Abstract

A numerical investigation of grain-boundary grooving by means of a Level Set method is carried out. An idealized polygranular interconnect which consists of grains separated by parallel grain boundaries aligned normal to the average orientation of the surface is considered. The surface diffusion is the only physical mechanism assumed. The surface diffusion is driven by surface curvature gradients, and a fixed surface slope and zero atomic flux are assumed at the groove root. The corresponding mathematical system is an initial boundary value problem for a two-dimensional Hamilton-Jacobi type equation. The results obtained are in good agreement with both Mullins’ analytical “small slope” solution of the linearized problem [14] (for the case of an isolated grain boundary) and with solution for the periodic array of grain boundaries (Hackney [9]).

1 Introduction

This paper presents the results of our work on numerical modeling and simulation of grain-boundary (GB) grooving by surface diffusion. Our ultimate goal is to develop and test a fast numerical approach for the simulation of formation and propagation of groove-like defects in thin film interconnects used in microelectronics (ME).
In modern ME industry, the quality and reliability of ME integrated circuits have become no less important than their performance. Some of the most vulnerable elements of ME circuits, susceptible to several types of mechanical failures, are the interconnects. These are metallic conductors which connect the active elements.

The defects (due to the small cross-section, high current density, mechanical stresses and presence of GBs acting as fast diffusion pathways) lead to the loss of electrical and mechanical integrity, i.e. to line opens or shorts. Thus, such defects are one of the main reliability concerns in advanced integrated circuits.

### 1.1 Mechanisms of Mechanical Failure in Interconnect Lines

In this section we describe some basic failure mechanisms in interconnects and outline an appropriate physical model.

Many properties of polycrystalline materials are affected by the intersection of GBs with external surfaces, especially in the presence of applied or internal fields. Common examples are growth of GB grooves and cavities \[10, 11\], stress voiding \[27\] and electromigration \[2, 12, 17, 21\].

In the absence of an external potential field, the GB atomic flux \(I_{GB} = 0\) and the corresponding groove profile evolves via surface diffusion under well-known conditions of scale and temperature (the so-called Mullins’ problem \[14\]). Mass transport by surface diffusion is driven by the surface Laplacian of curvature. Essentially, for convex surfaces, matter flows from high-curvature regions, while for concave surfaces the flow is from low curvature regions. In order to solve surface-diffusion problems, four different approaches have been taken. We refer the interested reader to the article by Zhang and Schneibel \[28\], where these approaches are discussed and to the references therein.

The physical origins of a GB flux may be gradients of the normal stress at grain boundaries \[7\] and/or electromigration forces \[3\]. GB grooving with a GB flux in real thin film interconnects is a complex problem. It requires sophisticated numerical modeling technique which can manage with such issues as aperiodic arrays of GBs, anisotropy of the surface tension, GB migration, formation of slits with a local steady-state shape in the near-tip region and bridging across the slits near their intersections with the surface left behind \[17\]. Level Set Method seems to be a good candidate for addressing the problems, however it has never been used yet to this aim. As the first step in application of LS Method to the problem of grooving with EM flux, we test in this paper LS Method over two simple -and already solved- grooving problems and compare the LS Method’ results with those obtained previously in \[14, 9\]. First is classical Mullins’ problem (GB grooving controlled by surface diffusion in an infinite bicrystal with a stationary GB). Second is GB grooving by surface diffusion in the periodic GB array of stationary GBs. The electromigration flux will be taken into account in the next publication.

Below we give more details related to the physical model.

- **Driving Forces and Diffusion Mobilities**

  In the absence of an electric current, the diffusion is driven by a variation in chemical potential, \(\mu\), which causes atoms to migrate from high potential to low potential regions. It may be shown that \[14\]

  \[
  \mu(K) = K\gamma\Omega,
  \]

  \[1.1\]
where $K$ is the surface curvature, $\gamma$ is the surface tension, and $\Omega$ is the atomic volume. Gradients of chemical potential are therefore associated with gradients of curvature.

In interconnects, GBs represent numerous fast diffusion pathways with high diffusion coefficient, $D$. As a matter of fact, the bulk diffusion can be neglected \[14\]. The diffusion flux along the GB, $I_{GB}$, is given by

$$I_{GB} = \frac{D\delta}{kT} \nabla \mu,$$

(1.2)

where $\delta \sim 10^{-8} cm$ is the GB thickness, $k$ the Boltzmann constant and $T$ the absolute temperature.

Let $\tau$ be the tangential direction to the surface profile in 2D. If $\mathbf{n} = (n_x, n_y)$ is the unit vector normal to the surface or GB, then the following relations hold:

$$\tau = (n_y, -n_x), \quad \frac{\partial K}{\partial \tau} = \nabla K \cdot \tau = \frac{\partial K}{\partial x} n_y - \frac{\partial K}{\partial y} n_x \equiv K_{\tau}.$$  

(1.3)

The surface diffusion flux along the groove walls is given by the formula

$$J = -B K_{\tau},$$

(1.4)

where

$$B = \frac{D\delta\gamma\Omega^{4/3}}{kT}$$

(1.5)

is known as Mullins’ constant. Note that $J$ is proportional to the first directional derivative of the curvature.

**Boundary Conditions**

The boundary conditions at the groove root are dictated by the local equilibrium between the surface tension, $\gamma$, and the GB tension, $\gamma_{gb}$. In the symmetric case of the GB ($x = 0$) normal to an original ($y = const.$) flat surface, the angle of inclination of the right branch of the surface at the groove root with respect to the $x$ axis is $\theta_0 = \sin^{-1}(\gamma_{gb}/2\gamma)$ (see Fig. \[\phantom{1}\]).

The rapid establishment of the equilibrium angle between the GB and the surface by atomic migration in the vicinity of the intersection develops some curvature gradient at the adjacent surface and thus induces a surface diffusion flux along the groove wall in the direction away from the groove root, opposite to the groove extension direction.

Other boundary conditions depend on the particular problem (presence or absence of GB flux, etc.)
2 Mathematical Model

2.1 The Conventional Approaches

An adequate mathematical model which captures the above physical phenomena in interconnects was developed first by Mullins [14] and extended by him and others [10, 11, 15]. It describes the evolution of the groove shape, \( y(x, t) \), and has the form of a transport equation

\[
y_t = -J_x = -B \left\{ (1 + y_x^2)^{-1/2} \left[ (1 + y_x^2)^{-3/2} y_{xx} \right] \right\}_x.
\]  

(2.1)

\( J \) and \( B \) are given in (1.4) and (1.5).

For an isolated GB at \( x = 0 \), the groove continues to develop because the material continues to move from the curved shoulder of the groove to the flat surface. The classical description is provided by an analytic solution (on the \( x > 0 \) side) of the linearized version of the equation (2.1) (the “small slope approximation”, SSA). The linearized equation has the form [14]

\[
y_t = -B y_{xxxx},
\]  

(2.2)

subject to the initial condition

\[
y(x, 0) = \text{const},
\]  

(2.3)

and the boundary conditions

\[
y_x(0, t) = \tan \theta_0 = m \ll 1,
\]  

(2.4)
\[ J(0, t) = y_{xxx}(0, t) = 0, \]
\[ y(x \to \infty, t) = \text{const} \quad \text{with all derivatives}. \]

The first condition in (2.4) is the small slope approximation itself. The second one reflects the absence of a GB flux \( I_{GB} \). The solution describes a profile with a constant shape whose size is increasing all the time.

Although this analytical approach describes some basic phenomena in interconnects, it is of limited use due to the restriction on the steepness of the slope. There are several numerical techniques which are widely used in modeling moving fronts, such as the marker/string (M/S) methods \(^{22}\) or the volume-of-fluid (VOF) methods \(^{8, 16}\). These methods deal directly with the evolution equation of type (2.1), and therefore are “explicit” methods. The M/S methods come from the Lagrangian approach to front evolution problems. In the Lagrangian approach, the grid is attached to the moving front. A known drawback of the Lagrangian approach is that it is not well-suited for the computation of bifurcating fronts. Besides, stability and local singularity problems are more emphasized in these methods than in methods based on Eulerian approach, such as the VOF method. The Eulerian approach, in which the front moves through a grid which is fixed in space, does not have these drawbacks, but - as it is known - here the fronts are diffused. In addition, some intricate (subcell) bookkeeping is required to properly keep track of fronts.

There are numerical approaches which are based on finite-element discretization of the computational region \(^{4}\). However, they result in complicated algorithms which involve many computational steps such as computations of the following: displacement field of material points from a reference configuration, the stress field as a result of diffusion in the solid and geometry update of interfaces. Besides, the computational complexity grows since higher resolution is required as the shape of the interface becomes more complicated. As a result, these methods are unable to handle very complex multidimensional boundary shapes.

2.2 The Proposed Solution: Usage of the Level Set Method

To “capture” the interface (rather than to track it), our method of choice is the “implicit” LS method. The method was introduced by Osher and Sethian and was further developed during the last several years (for an introduction to the LS methods and an exhaustive bibliography list see the monographs by Sethian \(^{23, 24}\)). The method enables to capture drastic changes in the shape of the curves (interfaces) and even topology changes.

The basic idea of the method consists of embedding the curve \( y(x, t) \) into a higher dimensional space. As a matter of fact, we consider the evolution of a two-dimensional field \( \phi(x, y, t) \) such that its zero level set, \( \phi(x, y, t) = 0 \), coincides with the curve of interest, \( y(x, t) \), at any time moment \( t \). The level set function \( \phi(x, y, t) \) can be interpreted as a signed distance from the curve \( y(x, t) \), which moves in the direction normal to itself.

The evolution of \( \phi(x, y, t) \) is described by an Hamilton-Jacobi type equation. A remarkable trait of the method is that the function \( \phi(x, y, t) \) remains smooth, while the level surface \( \phi = 0 \) may change topology, break, merge, and form sharp corners as \( \phi \) evolves. Thus, it is possible to perform numerical simulation on a discrete grid in
the spatial domain, and substitute finite difference approximation for the spatial and
temporal derivatives in time and space.

The evolution equation has the form

\[ \phi_t + F|\nabla \phi| = 0, \quad \text{given } \phi(x, t = 0). \]  \hfill (2.5)

The normal velocity, \( F \), is considered to be a function of spatial derivatives of \( \phi(x, y, t) \).

In many applications \( F \) is a function of the curvature, \( K \), and its spatial derivatives.

The curvature \( K \) may be computed via the level set function \( \phi \) as follows:

\[
K = \nabla \cdot n, \quad n = \frac{\nabla \phi}{|\nabla \phi|} = \left( \frac{\phi_x}{\left( \phi_x^2 + \phi_y^2 \right)^{1/2}}, \frac{\phi_y}{\left( \phi_x^2 + \phi_y^2 \right)^{1/2}} \right).
\]  \hfill (2.6)

Here \( n \) is “normal vector”, and it coincides with the (previously introduced) unit normal
to the surface, \( y(x, t) \), on the zero level set \( \phi = 0 \). Formulas (2.6) can be combined as follows

\[
K = \nabla \cdot \frac{\nabla \phi}{|\nabla \phi|} = \frac{\phi_{xx}\phi_y^2 - 2\phi_x\phi_y\phi_{xy} + \phi_{yy}\phi_x^2}{\left( \phi_x^2 + \phi_y^2 \right)^{3/2}},
\]  \hfill (2.7)

and the sign of \( K \) is chosen such that a sphere has a positive mean curvature equal to
its radius. In the case of surface diffusion in 2D,

\[
F = -BK_{\tau\tau},
\]  \hfill (2.8)

One drawback of the LS method stems from its computational expense. Its complexity seems to be as much as \( O(n^2) \) operations per time step, which is more than any Lagrangian method which necessitates \( O(n) \) operations per time step, where \( n \) is
the number of grid points in the spatial direction. It is possible, however, to reduce
the complexity of the LS method to \( O(n) \) using a local (another term is narrow band
(tube)) approach \cite{1, 20}. This is achieved by the construction of an adaptive mesh
around the propagating interface. We distinguish between the “near field”, which is a
thin band of neighboring level sets around the propagating front, and the “far field”
which contains the rest of the grid points. The evolution equation is solved only in the
near field. The values of \( \phi \) at grid points in the far field are not updated at all. When
the interface in motion reaches the edge of the narrow band, a new narrow band is built
around the current interface position. Note that this could be done without interface
reconstruction from the level set function (which requires some additional computa-
tions). We just have to examine the shift in the sign of \( \phi \) at grid points adjacent to
the interface. The width of the narrow band is determined as a balance between the
computation involved in the re-built and the calculations performed on far away points.

In most of the applications of the LS method to date, the driving forces were
proportional to the curvature (see \cite{23, 24} for review and discussion). There are only few
applications \cite{4, 5, 12} where the driving force is proportional to the second directional
derivative of the curvature (in the 3D case, to the surface Laplacian of curvature which
is constructed from the derivatives in each principal direction), which is the case for
the normal velocity function (2.8). Therefore, the present materials science problem
presents a rather new (from the mathematical point of view) application for the LS
method. As pointed out in \cite{5}, “this is an intrinsically difficult problem for three
reasons. First, owing to the lack of a nice maximum principle, an embedded curve need not stay embedded, and this has significant implications in attempting to analyze motion which results in topological change. Second, the equations of motion contain a fourth derivative term, and hence are highly sensitive to errors. Third, this fourth derivative term leads to schemes with very small time steps.”

2.3 Computational Algorithm

A typical computational domain is a rectangular box \([0, l_1; 0, l_2]\) of a material in 2D. The proposed computational algorithm consists of the following steps:

BEGIN ALGORITHM

1. Discretization - The entire computational region \(W\) is discretized using a uniform grid \(x_i = i\Delta x, y_j = j\Delta y, i = 0...N, j = 0...M\), where \(N\) and \(M\) are the number of grid points in \(x\)- and \(y\)- directions respectively. The functions are projected on this grid, so that \(\phi(x, y, t) = \phi_{i,j}(t)\).

2. Initialization - The initial interface, \(y(x, t = 0)\), is defined analytically, or as a set of points in \(W\) (the points lie on \(x = \text{const}\) grid lines, but not necessarily on \(y = \text{const}\) grid lines). In the latter case, we define a cubic spline \(\xi(x, t = 0)\) passing through these points in order to be able to perform further initializations. The function \(y(x, t = 0)\) needs not to be necessarily smooth (i.e., it may feature sharp corners, discontinuities, etc.), but, in our implementation it must be single-valued in order to make it possible to choose the sign of \(\phi\) (below). This is because we are only interested in the particular case of analyzing the motion of open curves which may be described by functions during the whole process of the evolution. We also define the near field and the far field. The width of the near field is usually 5 to 10 grid levels (points).

In the region \(W\), the level set function \(\phi\) is initialized as an exact signed distance function to the initial interface (see Fig. 3),

\[
\begin{align*}
\phi(x_i, y_j, t = 0) &< 0 \quad \text{if} \quad y_j < y(x, t = 0) \\
\phi(x_i, y_j, t = 0) &> 0 \quad \text{if} \quad y_j > y(x, t = 0) \\
\phi(x_i, y_j, t = 0) &= 0 \quad \text{if} \quad y_j = y(x, t = 0)
\end{align*}
\]  

(2.9). Since \(\phi(x, y, t = 0)\) is a signed distance function, then \(|\nabla \phi(x, y, t = 0)| = 1\).

3. Compute normal vector components and curvature using formulas (2.6), (2.7). The derivatives in (2.6), (2.7) (as well as in other functions of \(x, y\) except the gradient term in the evolution equation itself, see step 6) are discretized using the standard second order accurate central difference approximations. Fourth-order accurate approximations were tested also but we did not observe any particular increase in the global accuracy of the calculations. In addition, in this case, the implementation of the boundary conditions with the level set function is problematic due to the use of a wide stencil. The time step also needs to be reduced in order to have stability. We find that the standard central difference scheme works well for us.
4. **Compute** first directional derivative of the curvature, $K_\tau$, using the formula (1.3) and second directional derivative of the curvature, $K_{\tau\tau}$,

$$K_{\tau\tau} = \nabla [\nabla K \cdot \tau] \cdot \tau = \frac{-K_{xx}\phi_y^2 + 2K_{xy}\phi_x\phi_y - K_{yy}\phi_x^2}{\phi_x^2 + \phi_y^2} + \frac{K(K_x\phi_x + K_y\phi_y)}{(\phi_x^2 + \phi_y^2)^{1/2}} =$$

$$-\frac{K_{xx}\phi_y^2 + 2K_{xy}\phi_x\phi_y - K_{yy}\phi_x^2}{\phi_x^2 + \phi_y^2} + K[K_\tau + K_y(n_x + n_y) - K_x(n_y - n_x)].$$

We now have the normal velocity function (2.8) and the flux (1.4).

5. **Choose** time step. The CFL condition for the surface diffusion is

$$\Delta t_1 \leq \min(\Delta x, \Delta y)/B.$$  \hspace{1cm} (2.11)

The CFL condition for the Hamilton-Jacobi equation in updating the velocity is

$$\Delta t_2 \leq \min(\Delta x, \Delta y)/F_{max},$$  \hspace{1cm} (2.12)

where $F_{max}$ is the largest magnitude of the normal velocity in the computational domain. The adaptive time step $\Delta t$ is chosen as the smallest of the two.

6. **Compute** backward and forward gradient functions; **update** $\phi$ from the evolution equation using explicit time-stepping scheme. The solutions of equation (2.5) are often only uniformly continuous with discontinuous derivatives, no matter how smooth the initial data is [18, 19]. Simple central differencing is not appropriate here to approximate the spatial derivatives in $|\nabla \phi|$. Instead, we use Essentially Non-Oscillatory (ENO) type schemes for Hamilton-Jacobi equations as developed...
in \[18, 19, 25\]. More precisely, we use second-order ENO scheme given explicitly in \[29\]. To update \(\phi\) for one time step, the simplest method is to use Euler, i.e.

\[ \phi^{n+1} = \phi^n + \Delta t L(\phi^n), \]  

where \(L(\phi)\) is the spatial operator in \[27\].

7. **Update** near field. Check the sign of \(\phi\) at the grid points adjacent to the interface and compute the new locations of near field points.

**Go to step 3**

**END ALGORITHM**

**Remark 1:** To achieve a uniformly high-order accuracy in time, we replace \(2.13\) with the second-order Total Variation Diminishing (TVD) Runge-Kutta type discretization \[19, 25\], which reads

\[ \tilde{\phi}^{n+1} = \phi^n + \Delta t L(\phi^n) \]

\[ \phi^{n+1} = \phi^n + \frac{\Delta t}{2} \left[ L(\phi^n) + L(\tilde{\phi}^{n+1}) \right] \]

The necessary changes to the algorithm are obvious. The choice of such a low-order Runge-Kutta scheme is justified by the fact that the time step, dictated by stability requirements, is very small.

**Remark 2:** It is highly desirable that the level sets behave nicely, in the sense that two different level sets do not cross, and in fact remain roughly evenly spaced in time. In terms of the level set function \(\phi\), this corresponds to the fact that the gradient of \(\phi\) at any given point of a level set does not change dramatically over time. For the numerical method this translates into numerical stability. The best way to achieve this is to keep \(\phi\) close to the signed distance function (or even to keep it exactly equal to the signed distance function), thus keeping \(|\nabla \phi| \approx (=) 1\). The operations performed on \(\phi\) that accomplish it are called “reinitialization”. To summarize, reinitialization is the process of replacing \(\phi(x, y, t)\) by another function \(\tilde{\phi}(x, y, t)\) that has the same zero contour as \(\phi(x, y, t)\) but behaves better, and then taking this new function \(\tilde{\phi}(x, y, t)\) as the initial data to use until the next round of reinitialization. There are several ways to do this. The straightforward one (first proposed in \[13\] and recently used in \[2\]) is to interrupt the time-stepping, reconstruct the interface using some interpolation technique and directly compute a new signed distance function to the interface. This approach is very expensive and also may bring some undesirable side effects, such as oscillations in the curvature. Instead, we use the iteration procedure of \[26\]. The function \(\phi\) is reinitialized by solving the following Hamilton-Jacobi type equation to its steady state, which is the desired signed distance function:

\[ \phi_t = S(\phi_0) \left( 1 - |\nabla \phi| \right), \]

where \(S\) is a smoothed sign function

\[ S(\phi_0) = \frac{\phi_0}{\sqrt{\phi_0^2 + \epsilon^2}}, \quad \epsilon = \min(\Delta x, \Delta y). \]

The same second-order ENO and TVD Runge-Kutta schemes used for the solution of the equation \(2.3\) are used for the iteration of \(2.13\). As a rule, three or four
iterations are sufficient to evolve \( \phi \) close enough to the desired signed distance function. An important practical question is how frequently the reinitializations are applied. In some applications of the level set method the reinitializations could be triggered after a fixed number of time steps. However, we achieved the best results by reinitializing every time step in the band of level sets that contains points from the near field.

**Remark 3:** The evolving interface touches the vertical boundaries \( x = 0, x = l_1 \) by its ends and therefore any boundary conditions imposed on vertical walls influence the evolution of the front. This is why, depending on the nature of the problem, we either choose periodic b.c. at vertical walls or just an approximation of the derivatives at vertical walls by one-sided differences. At the horizontal walls, we always use one-sided differences. For illustration purposes, in Fig. 3 we present part of the cosine curve evolving under \( (2.3) \) with the speed function \( F = -0.1 K_{rr} \). Boundary conditions at vertical walls are periodic. Note that the speed of evolution slows as the curve approaches equilibrium state with \( K = 0 \) (line \( y = 0.5 \)). This is because the curvature, and hence its derivative, become smaller. In order to demonstrate the abilities of the method, in Fig. 4 we present the evolution of a non-smooth curve (step function) under the same speed law.

**Remark 4:** The very special feature of the presented implementation of the Level Set Method is the incorporation of physical boundary conditions into the Level Set numerical scheme. Most of the implementations known so far lack this complication. Usually only closed interfaces far away from any boundaries domains are considered while the evolution proceeds far away from the boundaries.
Figure 4: The evolution of a non-smooth curve (step function). The grid used is 100×100, 20000 time steps were made.

For the GB grooving by surface diffusion, two boundary conditions at the groove root are essential: these are conditions of type (2.4), reflecting the fixed slope of the interface and the absence of GB atomic flux. The boundary conditions we impose at $x = l_1$ are zero slope of the interface and zero flux. The first condition echoes the initial flat interface. The second condition guarantees the conservation of matter, i.e. a constant area under the groove profile during the evolution.

Special attention was given to the treatment of these boundary conditions within the framework of the Level Set method. Two methods were developed.

The simplest technique is the use of correction step in the iterative algorithm.

The fixed slope at the groove root is achieved in the following way: at every time step, the interface is reconstructed from the $\phi$-field and the locations of the two end-points of the interface (at $x = 0$ and $x = l_1$, respectively) are corrected in order to preserve the small-slope and the zero-slope conditions. Then, for all grid points that lie on grid lines $x = 0$ and $x = l_1$, it is sufficient to directly compute a new signed distances to the updated locations of the interface end points. This way we incorporate the new locations of the end points back into the $\phi$-field. This direct reinitialization is performed only for a few grid points that lie on vertical boundaries and, besides, this computation does not contain iteration loop. The zero flux conditions could be imposed locally, i.e. in the vicinity of the groove root and of the interface end-point at $x = l_1$, or along the the entire $x = 0$ and $x = l_1$ grid lines. After the computed values of $K_\tau$ are reset to zero, the $K_{\tau\tau}$ is computed according to eq. (2.10), where $K_{\tau} = 0$ at $x = 0, l_1$ and $K_{\tau} \neq 0$ otherwise. After multiplication by $-B$, this gives the values of the normal velocity function (2.8), corrected by the zero flux constraint.
Extension of the $\phi$-field beyond the GB makes use of Taylor expansion up to second order, as follows (also see eq. (2.6)):

$$\phi_{-1,j} = \phi_{0,j} - \phi_x \mid_{0,j} \Delta x = \phi_{0,j} - |\nabla \phi_{0,j}| \ n_x \mid_{0,j} \Delta x = \phi_{0,j} + |\nabla \phi_{0,j}| \sin \theta_0 \ \Delta x,$$

(2.17)

where $\phi_{-1,j}$ is one grid point beyond the GB. Equation (2.17) incorporates the groove root angle. Then we compute in (2.7) the curvature values, $K_{0,j}$, along the GB, using both the values of $\phi$ inside the computational domain ($\phi_{1,j}$) and outside ($\phi_{-1,j}$). This also gives us the values of $K_y |_{0,j}$. The zero flux condition is applied using equation (1.3) which, after substitution of normal vector components from (2.6) and rearrangement of the terms become

$$K_x \mid_{0,j} = K_\tau |\nabla \phi| + K_y \phi_x \phi_y \mid_{0,j} = -K_y \mid_{0,j} \tan \theta_0.$$  

(2.18)

Applying Taylor expansion again, we get the ghost values of the curvature:

$$K_{-1,j} = K_{0,j} - K_x \mid_{0,j} \Delta x,$$

(2.19)

where $K_x \mid_{0,j}$ is given by (2.18). Now all the data is known and we can compute the values of $K_{\tau\tau}$ from (2.10) and the values of the normal velocity from (2.8).

Both methods were successfully used in calculations.

3 Numerical results and discussion

Figures 5 to 8 show the groove profile having different slopes at the groove root, evolving under (2.5) with a speed function $F = -BK_{\tau\tau}$. We take $B = 0.025$. The profile is symmetric with respect to the GB at $x = 0$, therefore only its right part is calculated.
Figure 5: GB grooving by surface diffusion. The slope at groove root is $m = 6.55e - 02$. The initial interface is shown with dashed-dotted line, the numerical results obtained by means of the LS Method are shown with solid lines, the reference results of [14] are shown with dashed lines.

Figure 6: Same as Figure 5, but the slope at groove root is $m = 9.85e - 02$. 
Figure 7: Same as Figures 3, 5, but the slope at groove root is $m = 1.32e - 01$.

The results obtained by means of the LS Method are shown with solid lines, while reference results for Mullins’ problem (2.2)-(2.4) are shown with dashed lines. In all the three numerical experiments reported here the dimensions of the computational box are $[0., 0.08; 0., 0.02]$, the mesh is $120 \times 40$.

Our initial interface for the Level Set simulations already has the shape of Mullins’ groove. The reason we don’t have a flat interface $y(x, 0) = \text{const.}$ as an initial condition is that the LS formulation requires a non-zero initial curvature, otherwise the curve does not evolve at all (since $F = 0$ in this case). The initial interface in Figs. 3 - 7 is shown with dashed-dotted line.

The initial Mullins’ groove is obtained as follows: we integrate numerically the equation (2.2) using the method-of-lines approach. The time integrator is second-order Runge-Kutta and the spatial operator is discretized using second order central differences. The integration proceeds from $t = 0$ to $t = 8.0e - 09$. The initial and boundary conditions are (2.3) and (2.4), where $\theta_0 = \pi/48, \pi/32, \pi/24$ stands for Figs. 3 - 7, respectively. The corresponding slopes are $m = 6.55e - 02, 9.85e - 02, 1.32e - 01$.

The practical values used in experiments lie between 0.05 to 0.2 and the range of the groove depth in experiments is between 0.1$\mu$ and 1$\mu$. The reason we anticipate the use of the analytic solution to the Mullins’ problem (2.2)-(2.4) (either it exists) is the truncation of infinite series in which this solution is represented. The reference results for later times are also obtained using the described numerical procedure.

In [14], two kinetic laws were established (within the framework of the SSA). One concerns the evolution of the depth of the groove with respect to the maximum surface elevation (see Fig. 1). The depth, $d$, is governed by

$$d = 0.973 \ m \ (Bt)^{1/4}. \quad (3.1)$$
The other kinetic law concerns the evolution of the distance between the position of the groove root and that of the surface maximum. In the case of the symmetric groove, we call it the half-width, \( w \), of the groove. It is governed by

\[
w = 2.3(Bt)^{1/4}. \tag{3.2}
\]

From these expressions, we have the time independent ratio

\[
w/d = 2.3515/m. \tag{3.3}
\]

Under typical experimental conditions a groove of depth \( d = 0.3 \mu \) is formed within \( t = 10^4 \) sec (2.4 hr). It is shown in [14], that it would require approximately 8 days to triple this depth. This explains why in our numerical experiments the groove seems to stop developing at later times. The physical reason for this is the increase in the length of a path along which the surface diffusion takes place. As a rule, we stop the run when the groove doubles its depth or width.

For the slopes considered, we observe good qualitative agreement with Mullins’ solution. The small difference is due to two reasons. First, the results to which we compare are obtained by integrating the linearized equation (2.2), which is, strictly speaking, valid only for infinitesimal slopes. The slopes we choose are, of course, finite, and the governing equation we solve, i.e., the equation (2.5) is fully nonlinear. Second, there are inevitable area losses, since the LS method is not fully conservative. For bigger slopes, our grooves appear to be deeper and wider than Mullins’ one.

In Tables 1 to 3, the results for all three tests are summarized.

Table 1. Our results for GB grooving, compared with classical Mullins’ results. The slope at groove root is \( m = 6.55e - 02 \).

An interesting simple extension of the classical two-grain model is the case of a periodic array of grains separated by parallel GBs. In Fig. 8, we present the results for the evolution of a surface profile intersected by two GBs, \( i \) and \( i + 1 \). The physical boundary conditions at both groove roots are a constant slope of the surface and zero flux (for this example, the slope at groove roots is \( m = 9.85e - 02 \)). At short times, grooves develop at each grain boundary according to the solution for an isolated grain boundary, as presented in Figs. 5 - 7; grooving stops when, at sufficiently long times, identical circular arcs develop connecting adjacent GBs. The same result was obtained in [9] using Fourier method and the SSA.
Figure 8: Long-time evolution of surface profile intersected by two adjacent GBs. The initial surface for LS simulations is shown with dashed-dotted line.

4 Conclusions

The Level Set method was used to model the grain-boundary grooving by surface diffusion in an idealized polygranular interconnect which consists of grains separated by parallel GBs. The novel feature of the method is the treatment of physical boundary conditions at the groove root. The results obtained are in good agreement with the classical one (Mullins, [14]) for the case of an isolated grain boundary (two-grain case) and with more recent results of [9] for the case of periodic array of grains. One goal for future work is to apply electromigration influence on the grooving process. In addition, the algorithm and its software implementation will be used by materials scientists to pursue studies of GB grooving with an arbitrary electromigration flux, the various ratio of the GB to surface diffusivity which was predicted to critically affect the groove kinetics and shape account for various EM failure regimes [8].
