR = 2.13); (vi) motor symptoms: HR = 2.11, with better prediction for the MDS-UPDRS-II (HR = 4.75) than the 1987 UPDRS-II (HR = 1.29); (vii) DAT-SPECT (HR = 1.98); (viii) neuropsychological testing (regardless of cognitive complaint) (HR = 1.89); (ix) colour vision (HR = 1.69); (x) constipation (HR = 1.67); (xi) REM sleep without atonia (HR = 1.54, on combined analysis only); (xii) brief office-based cognitive tests (regardless of cognitive complaint) (MMSE/MoCA combined HR = 1.55); and (xiii) age (HR = 1.54 for above versus below mean).

In addition, systolic blood pressure drop at a cut-off of 10 mm (HR = 1.55) predicted outcome on unadjusted analysis, but not after adjusting for age, sex, and centre (HR = 1.37) (using a cut-off of 20 mm, the unadjusted HR was 1.37 (0.88–2.15) and adjusted HR was 1.20 (0.74–1.91). The MDS prodromal criteria (which combines numerous variables) predicted outcome with the highest hazard ratio (HR = 5.37).

By contrast, we saw no significant predictive differences according to sex, insomnia symptoms, daytime somnolence, restless legs syndrome, apnoea, urinary dysfunction, orthostatic symptoms, depression, anxiety, or substantia nigra ultrasound.

Secondary and sensitivity analyses

Among the 336 patients diagnosed with Lewy Body disease (i.e. excluding MSA), there were relatively few differences between patients who converted to dementia first versus parkinsonism first (Table 3). Age and sex were similar. All motor measures were similar except for quantitative motor testing, which was more likely to be abnormal in those developing dementia first (82.4%) than parkinsonism first (47.2%). Olfaction was similar in both groups, as were all sleep symptoms and polysomnographic variables. Autonomic symptoms were similar, as was orthostatic blood pressure drop, depression or anxiety. Although power was limited, we also saw no differences in proportion of patients with abnormal DAT-SPECT or substantia nigra ultrasound. The only variables that differed strongly (all \( P < 0.001 \)) were those that tested cognition, including office based cognitive testing, neuropsychological examination, and colour vision testing which predicted only dementia [note that colour vision predominantly tests visuoperceptual cognition in Parkinson’s disease (Bertrand et al., 2012)].

Excluding results from centres that already published data on these predictors did not substantially affect the hazard ratio. For example, the hazard ratio of UPDRS excluding Montreal (Postuma et al., 2012) was 3.04, versus 3.03 for entire group. The hazard ratio of olfaction excluding both Montreal (Postuma et al., 2011) and Innsbruck (Mahlknecht et al., 2015) was 2.53, versus 2.62.

Sample size calculations

Based on the time-to-event analysis, we estimated that 366 patients per arm would need to be recruited into a 2-year trial to have 80% power to find a 50% reduction in disease phenoconversion (i.e. 65 phenoconversion events; Table 4). Adjusting the study duration altered sample sizes roughly proportionally to the proportion in duration (e.g. 4-year trial = 192 per group, 1-year trial = 709 per group). Testing different effectiveness assumptions, a drug providing 80% reduction in phenoconversion would require 84 patients per group (12 phenoconversion events) while a 30% reduction would require 959 (190 phenoconversion events).

The most powerful single selection procedure (abnormal quantitative motor testing) reduced sample size to 166–197 patients; however, only 34% of the iRBD population had abnormal testing and so would be included in such a study.
Figure 2 Kaplan-Meier plot of disease-free survival of patients with iRBD stratified according to presence of motor and cognitive markers. Results are presented according to baseline assessment (i.e. patients who develop a de novo marker abnormality over the course of the follow-up remain in the ‘marker-free’ group). Solid line indicates patients with normal values, dashed line abnormal values. Hazard ratios (HRs) are with Cox proportional hazards, adjusting for age, sex, and centre, with 95% confidence intervals in parentheses.
Figure 3 Kaplan-Meier plot of disease-free survival of patients with iRBD stratified according to presence of sleep and psychiatric markers. Solid line indicates patients with normal values, dashed line abnormal values. Hazard ratios (HRs) are with Cox proportional hazards, adjusting for age, sex, and centre, with 95% confidence intervals in parentheses.
Figure 4 Kaplan-Meier plot of disease-free survival of patients with iRBD stratified according to presence of special sensory and autonomic markers. Solid line indicates patients with normal values, dashed line abnormal values. Hazard ratios (HRs) are with Cox proportional hazards, adjusting for age, sex, and centre, with 95% confidence intervals in parentheses.
on the other hand, other stratification strategies allowed more inclusions; selecting for abnormal olfaction allowed 67% eligibility with sample size of 247–262 per group, and selecting those who met the MDS prodromal criteria allowed 77% eligibility with sample size of 282–301 per group. Among two-factor combinations, the combination of olfaction and UPDRS retained 29% eligibility, and resulted in an estimated 15.7% annual conversion rate, translating into 157 patients per group.

**Discussion**

In this large multicentre study, we have confirmed the very high risk of Parkinson’s disease, dementia with Lewy bodies, and MSA in ‘idiopathic’ RBD, and have confirmed numerous predictors of outcome. These findings have implications for potential prevention/early treatment of the neurodegenerative synucleinopathies.

**Risk of disease**

As this is the largest study ever performed in iRBD, it has potentially the most precise estimates of phenoconversion rates. Overall, we found phenoconversion rates of 6.25% per year. This is broadly similar, although slightly lower than some previous estimates, including that of the only previous multicentre study (which found an 8% annual conversion; Postuma *et al.*, 2015). The reason for this
slightly lower estimate is unclear. One explanation could have been secular change; as a disease becomes increasingly recognized, milder/earlier cases (with lower conversion rates) come to attention. However, we found no clear evidence for this; those diagnosed after 2010 had a 19.2% 3-year risk of disease, compared to 16.9% among those before. It could also be possible that newer centres in the RBD Study Group might have different (i.e. more permissive) diagnostic procedures, which would imply increasing proportions of patients without true synucleinopathy. However, centres who participated in the original multicentre study did not have a higher risk than those without (e.g. original centres’ 3-year risk = 16.8%, versus 21.6% for new centres). We did note that annualized disease risk appeared to be lower from Years 0 to 2 than for subsequent years. This may indicate a potential selection bias; if examiners were reluctant to recruit patients who appeared on the threshold of parkinsonism or dementia, risk would be systematically underestimated (since patients would have to first develop mild signs, then full disease).

Another potentially key factor for phenoconversion may be the frequency and intensity of follow-up. Many patients do not recognize symptoms of parkinsonism/cognitive impairment, and are diagnosed only on in-person systematic examination. A striking illustration of the importance of follow-up intensity is the Montreal experience. In their 2009 report, which included patients followed clinically/ad hoc, conversion risk at 5 years was 18% (Postuma et al., 2009). However, 6 years later, a study from the same centre, this time concentrating exclusively upon patients followed systematically by a movement disorders specialist and neuropsychologist, found a 5-year risk of 47% (Postuma et al., 2015c). Moreover, we may see evidence of this in our cohort, as conversion estimates were higher when they were calculated starting from the first date of intensive in-person examination of Parkinson’s disease/dementia risk factors (olfaction, UPDRS, cognitive exam, etc).

For example, if conversion risk is tracked from performance of the first UPDRS Part III neurologist examination (a potential sign that more intensive follow-up has commenced), the estimated annual risk of conversion rises from 6.3% to 7.1%; see Table 4 for the potential effects of this on observed versus estimated sample size calculations. This might imply that a clinical trial with intensive

### Table 4 Sample size calculations for neuroprotective trials

| Population                              | Proportion of sample abnormal, % | Observed conversion rate, % | Adjusted conversion rate (adjusted for centre), % | Sample size per group - observed/adjusted |
|-----------------------------------------|----------------------------------|-----------------------------|--------------------------------------------------|------------------------------------------|
| All RBD                                 | 100                              | 6.25                        | 6.25                                             | 36/366                                   |

Sample size is calculated using a time-to-event analysis for a disease phenoconversion to either dementia or parkinsonism as the primary outcome. The calculation is for a 2-year trial, with accrual set at 0 (i.e. all patients are followed for exactly 2 years). The assumption is for a disease-modifying agent that reduces HR to 0.5 (65 phenoconversion events), with power = 80% at < 0.05 (two-tailed). For stratification, patients are included if they are abnormal for that test (or combination of tests). Note that the observed rate includes only those centres that performed the evaluation, at the time that the marker was first evaluated. The adjusted rate was calculated by dividing the overall observed rate in all centres that performed the marker (both normal and abnormal tests) by the median rate in all centres (thereby estimating the rate that would have been seen if all centres performed the test).

In these cases, MCI can be defined as either an abnormal neuropsychological test or office-based test, plus cognitive complaint. If both were performed and contradicted, the neuropsychological test result takes precedence.
periodic evaluations may find a higher conversion risk than observed in this study. Regardless of the conversion rate, it is clear that the large majority of idiopathic RBD patients in fact have prodromal synucleinopathy. So, while the term ‘idiopathic’ RBD is used here, we recognize that few patients are truly ‘idiopathic’ in the original sense of the term (i.e. unclear cause), and other terms such as ‘clinically isolated’ RBD may be more appropriate (Hogel et al., 2018).

**Predictive markers**

Although comparisons of hazard ratios across different predictors should be made with caution (because centres measured different variables), it nonetheless suggests numerous findings of interest. When analysed as a binary diagnostic test, there was no clear advantage of DAT-SPECT over either the UPDRS or quantitative motor testing (note that both DAT-SPECT and quantitative motor tests were defined by each centre as normal/abnormal with no harmonization procedures; harmonization might increase the hazard ratio). Note that this finding may be unique to iRBD patients, who have an extremely high prevalence of underlying synucleinopathy; in the general population, non-specific causes of motor slowing on quantitative motor tests (e.g. arthritis) may influence estimates more (Keezer et al., 2016; Jennings et al., 2017). Regardless, these quantitative motor tests were simple office-based tests that required <5 min to administer. Clearly these are strong candidates for selecting patients for future neuroprotective trials, and could even obviate the need for sophisticated imaging techniques if simpler trial design is required. This finding illustrates both the need to improve imaging techniques for prodromal disease and the considerable future potential for more precise quantitative motor markers (e.g. wearable or smartphone-based sensors).

It is not surprising that the highest hazard ratios were for motor and cognitive measures, since these are the primary means by which parkinsonism and dementia are defined; however, the high performance of olfactory testing as a predictor is notable, as it is also easily tested in office settings. Finally, no test appeared to be able to ‘rule out’ phenocconversion; many of those with normal testing still went on to develop parkinsonism and dementia. For example, the highest negative predictive value was seen for the MDS prodromal criteria, but even among those negative for criteria, 5% phenconverted at 3 years, 13% at 5 years, and 27% at 8 years (note that analysis is at baseline only, and presumably many of these patients would have developed abnormal markers before phenocconversion).

**Dementia-first versus parkinsonism-first**

The comparison between dementia-first and parkinsonism-first phenocconverters was notable for the similarity in predictive value between markers. Motor variables were highly predictive of dementia as well as parkinsonism (and for quantitative motor assessment, even more predictive of dementia than parkinsonism). This finding is consistent with previous studies which documented a longer/slower-progressing motor prodromal interval in dementia-first than parkinsonism-first convertors (Postuma et al., 2012); if their motor prodromal interval is longer in prodromal dementia patients, they would be more likely to be abnormal on a cross-sectional test. Overall, the only clear differentiating variable between dementia and parkinsonism was cognition itself. It is unclear whether the conversion to dementia versus parkinsonism first is related to a different ‘top-down’ synuclein spread upwards to cortex before the substantia nigra (Adler and Beach, 2016), or to effects of co-morbid pathology [i.e. if a person with RBD has co-morbid amyloid cortical pathology, even modest cortical deposition of synuclein could trigger rapid cortical neurodegeneration resulting in a dementia-first phenotype (Chetelat et al., 2013)].

**Sample size**

We calculated the sample size requirements for a definitive neuroprotective trial, using phenocversion as a categorical endpoint. Overall, sample sizes for a 2-year trial with HR = 0.5 ranged from 150 to 360 patients per group. In general, stratification strategies could decrease sample sizes, at the cost of reduced generalizability and less efficient recruitment. Of the selection strategies, the two most efficient appeared to be olfaction, which reduced sample size by 28.5% while retaining 67% of the sample as potential trial candidates, and the MDS prodromal criteria, which reduced sample size by 17.8% while retaining 77% of the sample. Of course, exact sample size calculations will depend on the specifics of a clinical trial; nevertheless, the fact that 24 centres combined to produce these estimates can provide some confidence for trial planners that sample sizes will be representative of the global experience. Notably, the total sample size for a future neuroprotective trial is less than the number of participants who were recruited to this study. So, it appears that a complete trial-ready population already exists in the centres of the International RBD Study Group.

**Limitations and strengths**

Some limitations of this study should be pointed out. First, this study is an amalgam of the research experience of 24 different centres; there was not a single protocol for testing predictors of disease, and protocols differed greatly between centres in terms of depth, follow-up intensity, predictors assessed, and methods/cut-offs for assessing them. Therefore, the predictive data will not be fully comparable to a single clinical trial setting, which would have a single testing protocol. Second, protocols for recruiting MCI varied; 23 of 24 centres recruited patients at baseline with MCI, but the largest centre (Barcelona) did not. There is no perfect way to harmonize these completely; for the primary analysis we elected to allow the Barcelona group to define disease conversion as de novo MCI, to prevent underestimation of
Institute of Health Research (Grant #286641) the Weston Foundation (grant #N/A) and the Fonds de la Recherche en Sante Quebec (#28915). The funding sources had no role in the collection, analysis, and interpretation of data; in the writing of the report; or in the decision to submit the paper for publication.
