Abstract. It is shown that the slow glitches in the spin rate of the pulsar B1822-09 can be explained by the reconstruction of the neutron star shape, which is not matched with the star rotation axis. Owing to the evolution of the inclination angle, i.e., the angle between the rotation axis and the axis of the 1agnetic dipole, under the action of the braking torque, there appears the disagreement between the rotation axis and the symmetry axis. After the angle between the axis of symmetry and the axis of the rotation achieves the maximum value of $\alpha \approx 2 \cdot 10^{-4}$, the shape of the neutron star becomes matching with the rotation axis. Such reconstruction is observed as the slow glitch.

However, it is clear that to notice during the observation time $\approx 10 - 20$ years the change of the inclination on the value of $10^{-9} \mathrm{rad} \approx 0.002$ is impossible. Thus, there exist only indirect conclusions about inclination angle evolution. They are based on the statistic of the distribution of pulsars over the value of $\chi$. But because we do not know this distribution at the birth time, and due to the selection effects we can’t now do the definite conclusion about inclination angle evolution.

Our work demonstrates the possibility to watch the changes of $\chi$ on the value of $2'$ during the time $\approx 10 \mathrm{years}$ though slow glitches observed from the pulsar B1822-09.

1. Introduction

All radio pulsars are known to retard their rotation. Periods of the rotation $P$ are gradually increasing with the rate of the order of $\dot{P} \approx 10^{-15} \mathrm{s}/\mathrm{s}$. As a result during the time $P/\dot{P} \approx 10^7 \mathrm{years}$ the rotation period becomes twice larger. At the same time the inclination angle $\chi$ – the angle between the rotation axis and the axis of the magnetic dipole – must changes also. The characteristic time of the evolution of the $\chi$ is the same as for the rotation period $P$. The change of the inclination angle is of $\approx 1$ during the evolution time. Change of the value of $\chi$ is due to the torque acting on the star is not parallel to the rotation axis. This torque not only retards the rotation but also turns the rotation axis in space. Increasing or decreasing of the $\chi$ depends on the mechanism of a neutron star energy losses. The angle $\chi$ approaches to the value when the energy losses are minimal. For the magnetodipole losses, if a pulsar radiates the electromagnetic magnetodipole waves, the angle $\chi$ goes to the zero value when the radiation is absent. Opposite, for the current losses, if a pulsar spends its energy for the creation and acceleration of plasma in a magnetosphere, and a star’s spin down is due to the electric currents flowing in a magnetosphere and closing on a star’s surface, the angle $\chi$ approaches to the value of $90^\circ$. In this case the electric current is minimal.

2. Observed properties of slow glitches from the pulsar B1822–09

The pulsar B1822–09 has the period $P = 0.769 \mathrm{s}$ ($\nu = 1/P = 1.3 \mathrm{s}^{-1}$), the period derivative $\dot{P} = 52.36 \times 10^{-15}$. It is the young pulsar with the age of $P/2\dot{P} \approx 2.3 \times 10^5 \mathrm{years}$. The pulsar observations during the time of 21 years at Puschino Radio Observatory show two class of the period variations. They are pulsar noise and glitches. The pulsar B1822-09 reveals the new kind of glitches unknown before – slow glitches (Shabanova 2005).

Figure 1 shows the frequency first derivative $\dot{\nu}$ and frequency residuals $\Delta \nu$ for PSR B1822-09 from 1985 to 2006. The local fits were performed over intervals of 200 days. The figure 1(b) presents the frequency residuals with respect to the simple spin down model based on the initial parameters of $\nu$ and $\dot{\nu}$, determined from 1991 to 1994. The narrow indicates the time at which the usual glitch of the magnitude $\Delta \nu/\nu = 8 \times 10^{-10}$ was observed. This moment divides the observations on two parts. After that time we observe three slow glitches.

During the interval from 1985 to 1994 we observed the distinct linear decreasing of the first derivative of the period. The value of the second derivative is $\ddot{\nu} = 9 \times 10^{-25} \mathrm{s}^{-3}$. The data from 1995 to 2006 show three jumps of values of $\dot{\nu}$ and $\Delta \nu$, which can be called as slow. The characteristic property of slow glitches is the gradual increasing of the rotation frequency during 200–300 days without subsequent relaxation. The increasing
3. Connection between the inclination angle and slow glitches

3.1. Reconstruction of a star’s shape

The neutron star shape has no the spherical symmetry. Due to the fast rotation its extension across the rotation axis is larger than that along. As a result the tensor of inertia of a star $J_{n\beta}$ has no equalled diagonal components. The value of $J_{zz}$ (the axis $z$ is directed along the rotation axis) is little larger than the components which are perpendicular to the rotation axis $J_{\perp\perp}$: $J_{zz} = J$, $J_{\perp\perp}$ = $J - \delta J$, $\delta J \ll J$. The ratio $\delta J/J$ is of the order of the ratio of the centrifugal force to the gravitation force

$$\frac{\delta J}{J} \approx \frac{\Omega^2}{G\rho_n}.$$ 

Here $\Omega$ is the frequency of a star’s rotation, $G$ is the gravitation constant, $\rho_n$ is a star’s density. Substituting the standard value of a neutron star density $\bar{\rho} = 5 \times 10^{14}$ g cm$^{-3}$, we obtain

$$\frac{\delta J}{J} \approx 1.2 \times 10^{-6} P^{-2} \left( \frac{\bar{\rho}}{\rho_n} \right).$$

If the inclination angle changes then the rotation axis deflects from the symmetry axis $z$ (the magnetic field is frozen to the star’s body). The axis of rotation begins to precess around the symmetry axis. That is described by relations $\Omega_x = \Omega \sin \alpha \cos \Phi$; $\Omega_y = \Omega \sin \alpha \sin \Phi$; $\Omega_z = \Omega \cos \alpha = \text{const}(t)$; $d\Phi/dt = \Omega \cos \alpha (\delta J/J)$, from which the period of precession $P_{pr}$ follows $P_{pr} = P(\delta J/J) \cos \alpha \approx 0.83 \times 10^6 P^3 (\rho_n/\bar{\rho}) (\cos \alpha)^{-1}$. For the pulsar B1822-09, which has the period $P = 0.769$ s, the precession period is equal to ($\alpha \ll 1$): $P_{pr} \approx 3.8 \times 10^5$ s = 4.4 days. This time is significantly less than the pulsar’s age $P/P = 1.5 \times 10^{13}$ s = 5 $\times 10^5$ years and the observation time. Averaging over the precession period $P_{pr}$, we get $< \Omega > = \Omega_z e_z$. The observed period is equal to $P = 2\pi/\Omega_z$.

The torque acting on the star results the spin down of a star ($P > 0$) and also changing of the inclination angle $\chi$. As a result the angle $\alpha$ increases. The star’s shape, initially matched with the rotation axis, becomes asymmetric with respect to the instant axis of rotation. The star, rotating around the axis not coinciding with the axis of symmetry, undergoes the stress. This stress intends to reconstruct the star’s shape in order to match it with the rotation axis. At $\alpha \neq 0$ the part of the centrifugal force is not compensating by the gravitation force. So, there exists the force directing tangent to the surface of constant density (see figure 2).

The force density $f$, acting on the unit volume, is $f = \rho_n \Omega^2 r_o$, where $r$ is the distance from the axis of rotation. The arising tangent stress equals $\tau = F/s = \alpha \Omega^2 \rho_n (h'/R - h') dh'$ (here $R$ is the star’s radius). The stress $\tau$ will intend to deflect the star matter column on
crust $\sigma(\rho_n)$. The elastic limit $\sigma$ is proportional to the value of $E$ and is of the small part of it, $\sigma(\rho_n) = \sigma_s(\rho_n/\rho_s)^{4/3}$ ($\sigma \approx 10^{-3}E$ on the Earth at the room temperature). The value $\sigma_s$ is the elastic limit for the neutron star crust at its surface. The condition $\tau = \sigma$ defines the limiting value of the angle $\alpha_1$ at which the crust matter will move under the action of stress. After that the star shape becomes symmetric with respect the rotation axis.

$$
\alpha_1 = \frac{\sigma_s}{\Omega^2 \rho_s RH} \int_0^h (1 + x^3)^{4/3} \frac{1}{(1 - \beta x)(1 + x^3)} dx',
$$

where $x = h/H$, $\beta = H/R \approx 10^{-3} \ll 1$. The right hand side of this expression has the minimum at $x = 2^{-1/3}$. This minimum does define the limiting value of the angle $\alpha_{cr}$. At this value of $\alpha$ the star will reconstruct its shape, and the matter motion will be mainly at the depth $h \approx 0.8H$,

$$
\alpha_{cr} = 1.9 \frac{\sigma_s}{\Omega^2 \rho_s RH}.
$$

The value of the plastic limit $\sigma$ depends strongly on the matter temperature. More exactly, on the ratio of the binding energy of atoms to the temperature. This ratio is proportional to the quantity $\rho_n^{-1/3}/T$. The matter density on the star’s surface $\rho_s \approx 10^5 g/cm^3$ is much greater than that for metals on the Earth $\rho_0 \approx 10^3 g/cm^3$. The star surface temperature is also much higher, $T \approx 10^6 K$.

So, the parameter $\rho_s^{-1/3}/T$ is of the order less than that for the Earth conditions, $\rho_0^{-1/3}/T_0 \approx 300 K$, namely $\rho_s^{-1/3}/T \approx 6.5 \times 10^{-2}(\rho_0^{-1/3}/T_0)(T/10^6 K)^{-1}$. Such value of the binding parameter corresponds to the strongly heating body, for which the plastic limit $\sigma$ is at least of the order less than that for the room temperature. Because of that we adopt the following value for $\sigma_s, \sigma_s \approx 10^{12} din/cm^2$. The obtained estimation of the critical value of the angle between the axis of rotation and the symmetry axis for the pulsar B1822-09 is $\alpha_{cr} \approx 2 \times 10^{-4}$. The angle $\alpha$ can not exceed this limit. During the evolution of the inclination angle $\chi$ the angle $\alpha$ increases from zero to $\alpha_{cr}$. Then, the crust reconstructs, and the angle $\alpha$ returns to zero value. This reconstruction is observed as a slow glitch.

### 3.2. Change of the star rotation frequency after the glitch

Let us discuss the behavior the star rotation frequency after the glitch. The value of $\Omega$ after the reconstruction $\Omega'$ can be determined form the condition of angular momenton conservation $J_{\Omega_0} = const$. After the glitch the angular velocity is directed along the symmetry axis, i.e. $J_{\alpha_{cr}} \Omega_{\alpha'} = J \Omega_{\alpha}'$. Thus, $\Omega_{\alpha} = \Omega(1 - \delta J/J) \sin \alpha \cos \Phi; \Omega_{\alpha'} = \Omega(1 - \delta J/J) \sin \alpha \sin \Phi; \Omega_{\alpha'} = \Omega \cos \alpha$. Here the quantity $\Omega$ is the star rotation frequency before the glitch. Let remind that the mean rotation frequency before the glitch is $< \Omega > = 2\pi / P = \Omega \cos \alpha$. Calculating of $\Omega'$, we
find the change of the star rotation $\Delta \Omega = \Omega' - \Omega = \Omega(\alpha^2/2)(1 - 2\delta J/J) \approx \Omega(\alpha^2/2)$. So,
\[
\frac{\Delta \Omega}{\Omega} = \frac{\alpha^2}{2} > 0.
\]
Indeed, the observed jumps $\Delta \Omega$ for PSR B1822-09 are positive and are of the order of $\Delta \Omega/\Omega \approx 10^{-8}$. These values are consistent with the estimation $\alpha_{cr} \approx 10^{-4}$, obtained above.

### 3.3. The rate of the inclination angle change

To achieve the value $\alpha \approx 10^{-4} = 21''$, and also the change of the same value it is necessary large enough time $t \approx (P/\dot{P})\alpha$. For a usual pulsar this time is of $3 \times 10^{5}$ years. PSR B1822-09 possesses the much higher value of the spin down $\dot{P} = 52.36 \times 10^{-15}$, and the corresponding time diminishes to $t \approx 50$ years. That is also large for the observations. But the pulsar B1822-09 is on their stage of evolution that this time becomes shorter and is of several years. The matter is while approaching the value of inclination angle $\chi$ to the limiting value (0 or $\pi/2$ depending on the mechanism of losses), when the energy losses become minimal, the change of $\chi$ becomes larger than that of $\Omega$. For the magnetodipole losses the invariant is the quantity $\Omega \cos \chi = \text{const}$. It gives the rate of $\chi$, $\dot{\chi} = -(\dot{P}/P)\cot \chi$. At the angle $\chi$ closed to zero, $\cot \chi \gg 1$ and $\chi \gg \Omega$. The time of changing of $\chi$ on the value of $\Delta \chi$ equals $t = (P/\dot{P})\Delta \chi \tan \chi \ll (P/\dot{P})\Delta \chi$. The same relation takes place also for the current losses. The invariant value for this case is $\Omega \sin \chi = \text{const}(\chi \neq \pi/2)$. The angle $\chi$ approaches $\pi/2$. The time is $t = (P/\dot{P})\Delta \chi \cot \chi$, and it is also smaller than $(P/\dot{P})\Delta \chi$ at $\chi \approx \pi/2$.

Existence of the interpulse in radio emission of PSR B1822-09 tell us that the value of $\chi$ is close to 0 or to $\pi/2$. Rankin (1990) determined this angle, $\chi \approx 86^\circ$. The conclusion that the angle $\chi$ close to the value of $\pi/2$ is confirmed by the fact that the shift between the main pulse and the interpulse is equal to $180^\circ$ and does not depends on the radio frequency (Gil et al., 1994).

One more argument in favor of orthogonal rotator ($\chi \approx \pi/2$) is the measuring braking index $n = \Omega\dot{\Omega}/\dot{\Omega}^2$ has the large value of $n \approx 145$. Such high value of the braking index, $n \gg 1$, means that the rate of change of the inclination angle $\chi$ is much larger than that of the rotation frequency $\Omega$. Taking into account only the rotation frequency evolution it is impossible to get such high value of $n$, $n \equiv 3$. In the relation $\dot{\Omega} = f(\Omega, \chi)$ at $n \gg 1$ the dependence on $\Omega$ becomes determinant $\dot{\Omega} \approx \chi \partial f/\partial \chi$. By this the braking index is $n \approx \chi(\Omega/\dot{\Omega})(\partial \ln f/\partial \chi)$. Thus, the braking index is defined by $\dot{\chi} \approx n(\Omega/\dot{\Omega})(\partial \ln f/\partial \chi)^{-1} \Omega/\dot{\Omega}$ at $n \gg 1$.

For the current losses which give the evolution of the inclination angle to $\pi/2$, $f(\chi) \propto \cos^2 \chi + \delta^2/4$ (Beskin, Gurevich, Istomin, 1993). Here the quantity $\delta$ is the angular size of the polar cap, $\delta = (1.95R\Omega/c)^{1/2} = 2.3 \times 10^{-2}(R/10\text{km})^{1/2} \approx 1.3^\circ$. The value of $\dot{\chi}$ has the sharp maximum near $\cos \chi \approx \delta/2$, at which $\chi = -\dot{\Omega}(\Omega/\dot{\Omega})\cos \chi/(\cos^2 \chi + \delta^2/4)$. The characteristic value of $\chi$ in the interval of angles $\pi/2 - \delta \approx \dot{\chi} = -\dot{\delta}^{-1}(\Omega/\dot{\Omega}) = \delta^{-1}P/P \approx 43P/P$. At such high rate the change of $\chi$ on the value of $\Delta \chi \approx 10^{-4}$ is during the time scale of several years. We suggest that the pulsar B1822-09 demonstrates such kind of evolution.

### 3.4. Comparison with observations

We consider that observed slow glitches of B1822-09 are reconstructions of the neutron star shape. We observed after 1995 three slow glitches of the pulsar rotation, $\Delta \nu_1/\nu = 1.2 \times 10^{-8}$, $\Delta \nu_2/\nu = 2.85 \times 10^{-8}$, $\Delta \nu_3/\nu = 2.75 \times 10^{-8}$. Knowing the relation $\alpha^2 = 2\Delta \nu/\nu$, we obtain the following estimations for the angles $\alpha_1 = 1.5 \times 10^{-4}$ ($\approx 30^\circ$), $\alpha_2 = 2.4 \times 10^{-4}$ ($\approx 50^\circ$), $\alpha_3 = 2.3 \times 10^{-4}$ ($\approx 48^\circ$). We see that observed values of $\alpha$ are close to the critical one $\alpha_{cr} = 2 \times 10^{-4}$, derived above from the condition of plastic limit. To achieve these angles we need the time of $t = \alpha/\dot{\chi}$.

For the orthogonal rotator ($\chi \approx \pi/2$) the quantity $\dot{\chi}$ is $\dot{\chi} = \delta^{-1}P/\dot{P} \approx 2.9 \times 10^{-12}s^{-1}$, and the time to achieve $\alpha = 2 \times 10^{-4}$ is $t = 7 \times 10^7s = 800\text{days}$. This time is in well agreement with observed intervals $t_2 \approx t_3 \approx 700\text{days}$.

Thus, we come to the conclusion that slow glitches observed from PSR B1822-09 is explained by the model of the neutron star reconstruction, when the symmetry of the star’s shape is restored by the plastic deformation in the crust. We also showed the pulsar B1822-09 is the orthogonal rotator, and $\chi \approx 90^\circ$. This is the confirmation of the current losses conception.

### 4. Conclusion

We showed that the probable reason of slow glitches of the pulsar B1822-09 is the fast change of its inclination angle $\chi$. During slow glitches the inclination angle changes on the value of $2^\circ$ for 10 years. Significant increasing of the rate $\dot{\chi}$ takes place when the angle $\chi$ approaches $90^\circ$, and the condition $\pi/2 - \chi \approx \delta$ is fulfilled ($\delta$ is the angular size of the polar cap $\delta \approx (2R\Omega/c)^{1/2}$). In this region of angles $\chi = \delta^{-1}P/\dot{P} \gg \dot{P}/P$.

For the fast evolving pulsars like Crab, Vela or B1509-58, for which the ratio $\dot{P}_{-15}/P$ is large quantity of $10^3 - 10^4$, the time of accumulation of angle $\alpha_{cr}$ is of the order of one year. They have to demonstrate slow glitches. But they have came to the state when $\chi = 90^\circ$. For another group of pulsars with the ratio $\dot{P}_{-15}/P \approx 10^2$, the accumulation time is of 30 years. And only for the pulsar B1822-09, which has the angle $\chi$ close to $90^\circ$, but not equal that value, the accumulation time is of several years.
