Supporting Information

ABSTRACT: We present a novel optical transient absorption and reflection microscope based on a diffraction-limited pump pulse in combination with a wide-field probe pulse, for the spatiotemporal investigation of ultrafast population transport in thin films. The microscope achieves a temporal resolution down to 12 fs and simultaneously provides sub-10 nm spatial accuracy. We demonstrate the capabilities of the microscope by revealing an ultrafast excited-state exciton population transport of up to 32 nm in a thin film of pentacene and by tracking the carrier motion in p-doped silicon. The use of few-cycle optical excitation pulses enables impulsive stimulated Raman microspectroscopy, which is used for in situ verification of the chemical identity in the 100–2000 cm⁻¹ spectral window. Our methodology bridges the gap between optical microscopy and spectroscopy, allowing for the study of ultrafast transport properties down to the nanometer length scale.

The performance of all optoelectronics materials is critically dependent on efficient carrier transport. Our understanding of the associated transport characteristics commonly relies on the interpretation of indirect measurements such as microwave conductivity, photoluminescence quenching, terahertz photoconductivity, or time-of-flight techniques, which determine charge carrier mobilities or diffusion constants. While these methods successfully describe transport in spatially homogeneous materials, they lack access to nanoscopic morphologies which can affect the deduced transport parameters. In particular, next-generation semiconductors such as hybrid metal-halide perovskites, organic semiconductors, quantum dot films, and monolayer 2D semiconductors exhibit spatial heterogeneity on length scales as small as 10 nm, which need to be accessed to fully understand and optimize their charge carrier transport behavior in devices.

Furthermore, the photophysics of optoelectronic materials often involve sub-100 fs photodynamics, typically resolved using femtosecond transient absorption or reflection spectroscopy. These ultrafast processes are implicated to be of relevance in spatial charge carrier (or exciton) transport, but the associated transport parameters are indirectly inferred from the obtained kinetics, which are intrinsically averaged over all morphologies within the probe spot (50–100 μm). In contrast, spatially localized measurement techniques such as transient optical microscopy currently achieve a spatial accuracy of ∼10–50 nm but are limited to time resolutions of ∼100–300 fs, which are insufficient to access the earliest photodynamics. Here we overcome these limitations and explore the impact of ultrafast processes on the spatiotemporal carrier dynamics in optoelectronic materials by introducing a time-resolved transient absorption and reflection microscope capable of delivering sub-10 nm spatial accuracy with temporal resolutions down to 12 fs. In thin pentacene films, our technique resolves rapid spatial expansion occurring during the singlet fission process, which is completed within 200 fs after photoexcitation. In contrast, in p-doped silicon we observe charge carrier transport dynamics matching previously published reports even at the earliest time scales. In addition, our high temporal resolution allows us to chemically characterize the sample region in a universal fashion via impulsive stimulated Raman scattering.

Our experimental approach consists of an ultrafast pump–probe experiment coupled to a single-objective wide-field optical microscope (Figure 1a). An analogous to our previously reported implementation of wide-field femtosecond transient absorption microscopy, we generate temporally compressed broadband pulses spanning wavelengths from 520 to 640 nm (pump) and from 660 to 900 nm (probe). However, instead of using wide-field pump pulses we now focus the pump pulses tightly onto the sample by sending them through a high numerical aperture (NA = 1.1) oil-immersion objective, which results in a near-diffraction-limited Gaussian excitation profile.

After the pump pulses have photoexcited the sample and generated a localized carrier population, we spatially resolve the photoinduced transient response by imaging time-delayed wide-field probe pulses onto an emCCD. To achieve the highest temporal resolution, we employ a single-lens high-NA oil-immersion objective instead of the more conventional flat-field and chromatic aberration-corrected multicomponent objectives. This choice compromises the absolute imaging capability but only weakly affects a differential pump–probe experiment over a small field of view (see also Supporting Information, section 2), allowing us to compress our pump pulses to 9.8 fs with commercially available optical elements (Figure 1c, green line; Supporting Information, section 1.2). We remark that near-IR pulses (650–950 nm) can be temporally compressed to sub-10 fs for high-NA multicomponent microscope objectives using advanced pulse-shaping methods.21,22 Similar results for visible pulses (550–650 nm) are, however, lacking because of the significantly larger dispersion corrections required for this wavelength range.

The probe pulses in our setup are temporally compressed to 6.8 fs (Figure 1c, orange line) for the transmission channel, resulting in an effective time resolution of 11.9 fs (Figure 1d). In the reflection channel (Figure 1e), we use chirped probe pulses (∼700 fs), which in combination with bandpass-filtered detection results in a temporal resolution of ∼50 fs (see main text for corresponding diffusion coefficient). Early time delays (<75 fs) were ignored because of coherent artifact contributions (gray shaded region).

Figure 2. Femtosecond transient absorption microscopy of a thin pentacene film (∼120 nm) measured in transmission. (a) Differential transmission image at 1 ps after photoexcitation. Scale bar depicts 500 nm. (b) Transient kinetics at the central pixel of the point-spread function (gray line, left axis) and retrieved amplitude of a two-dimensional (2D) Gaussian fit (orange line, left axis, scaled for clarity). The corresponding retrieved 2D Gaussian standard deviation (green line, right axis) is also shown. (c) Mean-square displacement (MSD) curve relative to a time delay of 75 fs. The MSD is well-described by two linear diffusion regimes with the indicated slopes (see main text for corresponding diffusion coefficient). Early time delays (<75 fs) were ignored because of coherent artifact contributions (gray shaded region).

(σ = 115 nm; Figure 1b and Supporting Information, section 1.1). After the pump pulses have photoexcited the sample and generated a localized carrier population, we spatially resolve the photoinduced transient response by imaging time-delayed wide-field probe pulses onto an emCCD.

To achieve the highest temporal resolution, we employ a single-lens high-NA oil-immersion objective instead of the more conventional flat-field and chromatic aberration-corrected multicomponent objectives. This choice compromises the absolute imaging capability but only weakly affects a differential pump–probe experiment over a small field of view (see also Supporting Information, section 2), allowing us to compress our pump pulses to 9.8 fs with commercially available optical elements (Figure 1c, green line; Supporting Information, section 1.2). We remark that near-IR pulses (650–950 nm) can be temporally compressed to sub-10 fs for high-NA multicomponent microscope objectives using advanced pulse-shaping methods.21,22 Similar results for visible pulses (550–650 nm) are, however, lacking because of the significantly larger dispersion corrections required for this wavelength range.

The probe pulses in our setup are temporally compressed to 6.8 fs (Figure 1c, orange line) for the transmission channel, resulting in an effective time resolution of 11.9 fs (Figure 1d). In the reflection channel (Figure 1e), we use chirped probe pulses (∼700 fs), which in combination with bandpass-filtered detection results in a temporal resolution of ∼50 fs (see the Supporting Information, section 1.2 for details).23 While it is straightforward to compress the probe pulses for our microscope objective by adding an additional set of third-order compensated chirped mirrors into the beam path, as illustrated for the pump pulse, we opted to demonstrate that chirped probe pulses can be used equivalently if a simpler
implementation with marginally lower temporal resolution (∼50 fs) is desired. We incorporated two complementary probe channels to accommodate a broad range of samples irrespective of their optical properties. In the transmission channel, the probe is loosely focused onto the sample by a concave mirror (Figure 1d, Gaussian illumination area of σ ≈ 8 μm), whereas in the reflection channel, the probe is focused into the back-aperture of the high-NA objective with an additional wide-field lens (Figure 1e, Gaussian illumination area of σ ≈ 4 μm). Prior to detecting the probe, we insert narrow-bandpass filters into the detection path to gain access to wavelength-resolved spatiotemporal dynamics, while simultaneously removing optical artifacts associated with chromatic aberrations.

To demonstrate the capabilities of our microscope, we first imaged the spatiotemporal dynamics of a ∼120 nm thin film of the singlet fission material pentacene (Pc) in transmission. Following photoexcitation to S1, Pc undergoes singlet fission to form a correlated triplet—tripllet (3T) state on a sub-100 fs time scale, which can be followed by monitoring the growth of the photoinduced absorption band at 790 nm. We remark that this wavelength range is free from other overlapping spectral features16 as responsible factors for this fast diffusion regime (Figure S9), eliminating carrier-recombination artifacts from our measurements. Considering the diffusion coefficient and retrieved singlet fission lifetime, we can estimate the effective carrier diffusion length for this fully temporally resolved ultrafast regime as $L_{\mathrm{fast}} = \sqrt{D \tau} = 32.2 \pm 2.1$ nm.

To generalize this result, we repeated the same experiment by detecting different probe wavelengths (Supporting Information, section 4). Within a probe range from 710 to 790 nm, coinciding with the photoinduced 3T absorption band in Pc (Figure S7), we retrieve identical fast diffusion coefficients within error margins. These results firmly rule out refractive index artifacts15 or competing overlapping spectral features16 as responsible factors for this fast diffusion regime.

The extraordinary high diffusion coefficients ($D_{\text{fast}}$) and associated carrier lengths ($L_{\text{fast}}$) thus point to a previously unknown transport regime during the earliest times following photoexcitation in Pc.

While a detailed interpretation of the above results is beyond the scope of this work, the established photophysics of Pc allows us to provide a first qualitative explanation of our results.24,30,34,35 We speculate that the initially delocalized photoexcited S1 wave function could undergo ultrafast spatial
broadening \( \Delta \omega_{\text{lo}} \) during the formation of a more delocalized \( ^1\text{T} \text{T} \) wave function within a coherent transport regime. This rapid initial expansion is followed by a slower population expansion over several picoseconds, and the lower diffusion coefficient \( \Delta \omega_{\text{lo}} \) indicates an incoherent hopping mechanism which could be associated with the formation of an entangled but spatially separated \(^1\text{T} \text{T} .. \text{T} \) state.\(^{30}\) Further theoretical work is, however, critical to elucidate the origins of both the fast and slow regimes of the observed spatiotemporal behavior.

In addition to our ability to visualize exciton population transport in \( \text{Pc} \) during singlet fission, the high temporal resolution of our setup allows us to also monitor the chemical fingerprint of the excitation spot via impulsive stimulated Raman scattering for in situ verification of the chemical composition of the probed sample region.\(^{37–39}\) To highlight this capability, we conducted the same experiment on \( \text{Pc} \) at higher excitation densities, to achieve an increased signal-to-noise ratio, and resolved pronounced oscillatory modulations on top of the electronic background signal (Figure 3a, \( \sim 25 \text{ fs} \) period, see inset). To extract the associated impulsive Raman spectrum, we computed the Fourier power spectrum of the oscillatory modulations after removing the slowly varying electronic background signal (Figure 3b). The retrieved spectrum is in excellent agreement with the ground-state Raman spectrum of \( \text{Pc} \) thin films and is dominated by modes at 1193 (\( \sim 28 \text{ fs} \) period) and 1371 cm\(^{-1} \) (25 fs period).\(^{30}\) The oscillatory components are also reproduced by applying a two-dimensional Gaussian fitting routine outlined above (Figure 3, orange line). We remark that the appearance of such coherent oscillations in the time domain corroborates the high temporal resolution deduced from our external pulse characterization (Supporting Information, section 1.2).

To highlight how our approach can be applied for optically thick or nontransparent materials, we investigated the ultrafast spatiotemporal properties of p-doped Silicon (Si) using the reflection channel of our microscope. Si is a prototypical, well-characterized material commonly used in solar cells, which is nontransparent to visible light and therefore cannot be measured in transmission. Here, we recorded transient reflection images probed above the optical bandgap (740 nm). A typical point-spread function at a time delay of 2.8 ps shows a negative, isotropic differential reflectivity signal in the form of an Airy disk, in agreement with previous reports (Figure 4a).\(^{33}\) The associated photodynamics exhibit an initial rise with a decay time constant of 207 ± 22 fs followed by a slower decay time of 11.29 ± 1.1 ps (Figure 4b, gray line).

Analogous to our analysis on \( \text{Pc} \), we described each transient reflection image with a two-dimensional isotropic Gaussian function to analyze the spatial profiles. The retrieved time-dependent amplitudes match the central pixel amplitudes (Figure 4b, orange line), as previously observed for \( \text{Pc} \). Interestingly, despite the two temporal regimes identified in the signal amplitude, the corresponding standard deviation displays only a single rise from \( \sim 190 \text{ nm} \) at 100 fs to 205 nm at 3 ps (Figure 4b, green line), sufficient to be resolved with the spatial accuracy of \( \sim 2.7 \text{ nm} \) obtained in this experiment (see Supporting Information, section 2). The corresponding diffusion coefficient in our time window can be estimated from the MSD relative to \( t_0 = 90 \text{ fs} \) using eq 1 and yields \( D = 8.6 \pm 0.5 \text{ cm}^2 \text{ s}^{-1} \), in agreement with previously reported values (Figure 4c).\(^{19,33}\) Our results suggest that the diffusion characteristics in Si at the earliest times (\( \sim 100 \text{ fs} \) to 3 ps) after photoexcitation are equivalent to the pico- or nanosecond time scales that have been reported with alternative measurement techniques.\(^{19,20,33}\)

Apart from the improved temporal resolution, our transient absorption and reflection microscope differs significantly from previous implementations because of its wide-field imaging detection. Earlier studies\(^{15–18}\) almost exclusively rely on confocal microscopy,\(^{33}\) in which the transient image is reconstructed after scanning a tightly focused probe beam across the sample. The benefits and drawbacks of wide-field microscopy compared to confocal microscopy have been extensively reviewed in the literature and apply similarly for transient microscopes.\(^{41}\) While we have demonstrated an ultrafast wide-field microscope, because of its easier construction, our approach can readily improve the time resolution of a transient confocal microscope by simply replacing the relevant objective lenses with low-dispersion objectives and adding commercially available pulse compression optics (see Experimental Methods).

We emphasize that care has to be taken in the interpretation and comparison of the respective transient point-spread functions, which will appear as Airy disks for a wide-field microscope (e.g. Figure 2a) instead of a two-dimensional Gaussian function for a confocal microscope.\(^{15–18}\) Critically, while the underlying phase interference effects in our microscope may seem deleterious at first, they in principle allow the ultrafast tracking of three-dimensional carrier motion over the spatial coherence length of our probe pulses (\( \sim 2 \mu \text{m} \))
by carefully evaluating the corresponding point-spread functions (particularly in the reflection channel).\textsuperscript{33,42}

Taken together, we have demonstrated ultrafast transient absorption and reflection microscopy which meets the time and length scale requirements of optoelectronic processes by achieving an effective temporal resolution down to 12 fs in transmission and \(\sim 50\) fs in reflection mode, with simultaneous sub-10 nm spatial accuracy. This spatiotemporal capability enabled us to uncover a previously unobserved ultrafast linear transport regime in Pc films indicative of a highly spatially delocalized \(1\)TT wave function which corresponds to carrier transport lengths of up to 32 nm from the initial excitation spot. In contrast, p-doped Si did not show any ultrafast spatial expansion but instead followed its reported long time diffusive behavior. An inherent benefit of our approach is the ability to simultaneously monitor the chemical identity of the selected region via impulsive stimulated Raman scattering alongside the spatiotemporal dynamics. The combination of these functionalities provides comprehensive insight into charge carrier and exciton population transport in a wealth of materials with morphological and chemical specificity.\textsuperscript{43} Consequently, our approach can be readily applied to heterojunctions and other inhomogeneous morphologies to elucidate interfacial population transport.

**EXPERIMENTAL METHODS**

**Experimental Setup.** Pulses were provided by a Yb:KGW amplifier (1030 nm, 200 fs, 200 kHz, 5 W, Pharos, Light Conversion) which seeded two white light continuum stages for probe and pump pulse generation. Probe pulses were produced in a 3 mm YAG crystal and spectrally filtered in a home-built 4F single-prism filter to adjust the bandwidth to 660–900 nm. Subsequently, the probe pulses were compressed to 6.8 fs with third-order corrected chirped mirrors (DCM9, Venton) and by optimizing the prism insertion in the spectral filter. Probe pulses were only compressed for the transmission channel (see further explanation in Supporting Information, section 1). Consequently, they experienced a temporal chirp of \(\sim 700\) fs in the spectral region from 660 to 900 nm in the reflection channel due to the additional dispersion caused by the wide-field and objective lens. Pump pulses were produced in a 3 mm sapphire crystal for increased bandwidth, spectrally adjusted by a 650 nm short-pass filter (FESH650, Thorlabs), and subsequently compressed to 9.8 fs by two sets of third-order compensated chirped mirrors (109811, Layertec) in combination with a wedge-prism pair, accounting for all optical components including the microscope objective. We additionally cleaned the spatial mode of the pump pulses by means of a 40 \(\mu m\) pinhole, which is imaged into the back-aperture of the objective to achieve near-diffraction-limited focusing at the sample. To set up the time-dependent pump–probe sequence, we modulated the pump pulses at 15 Hz via a mechanical chopper (Thorlabs) and temporally delayed the probe via a computer-controlled closed-looped piezo translation stage (P-625.1CL, PhysikInstitute).

An emCCD (Rolera Thunder, QImaging) detected the transmitted or reflected probe pulses via a high numerical aperture oil-immersion objective (NA = 1.1, 100\times magnification) in combination with an F = 500 mm tube lens (AC254-500-B, Thorlabs) resulting in 55.5 nm/pixel. To avoid pump light detection, we inserted a 650 nm long-pass filter (FELH650, Thorlabs) in front of the emCCD in addition to a narrow bandpass filter (FB790-10 for pentacene and FB740-10 for silicon, Thorlabs) as shown in Figure 1a.

An automatic focus control loop based on total internal reflection of a reference continuous wave laser (405 nm) was used to stabilize the focus position via an objective piezo (NP140, Newport) in pentacene.\textsuperscript{45} The same approach could not be applied to silicon. Instead, we measured eight different sample locations (experimental time 4 min/sample location) and averaged the results. During this time scale no significant focus drift was observed as verified by monitoring the autofocus performance during the measurements on pentacene.

The camera exposure time was set to 9 ms for pentacene and 12 ms for silicon at a camera frame rate of 30 Hz. For the experiments on pentacene shown in Figures 2 and 3, the photoexcited carrier densities were \(2.90 \times 10^{18}\) and \(9.01 \times 10^{18} \text{cm}^{-3}\),\textsuperscript{45} respectively, and \(1.67 \times 10^{18} \text{cm}^{-3}\) for silicon (Figure 4),\textsuperscript{20} as calculated from the peak energy of the pump pulse.\textsuperscript{43} Both experiments were conducted by adjusting the polarization of the pump and probe beams to magic angle.

**Data Analysis.** Normalized differential images were calculated from the raw images after subtraction of the dark counts and described for each time delay with an isotropic two-dimensional Gaussian function according to
\[ G(x, y) = A \exp \left( -\frac{(x - x_0)^2 + (y - y_0)^2}{2\sigma^2} \right) + \text{offset} \]

where \( A \) encodes the signal amplitudes; \( x_0 \) and \( y_0 \) are the position, and \( \sigma \) is the standard deviation. Initial guesses for the position were taken from the center of mass position of each image; the amplitude was taken from the corresponding pixel amplitude, and we set \( \sigma = 100 \text{ nm} \) and offset = 0.

We note that this approach does not describe the diffraction rings present in the Airy disk. This results in a systematic overestimation of the fitted signal amplitude, and we therefore scaled the reported amplitudes in Figures 2 and 4 to emphasize the correct reproduction of the transient kinetics. Importantly, our analysis focuses on evaluating time-dependent deviations from the correct reproduction of the transient kinetics. Especially for the standard deviation parameter, any error in describing the full point-spread function will translate into a small systematic deviation from the actual value, which will be inconsequential for assessing temporal changes.

Population kinetics were modeled with a sum of two exponentially decaying Gaussian functions, and stated error bars in the retrieved lifetimes correspond to the standard deviation error.
