ABSTRACT

Gamma-ray bursts (GRBs) prompt emission spectra are often fitted with the empirical “Band” function, namely two power laws smoothly connected. The typical slope of the low energy (sub-MeV) power law is \( \alpha_{\text{Band}} \approx -1 \). In a small fraction of long GRBs this power law splits into two components such that the spectrum presents, in addition to the typical \( \sim \text{MeV} \) peak, a break at the order of a few keV or hundreds keV. The typical power law slopes below and above the break are \(-0.6\) and \(-1.5\) respectively. If the break is a common feature, the value of \( \alpha_{\text{Band}} \) could be an “average” of the spectral slopes below and above the break in GRBs fitted with Band function. We analyze the spectra of 27 (9) bright long (short) GRBs detected by the Fermi satellite finding a low energy break between 80 keV and 280 keV in 12 long GRBs, but in none of the short events. Through spectral simulations we show that if the break is moved closer (farther) to the peak energy a relatively harder (softer) \( \alpha_{\text{Band}} \) is found by fitting the simulated spectra with the Band function. The hard average slope \( \alpha_{\text{Band}} \approx -0.38 \) found in short GRBs suggests that the break is close to the peak energy. We show that for 15 long GRBs best fitted by the Band function only, the break could be present, but it is not identifiable in the Fermi/GBM spectrum, because either at low energies, close to the detector limit for relatively soft \( \alpha_{\text{Band}} \leq -1 \), or in the proximity of the energy peak for relatively hard \( \alpha_{\text{Band}} \geq -1 \). A spectrum with two breaks could be typical of GRB prompt emission, though hard to identify with current detectors. Instrumental design such that conceived for the THESEUS space mission, extending from 0.3 keV to several MeV and featuring a larger effective area with respect to Fermi/GBM, can reveal a larger fraction of GRBs with a spectral energy break.

Key words. gamma-ray burst: general

1. Introduction

The prompt emission spectra of Gamma-Ray Bursts (GRBs) are usually described by empirical functions. The most commonly used is the Band function (Band et al. 1993), which consists of two smoothly-connected power-laws \( N(E) \propto E^{\alpha_{\text{Band}}} \) and \( N(E) \propto E^{\beta_{\text{Band}}} \) describing the photon spectrum at low and high energies, respectively. Spectral studies of long GRBs (LGRBs; i.e. observed duration > 2 seconds; Kouveliotou et al. 1993) detected by the Burst And Transient Source Experiment (BATSE) on board the Compton Gamma Ray Observatory (CGRO) showed that, on average, \( \alpha_{\text{Band}} \approx -1, \beta_{\text{Band}} \approx -2.3 \) and the \( E^2 N(E) \) spectral energy distribution peaks at \( E_{\text{peak}} \approx 300 \text{ keV} \) (Kaneko et al. 2006). Similar results were obtained by spectral studies of GRBs detected by the Fermi Gamma-ray Burst Monitor (GBM; Gruber et al. 2014; von Kienlin et al. 2020; Nava et al. 2011) and the BeppoSAX Gamma-Ray Burst Monitor (GRBM; Frontera et al. 2009). Short GRBs (SGRBs) have on average a harder

\[ \alpha_{\text{Band}} \approx -0.6 \] (Ghirlanda et al. 2004, 2009) and a larger observed peak energy.

Recently, in a sizable fraction of LGRBs detected simultaneously by the Burst Alert Telescope (BAT) and the X-Ray Telescope (XRT) aboard the Neil Gehrels Swift Observatory (hereafter Swift), and in the brightest GRBs detected by Fermi/GBM it was found that (a) a low energy spectral break is present, between \( \sim 1 \) and few hundreds keV, and (b) the slopes of the power-law below and above this break are consistent with the values expected from synchrotron emission (Oganesyan et al. 2017, 2018; Ravasio et al. 2018, 2019). The consistency of GRB spectra with synchrotron emission was also proved by direct fits with a synchrotron model (Oganesyan et al. 2019; Chand et al. 2019; Burgess et al. 2020; Ronchi et al. 2020). The interpretation of these results within the leptonic synchrotron scenario is quite challenging, requiring a small magnetic field (\( \sim 10 \) G) and a large dissipation radius (10^{16–17} cm) (Kumar & McMahon 2008; Daigle et al. 2011; Beniamini & Pirani 2013; Oganesyan et al. 2019; Ronchi et al. 2020). Synchrotron emission from protons

1 Accounting for the different redshift distributions, the peak energy of short and long become similar.
has been proposed as a possible solution (Ghisellini et al. 2020), but the matter is still under debate (Florou et al. 2021).

While the presence of a low energy spectral break has been identified in a subsample of GRBs, a sizable fraction of GRB spectra are well fitted by single break functions where the break energy corresponds to $E_{\text{peak}}$. If the presence of an additional break located at lower energies is a common feature in GRB spectra, its non detection could be due to several factors. For spectra with a low signal-to-noise (S/N) ratio the identification of a change in slope might be difficult. Also, if the break is either close to the peak energy or below the low energy edge of the instrument sensitivity, a spectral fit would be unable to identify the break. Burgess et al. (2015) studied how the Band function fits spectra simulated assuming a synchrotron or a synchrotron plus black–body model.

In this work we investigate the possibility that the low energy spectral break is a common feature in GRB spectra, and that the average spectral index $\alpha_{\text{Band}} \sim -1$ is an average value between the two power-law segments below and above the break energy. To this aim we analyze bright long and short GRBs detected by Fermi (§2.3) in search for a statistically significant evidence of the low energy spectral break. Through spectral simulations we study how the value of $\alpha_{\text{Band}}$ becomes relatively harder (softer) by moving the break closer to (farther from) the peak energy (§4). We derive (§4.2) limits on the possible location of the break energy in GRBs whose spectrum is best fitted by the Band function (i.e. with no evidence of a break). We discuss and summarize our results in §5.

2. The sample

To perform our investigation, we need first to characterize the low energy part of GRB spectra, searching for possible spectral breaks like those recently reported in a number of events. To this aim, we select GRBs detected by the GBM (8 keV–40 MeV; Meegan et al. 2009) and apply selection criteria that maximize the probability to i) perform reliable spectral analysis and ii) identify the presence of a spectral break at low energies, well distinguished from the spectral peak energy. This can be achieved by selecting GRBs with large fluence and large $E_{\text{peak}}$ values, as they have better chances to display the low energy break $E_{\text{break}}$ within the sensitivity energy range of the GBM, given that their typical separation is $E_{\text{break}}/E_{\text{peak}} \sim 0.1$ (Ravasio et al. 2019).

For these reasons, from the online Fermi catalog, which contains 2669 GRBs up to April 2020, we select LGRBs\(^2\) with fluence $> 10^{-4}$ erg cm$^{-2}$ (integrated over the 10–1000 keV energy range) and observed peak energy $E_{\text{peak}} > 300$ keV, and SGRBs with fluence $> 5 \times 10^{-6}$ erg cm$^{-2}$ and $E_{\text{peak}} > 300$ keV. This selection is based on the values of fluence and peak energy reported in the catalog and corresponding to the fit of the time-integrated spectrum with the Band function. We excluded GRB 090902B since the presence of a power-law component (in addition to a multi–temperature black body - Ryde et al. 2010; Liu & Wang 2011; Pe'er et al. 2012), hampers the identification of the spectral break at low energies. Our selection results in 27 long and 9 short GRBs.

3. Spectral analysis

The Fermi/GBM consists of 12 sodium iodide (NaI - 8–1000 keV) and 2 bismuth germanate (BGO - 0.2–40 MeV) detectors. For each burst we analyzed the data from two NaI detectors and one BGO, selected as those with the smallest GRB position angle with respect to the detector normal.

We used the public tool gtburst\(^4\) to retrieve spectral CSPEC data from the Fermi Data Server.\(^5\) We extract the time integrated spectrum over the time interval $T_{90}$ reported in the Fermi catalog. In the case of GRB 130427A and GRB 160625B, which have a multi-peaked, long-duration light curve, we consider the brightest portion of the light curve by selecting the time intervals 3.0 – 15 s and 188 – 210 s, respectively.\(^6\) The background spectrum has been estimated by selecting two time intervals before and after (far from) the GBM emission episode. The latest detector response matrices for each event were obtained through gtburst.

Standard energy selections\(^7\) for the analyzed spectra were applied (8–900 keV for NaI and 0.3–40 MeV for BGO) and the 30-40 keV range was excluded to avoid contamination of inaccurate modeling of the Iodine K-edge line at 33.17 keV in the response files. The spectral data of the two NaI and one BGO were fitted together accounting for an inter-calibration constant parameter.

The extracted spectra were analyzed with XSPEC\(^8\) (v12.10.1). All spectra were fitted with two different spectral models:

- the Band function (Band et al. 1993), often used to fit GRB spectra (Preece et al. 1998; Kaneko et al. 2006; Ghirlanda et al. 2002; Nava et al. 2011b; Sakamoto et al. 2011; Gruber et al. 2014; Yu et al. 2016; Lien et al. 2016; Goldstein et al. 2012; Frontera et al. 2000):

$$N(E) \propto \begin{cases} E^{\alpha} e^{-E/E_2^n}, & \text{if } E \leq (\alpha - \beta)E_0 \\ \left[(\alpha - \beta)E_0\right]^{(\alpha - \beta)E_0 e^{(\beta - \alpha)E_0}}, & \text{if } E > (\alpha - \beta)E_0 \end{cases}$$

(1)

where $\alpha$ and $\beta$ are the photon indices of the power-laws below and above, respectively, the e-folding energy $E_0$. $N(E)$ has units of ph cm$^{-2}$ s$^{-1}$ keV$^{-1}$. For $\beta < 2 < \alpha$ the spectrum in the $E^2 N(E)$ representation peaks at $E_{\text{peak}} = E_0(\alpha + 2)$.\(^3\)

- the double smoothly-broken power law function (2SBPL hereafter, Ravasio et al. 2018):

$$N(E) \propto \left[\left(\frac{E}{E_{\text{break}}}\right)^{-\alpha_1 n_1} + \left(\frac{E_{\text{break}}}{E}\right)^{-\alpha_2 n_2}\right]^{-1/n_1}$$

(2)

$$E_j = E_{\text{peak}} \cdot \left(\frac{\alpha_2 + 2}{\beta + 2}\right)^1 \left[\left(\frac{E_j}{E_{\text{peak}}}\right)^{-\alpha_1 n_1} + \left(\frac{E_{\text{peak}}}{E_j}\right)^{-\alpha_2 n_2}\right]^{-1/n_2}$$

(3)

where $E_j$ and $E_{\text{peak}}$ are the peak of the $vF_v$ spectrum and the break energy, respectively. The parameters $\alpha_1$ and $\alpha_2$ are

Article number, page 2 of 10
the power-law indices below and above the break energy, $\beta$ is the power-law index above the peak energy. The parameters $n_1$ and $n_2$ set the sharpness of the curvature around $E_{\text{break}}$ and $E_{\text{peak}}$, respectively. Following Ravasio et al. (2019), we assumed $n_1 = n_2 = 2$.

In the following, in order to distinguish the spectral parameters of these two fitting functions, we call $\alpha_{\text{Band}}$ and $\beta_{\text{Band}}$ the photon indices of the Band function and $\alpha_{1,2\text{SBPL}}$ and $\alpha_{2,2\text{SBPL}}$ the photon indices of the 2SBPL below the peak energy and $\beta_{2\text{SBPL}}$ above it.

The large number of counts of the extracted spectra allow us to fit the spectra and search for the best fit parameters by minimizing the $\chi^2$ statistics. We adopt the Akaike Information Criterion (AIC - Akaike 1974) to compare the fits obtained with the 2SBPL and Band functions and choose the best one. We recall that $AIC = 2k - 2\ln(L)$, where $k$ is the number of free parameters in the model and $L$ is the maximum value of the likelihood function $L$ obtained by varying the free parameters. For Gaussian-distributed variables $\chi^2 \sim -2\ln(L)$. If $\Delta AIC = AIC_{\text{Band}} - AIC_{2\text{SBPL}} \geq 6$, the Band fit has $\lesssim 5\%$ probability of describing the observed spectrum better than the 2SBPL function (Akaike 1974); in such case, we consider the 2SBPL a better fit and thus consider the presence of a break as statistically significant at the 95% confidence level.

### 3.1. Fit results: best fit model

The fit results for LGRBs are reported in Table 1 and 2. The fit results for SGRBs are shown in Table 3. The errors on the parameters represent the $1\sigma$ confidence.

We find that:

- twelve (out of 27) LGRBs have a low energy break, i.e. their spectra are best fitted by the 2SBPL function ($\Delta AIC \geq 6$). The spectral parameters are reported in Table 1.
- the remaining fifteen LGRBs are well fitted by the Band function and, according to the AIC criterion, there is no improvement using the 2SBPL function. Their spectral parameters are reported in Table 2.
- all SGRBs are well fitted by the Band function. In six SGRBs we could only derive an upper limit on $\beta_{\text{Band}}$, indicating that also a cutoff power-law function could be a good fit to the spectra (see e.g. Ghirlanda et al. 2004).

In the LGRB 160509A, we find a well constrained $E_{\text{break}} \approx 80$ keV but the peak energy of the 2SBPL is undetermined by fitting the GBM data. Only in this case, we exploited the LAT Low Energy (LLE) data to better constrain the high-energy index $\beta$ and thus $E_{\text{peak}}$. With gtburst we extracted the time-integrated spectrum from the LLE data and performed a joint GBM-LLE spectral fit over the 10 keV–300 MeV energy range. Assuming an intercalibration normalization factor between LAT-LLE and NaI detectors of 1, we obtained an estimate of $E_{\text{peak}} \approx 2071$ keV for GRB 160509A (Table 1).

### 3.2. Fit results: spectral indices below $E_{\text{peak}}$

Figure 1 (top panel) shows the distribution of the spectral index $\alpha_{\text{Band}}$ for the entire sample. The blue histogram corresponds to LGRBs without the break and the green dashed histogram is for SGRBs (all without a break). For comparison it is also shown the distribution of $\alpha_{\text{Band}}$ for the 12 LGRBs whose spectrum is better fitted by the 2SBPL.

In the bottom panel of Fig. 1 we show the distributions of the indices $\alpha_{1,2\text{SBPL}}$ (red) and $\alpha_{2,2\text{SBPL}}$ (violet) for the 12 LGRBs best fitted by the 2SBPL (i.e. with identified low-energy spectral break). The characteristic values (mean, median and $1\sigma$ dispersion) of the distributions in Fig. 1 are reported in Table 4 and 5.

From the comparison of the distributions shown in Fig. 1 we find that:

1. SGRBs (green dashed histogram) have a harder spectral slope $\alpha_{\text{Band}}$ than LGRBs without a break (blue histogram). A Kolomogorov-Smirnov (KS) test among the two distributions returns a $p$-value of 0.004, rejecting the null hypothesis of being drawn from the same underlying distribution. This is consistent with previous studies (Ghirlanda et al. 2004, 2009).
2. the value of $\alpha_{\text{Band}}$ for LGRBs with a break (orange histogram in Fig. 1 top panel) is on average harder (see Table 4) than the value for LGRBs with no break (blue histogram). However, the two distributions are not distinguishable (a KS test between the orange and blue distributions has a chance probability $p = 0.08$).
3. the distributions of $\alpha_{1,2\text{SBPL}}$ and $\alpha_{2,2\text{SBPL}}$ (red and violet histograms in Fig. 1 bottom panel) are peaked at $-0.71$ and $-1.71$, not far from the typical values $-2/3$ and $-3/2$ expected through the error method built in XSPEC

9 through the error method built in XSPEC
10 https://heasarc.gsfc.nasa.gov/W3Browse/fermi/fermille.html
11 For all the statistical tests we have set the significance level at 0.05, i.e. we accept the null hypothesis if $p > 0.05$.

The parameters obtained by fitting a Band function are shown in column 2 for comparison. The parameters concerning the Band function (columns 2 - 4) and the 2SBPL function (columns 5 - 9) are defined in Eqs. (1) and (2), respectively. The reduced $\chi^2$ values (3) and the AIC for each fit are shown in columns 10 - 13. Both errors and upper limits are calculated at 1σ confidence level. Energies are expressed in keV.
for synchrotron spectrum from marginally fast cooling electrons;

Table 2. Results of the fits for GRB best fitted by a Band function. Analysed GRBs are listed in column 1 (in parenthesis, the trigger name according to the Fermi catalog). The parameters regarding the Band function (columns 2 - 4) are defined in Eq. 1. The reduced $\chi^2$ statistics ($\chi^2_r$) and the AIC for each fit are shown in columns 5 – 6. Both errors and upper limits are calculated at 1$\sigma$ confidence level. Energies are expressed in keV.

| $\alpha_{2,2SBPL}$     | -1.71                       | -1.69             | [-1.82, -1.62]  |

Table 5. Characteristic values (mean, median and 68% interval) of the distributions of $\alpha_{1,2SBPL}$ and $\alpha_{2,2SBPL}$ shown in the bottom panel of Fig. 1 for the 12 LGRBs best fitted with the 2SBPL.

4. LGRBs without a break have an $\alpha_{\text{Band}}$ distribution slightly softer than $\alpha_{1,2SBPL}$ but harder than $\alpha_{2,2SBPL}$ (cfr. the blue histogram in the top panel with the red and violet histogram in
the bottom panel of Fig. 1 respectively). This might suggest that when the spectral data are not sufficient to constrain and identify a spectral break, the Band function returns a value of the low-energy index that is an average between the index $\alpha_{1,2SBPL}$ and $\alpha_{2,SBPL}$. This possibility will be investigated with simulations in the next section;
5. the distribution of $\alpha$ bands of SGRBs (green) is similar to the $\alpha_{1,2SBPL}$ distribution of LGRBs with break: a KS test between the two returns $p = 0.16$. This suggests that the power-law segment $\alpha_{2,SBPL}$ separating $E_{\text{break}}$ from $E_{\text{peak}}$ is not present in SGRBs, i.e. $E_{\text{break}} \sim E_{\text{peak}}$.

4. Origin of the value $\alpha_{\text{Band}} \sim -1$

The spectral analysis performed in this paper confirmed the presence of two classes of LGRBs: those requiring two-power-law segments ($\alpha_{1,2SBPL}$ and $\alpha_{2,SBPL}$) to describe the spectrum at energies $E < E_{\text{peak}}$, and those for which this part of the spectrum is well described by a single power-law ($\alpha_{\text{Band}}$). Since the values of $\alpha_{\text{Band}}$ are typically softer than $\alpha_{1,2SBPL}$ but harder than $\alpha_{2,SBPL}$, we investigate the possibility that spectra best fitted by Band are hiding a spectral break that is difficult to identify with a certain statistical significance due to the lack of enough signal at low energies, and/or to the proximity of $E_{\text{break}}$ to $E_{\text{peak}}$, and/or to the proximity of $E_{\text{break}}$ to the low energy edge of the GBM sensitivity. If this is correct, we would expect to see a dependence of $\alpha_{\text{Band}}$ on the values of $E_{\text{break}}$ and $E_{\text{peak}}$ and on their separation. Specifically, we expect that when the underlying spectrum has a break, the fit with the Band function would return a hard $\alpha_{\text{Band}} \sim \alpha_{1,2SBPL}$ when $E_{\text{break}} \sim E_{\text{peak}}$, and, conversely, a soft $\alpha_{\text{Band}} \sim \alpha_{2,SBPL}$ when $E_{\text{break}} \ll E_{\text{peak}}$. A strong correlation is not expected, as the value of $\alpha_{\text{Band}}$ should depend not only on the ratio $R_b = E_{\text{break}}/E_{\text{peak}}$, but also on the absolute value of $E_{\text{peak}}$ (or, equivalently, $E_{\text{break}}$), and also on the specific values of $\alpha_{1,2SBPL}$ and $\alpha_{2,SBPL}$. To better investigate this effect and its presence in the spectra, we performed a set of simulations that are described in the following sections.

4.1. Band function response to a spectral break

In this first subsection we investigate how the presence of a spectral break generally affects the results of a fit performed using the Band function. We simulate GRB prompt spectra with input model 2SBPL, keeping fixed all the parameters and varying solely $E_{\text{break}}$. The adopted input parameters are $\alpha_{1,2SBPL} = -0.65$, $\alpha_{2,SBPL} = -1.67$, $E_{\text{peak}} = 1000$ keV, $\beta_{2SBPL} = -2.5$. These input values have been chosen in order to reproduce a typical LGRB of our sample (see the fit results in §3). For these simulations, we use the GBM background and response matrix files from one of the GRBs in our sample. We verified that choosing different background and response matrix files belonging to any other GRB in our sample does not affect the simulation results.

Each simulated spectrum is then fitted with the input model (a 2SBPL with parameters free to vary) and also with a Band function. For each value of $E_{\text{break}}$, we repeated the simulation 200 times, obtaining (for each parameter and for the reduced chi-square) a distribution of values. From these distributions we extracted the mean value and its 68% confidence interval. Figure 2 shows the parameters returned by the Band fits as a function of the position of the energy break. This exercise is repeated for two different cases, with a rather high average S/N ratio.

12 calculated as $(s-b)/\sqrt{b}$, where $s$ and $b$ are the source and background estimated counts, respectively (see e.g. Dereli-Bégué et al. 2020). (~ 21, input parameters used for the 2SBPL function used for the simulations ($\alpha_{1,2SBPL},\alpha_{2,SBPL},E_{\text{peak}},\beta_{2SBPL}$) are marked by dashed horizontal lines. We distinguish the best fitting model according to our criterion based on the AIC (in Fig. 2 diamonds: 2SBPL, circles: Band).

The values of $\alpha_{\text{Band}}$ obtained fitting the simulated spectra with the Band function (orange symbols in the top panel) correlate with $E_{\text{break}}$: a low value of $E_{\text{break}}$ makes $\alpha_{\text{Band}} \approx \alpha_{2,SBPL}$. On the other hand, as $E_{\text{break}}$ increases (and approaches $E_{\text{peak}}$ which in this example is 1 MeV) $\alpha_{\text{Band}} \approx \alpha_{1,2SBPL}$. In between, the value of $\alpha_{\text{Band}}$ is an average of $\alpha_{1,2SBPL}$ and $\alpha_{2,SBPL}$, depending on the position of $E_{\text{break}}$. Given the presence of only a single break in the Band function (i.e. $E_{\text{peak}},\text{Band}$) also the other parameters ($\beta_{\text{Band}}$ and $E_{\text{peak}},\text{Band}$) depend on the position of the break: $\beta_{\text{Band}}$ (blue symbols) always assumes softer values compared to the input one, unless $E_{\text{break}} \sim E_{\text{peak}}$, $E_{\text{peak}},\text{Band}$ (green symbols) is an average of $E_{\text{break}}$ and $E_{\text{peak}}$ of the 2SBPL function and approaches the input value when $E_{\text{break}}$ is very low or when $E_{\text{break}} \sim E_{\text{peak}}$.

These results hold for both cases of the S/N. The main difference is in the uncertainties on the best fit parameters (larger for the case with lower S/N) and, most notably, on the behavior of the $\chi^2_r$. In the case with lower S/N, the $\chi^2_r$ of the Band fit is always acceptable (~ 1), no matter the value of $E_{\text{break}}$. This shows that, even though the input spectrum has a spectral break and this break falls within the GBM energy range, in a spectrum with a relatively low S/N the identification of the break is not possible, and the best fit model is a Band function. Note that a fluence of 3.5 $\cdot$ 10$^{-3}$ erg cm$^{-2}$ or less is representative of the majority of LGRBs detected by Fermi/GBM. If the S/N is increased by a factor of 10 (left-hand panel) the $\chi^2_r$ of the fit with the Band function depends on $E_{\text{break}}$: only when the break is at the very low energy end of the GBM spectral range ($E_{\text{break}} \leq 10$ keV) or close to $E_{\text{peak}}$ ($E_{\text{break}} \geq 500$ keV) the fit with the Band function returns an acceptable $\chi^2_r$. Despite the high S/N, in such cases the break is hardly identifiable ($\Delta \text{AIC} < 6$).

Finally, we notice that even when the Band function returns an adequate fit, (i.e. when $E_{\text{break}} \leq 10$ keV or $E_{\text{break}} \sim E_{\text{peak}}$) the resulting values of $\alpha_{\text{Band}}, R_b$ and $E_{\text{peak}},\text{Band}$ might largely deviate from the values of the input spectrum.

4.2. Spectral simulations: $R_b - \alpha_{\text{Band}}$ trend

In order to further investigate the $R_b - \alpha_{\text{Band}}$ trend, we focus first on the 12 LGRBs analyzed in this work that have a spectral break $E_{\text{break}}$. In Fig. 3 we show (orange symbols) their ratio $R_b = E_{\text{break}}/E_{\text{peak}}$ (from the fits of the 2SBPL) versus $\alpha_{\text{Band}}$ (from the fit of the same spectrum with the Band function). LGRBs with a break are located in the range $R_b \in [0.04, 0.5]$ and, if their spectra are fitted with the Band function, the resulting $\alpha_{\text{Band}}$ is in the range $\alpha_{\text{Band}} \in [-1.1, -0.2]$. A broad trend in the $R_b - \alpha_{\text{Band}}$ plane appears among the points. The Pearson correlation coefficient is 0.56 and the associated chance probability value $p = 0.05$.

For each of these GRBs, we simulated\footnote{Spectral simulation performed within XSPEC with the fakeit tool.} spectra with the 2SBPL function with parameter values fixed to the best fit values (reported in Table 1) except for $E_{\text{break}}$, that we vary between 0.01$E_{\text{peak}}$ and $E_{\text{peak}}$. For each GRB, we used the corresponding GBM background and response matrix files for the correspondingly different breaks and a S/N ratio that is approximately a factor 10 lower (~ 2.7, right-hand panel). They represent simulated spectra of a GRB with a fluence of $\sim 3.5 \cdot 10^{-4}$ erg cm$^{-2}$ and $\sim 3.5 \cdot 10^{-5}$ erg cm$^{-2}$, respectively.
Fig. 2. Band function parameters as a function of the position of the energy break $E_{\text{break}}$ of the 2SBPL function. Each plot shows the parameters of the Band function fitted to a series of spectra simulated assuming the 2SBPL function whose parameter values are marked by the horizontal dashed lines. Top: low-energy slope $\alpha_{\text{Band}}$ (orange symbols) and high-energy slope $\beta_{\text{Band}}$ (blue symbols); middle: energy peak $E_{\text{peak, Band}}$ (green symbols); bottom: fit $\chi^2$ (red symbols). Left: spectrum characterized by a $S/N \sim 21$ ($\text{fluence} \sim 3.5 \times 10^{-4} \text{erg cm}^{-2}$); right: spectrum characterized by $S/N \sim 2.7$ ($\text{fluence} \sim 3.5 \times 10^{-5} \text{erg cm}^{-2}$). Data is represented as circles when the best fitting model is Band, as diamonds when the best fitting model is 2SBPL.

In Fig. 3 we show, for each one of the 12 LGRBs, the corresponding $\alpha_{\text{Band}}$ returned by the fit with the Band function for each input value of $R_E$ (orange dashed line). These curves show that $\alpha_{\text{Band}}$ depends on the relative position between break and peak energy, with small ratios resulting in soft spectra and large ratios resulting in harder spectra, as expected. These simulations show that the value of $\alpha_{\text{Band}}$ is a “weighted” mean of the $\alpha_{1,\text{2SBPL}}$ and $\alpha_{2,\text{2SBPL}}$ slopes. Moreover, different curves show similar trend, showing that the different values of $E_{\text{peak}}$ and input $\alpha_{1,\text{2SBPL}}$ and $\alpha_{2,\text{2SBPL}}$ are responsible for the dispersion in the plane. The dispersion of the curves is similar to the dispersion in the real data.

From the tracks of the orange dashed lines shown in Fig. 3 we can speculate that, when the best fit model is a Band function, values of $\alpha_{\text{Band}}$ harder than $\sim -1.0$ could be consistent with the presence of an $E_{\text{break}}$ in the proximity (i.e. till one order of magnitude lower) of $E_{\text{peak}}$, while values softer than $\sim -1.0$, could indicate the presence of $E_{\text{break}}$ far from (i.e. more than one order of magnitude lower than) $E_{\text{peak}}$. This possibility is investigated in the next section, through spectral simulations.

4.3. Spectral simulations: origin of the spectra without a low-energy break

Fifteen LGRBs in our sample do not show the presence of a low-energy spectral break. Through spectral simulations, we now propose to investigate if it is still possible for these GRBs to have a low energy break, even though the best fit model is a simple Band function. The simulation now assumes that also in these 15 GRBs the spectrum has the shape of the 2SBPL function and infers constraints on its parameters by requiring that the fit with the Band function is not only acceptable but also preferred over a 2SBPL, and returns as best fit values the same values as the real spectrum.

Based on the trend found between $R_E$ and $\alpha_{\text{Band}}$, we would expect that if the spectrum is intrinsically a 2SBPL and $E_{\text{break}}$ lies at low energies, the Band function could adequately fit the...
Fig. 3. The twelve LGRBs best fitted by a 2SBPL (Table 1) are shown with orange symbols. Their value of $R_E = E_{\text{break}} / E_{\text{peak}}$ is shown vs. the value of the index $\alpha_{\text{Band}}$ that is obtained by fitting their spectrum with a Band function. SGRBs (whose spectrum is always best fitted by the Band function) are here represented assuming that, if the underlying spectrum were 2SBPL, it should have $E_{\text{break}} \sim E_{\text{peak}}$ (green symbols). The orange dashed lines show the results of simulations (see §4.2); blue arrows represent the upper and lower limits on $R_E$ for the 15 LGRBs whose spectra are best fitted by Band (see §4.3).

simulated spectrum and result in $\alpha_{\text{Band}} \sim \alpha_{2,\text{SBPL}}$. Similarly, if the spectrum is intrinsically a 2SBPL and $E_{\text{break}}$ lies close to $E_{\text{peak}}$, the Band function could return $\alpha_{\text{Band}} \sim \alpha_{1,\text{SBPL}}$. For each burst the spectra simulated with the 2SBPL function maintain the same fluence of the real GRB.

We repeat the simulations for different values of the 2SBPL parameters. In particular:

- $\alpha_{1,\text{SBPL}}$ is sampled uniformly within the range $\alpha_{1,\text{SBPL}} \in [-0.6, -0.87]$ with steps of 0.03;
- $\alpha_{2,\text{SBPL}}$ is sampled uniformly in the interval $\in [-1.1, -1.9]$ with steps of 0.03;
- $E_{\text{break}}$ is sampled between 2 and 50 keV with steps of 2 keV;
- $\beta_{\text{SBPL}}$ is fixed to the value obtained from the fit with the Band function.

For each combination of parameters, we simulate 10 spectra. We assume the background and response matrix files of each GRB for these simulations. They are then refitted with both the 2SBPL and Band functions. From the built parameter distributions we derive the mean values and 68% confidence interval.

Once we refit the spectrum with a Band function we accept the simulation if the Band fit satisfies the following conditions:

- it is statistically equivalent to the fit with the 2SBPL, i.e. $\Delta \text{AIC} < 6$;
- its $\alpha_{\text{Band}}$ and $\beta_{\text{Band}}$ are consistent, within 1$\sigma$, with the values inferred from the real spectrum;
- its $E_{\text{peak}}$ is consistent, within 3$\sigma$, with the value inferred from the real spectrum.

For each of the 15 LGRBs which do not explicitly show a break, we find a significant number of parameters’ combinations for which the 2SBPL functions were able to satisfactorily reproduce the real spectrum.

In particular, for all these LGRBs we are able to set either a plausible maximum or minimum value for $E_{\text{break}}$ and constrain either $\alpha_{2,\text{SBPL}}$ or $\alpha_{1,\text{SBPL}}$ in an interval. These are represented with the blue arrows in Fig. 3. The limits for $E_{\text{break}}$ and the low-energy slopes intervals are listed in Table 6 and Table 7.

5. Discussion and Conclusions

The prompt emission spectra of long GRBs are often fitted with the Band function, two power laws smoothly joined at the $\nu F_\nu$.
peak. The low energy index (below the peak energy $E_{\text{peak}}$), $\alpha_{\text{Band}} \sim -1$ has been argued as an argument against the interpretation of the prompt emission as synchrotron (see e.g. Preece et al. 1998; Frontera et al. 2000; Ghirlanda et al. 2002). Recently different groups identified a break, $E_{\text{break}}$, at low energies below $E_{\text{peak}}$ (Oganesyan et al. 2017, 2018, 2019; Ravasio et al. 2019) and this work. The horizontal lines indicate the observational energy range of the instrumentation aboard THESEUS.

According to these works, the prompt emission spectra of the brightest GRBs can be described with three power laws (with indexes $\alpha_{\text{1SBPL}}$, $\alpha_{\text{2SBPL}}$, and $\alpha_{\text{Band}}$) smoothly joined at the two breaks, namely $E_{\text{break}}$ and $E_{\text{peak}}$.

If the spectrum is a 2SBPL, our simulations described in §4.1 show that when $E_{\text{break}}$ is close to $E_{\text{peak}}$ or below the low energy threshold ($E_{\text{min}}$) of the instrument, the Band function gives $\alpha_{\text{Band}} \sim \alpha_{\text{2SBPL}}$ and $\alpha_{\text{Band}} \sim \alpha_{\text{1SBPL}}$, respectively. Values of $\alpha_{\text{Band}} \sim -1$ correspond to $E_{\text{break}}$ between $E_{\text{min}}$ and $E_{\text{peak}}$. Through the spectral analysis of sample of GRBs, selected with different criteria, Burgess et al. (2020) find that, when $E_{\text{break}} \leq E_{\text{peak}}$, the values of $\alpha_{\text{Band}}$ are distributed approximately in $[-1.7, -0.5]$. We argue that, if the break is a common feature of GRB spectra, the value of $\alpha_{\text{Band}}$ is a proxy of its position with respect to $E_{\text{peak}}$.

This hypothesis is verified through the spectral analysis of a sample of 27 long and 9 short GRBs selected, within the Fermi sample, with large fluence and large $E_{\text{peak}}$ ($\gtrsim 4 \times 10^{46}$ erg cm$^{-2}$) in order to ease the search of $E_{\text{break}}$ if present. In 12/27 long GRBs we find $E_{\text{break}}$ i.e., the 2SBPL better fits the data with respect to Band. Using these events as templates, through spectral simulations, we find that if the break is moved within the range delimited by $E_{\text{peak}}$ and $E_{\text{min}}$, the fit with Band results in a softer (if $E_{\text{break}}$ departs from $E_{\text{peak}}$) or harder (if $E_{\text{break}}$ approaches $E_{\text{peak}}$) low energy index $\alpha_{\text{Band}}$ (dashed orange lines in Fig. 5). At the extreme the values of $\alpha_{\text{1SBPL}}$ and $\alpha_{\text{2SBPL}}$ are found. Indeed, none of the short GRBs analyzed has a break but a relatively hard $\alpha_{\text{Band}}$ which we suggest corresponds to $E_{\text{break}}$ lying close to $E_{\text{peak}}$. Through dedicated spectral simulations (§4.3) we show that the 15 long GRBs best fitted by the Band function only (i.e. apparently without a break) could instead have a break close to $E_{\text{peak}}$, corresponding to $\alpha_{\text{Band}} \sim -1$ (upward arrows in Fig. 5), or close to $E_{\text{min}}$ if $\alpha_{\text{Band}} < -1$ (downward arrows in Fig. 5).

Our analysis suggests that the low energy break could be a feature more common than what can be inferred by direct spectral analysis. Indeed, the identification of the break in the spectra of GRBs detected by Fermi or Swift, now possible only for a limited number of events (shown in Fig. 5), is hampered by 1) the separation of $E_{\text{break}}$ from $E_{\text{peak}}$ and 2) the spectral signal-to-noise ratio. We have shown (right panel of Fig. 5) that a burst with a typical fluence (e.g. $5 \times 10^{46}$ erg cm$^{-2}$) detected by Fermi/GBM can be fitted by Band even if it has an additional break. These effects concur to explain why in approximately half of the selected GRBs we could not find $E_{\text{break}}$ but, through simulations, we could set an upper/lower limit to its possible value.

With the currently available instruments, Swift and Fermi, it was possible to find $E_{\text{break}}$ in a limited number of GRBs and with $E_{\text{break}}$ at X-ray ($\lesssim 10$ keV) and γ-ray ($\sim$ tens - hundreds keV) energies (Fig. 4). A few values of $E_{\text{break}}$ between 10 and 100 keV are found.

Our results (Fig. 5 - bottom panel) show that the distributions of $\alpha_{\text{1SBPL}}$ and $\alpha_{\text{2SBPL}}$ are close to but slightly softer than the values predicted by synchrotron emission in moderate fast cooling regime (Daigne et al. 2011), i.e. -3/2 and -2/3, respectively. This is partly due to our fits with the 2SBPL function rather than with the synchrotron model (see e.g. Burgess et al. 2015; Burgess et al. 2020) and to the fact that we analyze time integrated spectra to exploit the largest S/N ratio in search of $E_{\text{break}}$. Time resolved spectral analysis, indeed, often finds harder spectral slopes (Nava et al. 2011; Acciari & Rhode 2017) and, as shown by Ravasio et al. (2019), the distributions of $\alpha_{\text{1SBPL}}$ and $\alpha_{\text{2SBPL}}$ are closer to the typical synchrotron values.

### Table 6.

| Name            | $\alpha_{\text{1SBPL}}$ Range | $E_{\text{break}}$ Max |
|-----------------|-------------------------------|------------------------|
| 090323(002)     | $[-1.48, -1.18]$              | 30                     |
| 130504(978)     | $[-1.42, -1.18]$              | 12                     |
| 130606(497)     | $[-1.24, -1.12]$              | 12                     |
| 140206(275)     | $[-1.60, -1.36]$              | 18                     |
| 170210(116)     | $[-1.37, -1.14]$              | 24                     |
| 170527(480)     | $[-1.34, -1.15]$              | 24                     |

### Table 7.

| Name            | $\alpha_{\text{1SBPL}}$ Range | $E_{\text{break}}$ Min |
|-----------------|-------------------------------|------------------------|
| 090926(181)     | $[-0.83, -0.80]$              | 220                    |
| 100414(997)     | $[-0.68, -0.54]$              | 126                    |
| 101123(952)     | $[-1.02, -0.94]$              | 182                    |
| 120526(303)     | $[-0.90, -0.83]$              | 372                    |
| 120624(933)     | $[-1.05, -0.93]$              | 320                    |
| 120711(115)     | $[-0.95, -0.84]$              | 440                    |
| 130306(991)     | $[-0.98, -0.72]$              | 86                     |
| 160905(471)     | $[-0.90, -0.84]$              | 572                    |
| 170214(649)     | $[-0.92, -0.86]$              | 157                    |

$E_{\text{min}}$, the fit with Band results in a softer (if $E_{\text{break}}$ departs from $E_{\text{peak}}$) or harder (if $E_{\text{break}}$ approaches $E_{\text{peak}}$) low energy index $\alpha_{\text{Band}}$ (dashed orange lines in Fig. 5).
With the Transient High-Energy Sky and Early Universe Surveyor (THESEUS) mission (Amati et al. 2018, Amati et al. 2021) proposed to ESA within the M5-class selection call, we expect that the spectral break will be detected in a larger fraction of events (Ghirlanda et al. 2021). The large effective area and the wide energy range covered by the two instruments on board THESEUS, Soft X-ray Imager (SXI, 0.3-5 keV) and X-Gamma rays Imaging Spectrometer (XGIS, 2 keV–few MeV), will provide us prompt emission spectra with high statistics from which $E_{\text{break}}$ will be measured over a wider fluence range than what is now possible.
