ABSTRACT
We investigate the evolutionary connection between local infrared (IR)-bright galaxies (log \( L_{\text{IR}} \geq 11.4 \ L_\odot \)) and quasars. We use high-angular resolution (~0.3–0.4 arcsec ~ few hundred parsecs) 8–13 \( \mu \)m ground-based spectroscopy to disentangle the active galactic nuclei (AGN) mid-IR properties from those of star formation. The comparison between the nuclear 11.3 \( \mu \)m polycyclic aromatic hydrocarbon feature emission and that measured with Spitzer/Spitzer Infrared Spectrograph indicates that the star formation is extended over a few kpc in the IR-bright galaxies. The AGN contribution to the total IR luminosity of IR-bright galaxies is lower than in quasars. Although the dust distribution is predicted to change as IR-bright galaxies evolve to IR-bright quasars and then to optical quasars, we show that the AGN mid-IR emission of all the quasars in our sample is not significantly different. In contrast, the nuclear emission of IR-bright galaxies with low AGN contributions appears more heavily embedded in dust although there is no clear trend with the interaction stage or projected nuclear separation. This suggests that the changes in the distribution of the nuclear obscuring material may be taking place rapidly and at different interaction stages washing out the evidence of an evolutionary path. When compared to normal AGN, the nuclear star formation activity of quasars appears to be dimming, whereas it is enhanced in some IR-bright nuclei, suggesting that the latter are in an earlier star formation-dominated phase.

Key words: galaxies: active – galaxies: evolution – quasars: general – galaxies: Seyfert – infrared: galaxies.

1 INTRODUCTION
The evolutionary connection between ‘cool’ (IRAS 25–60 µm colours $f_{25}/f_{60} ≲ 0.3$) ultraluminous infrared (IR) galaxies (ULIRGs, defined to have $8–10000 \mu$m IR luminosities $L_{IR} > 10^{12} L_{\odot}$), to ‘warm’ ($f_{25}/f_{60} \gtrsim 0.3$) ULIRGs and optical quasars was proposed almost 30 yr ago (Sanders et al. 1988). In this scenario, IR-bright activity and in particular, ULIRG activity is triggered by interactions between gas-rich galaxies that merge, go through an optical quasar phase and eventually evolve into elliptical galaxies (see review by Sanders & Mirabel 1996). Numerical simulations predict that during the merger phase, both intense star formation and a dust-enshrouded active galactic nucleus (AGN) phase co-exist in the dusty nuclear regions of most ULIRGs before energetic feedback from an AGN and/or star formation clears this scenario, IR-bright activity and in particular, ULIRG activity is thought to be driven by high angular resolution, we are able to isolate nuclear scales of a few hundred parsecs where the AGN and star formation processes are believed to be more tightly coupled (Hopkins & Quataert 2010). We observed a sample of local LIRGs and ULIRGs with IR luminosities $log L_{IR} \geq 11.4 L_{\odot}$, at these luminosities most systems are interacting galaxies or mergers (see e.g. Hung et al. 2014; Larson et al. 2016, and references therein). We dub these systems ‘IR-bright galaxies’. As a comparison sample, we observed optical quasars which are mostly Palomar–Green (PG) quasars from the bright quasar sample (Schmidt & Green 1983). Among the IR-bright galaxy sample, there are four IR-bright PG quasars (see Section 2 for more details on our definition). These quasars tend to show more pronounced merger-induced morphological anomalies and thus might be at an earlier evolutionary stage than IR-faint quasars (Veilleux et al. 2009b). Cao et al. (2008) reached a similar conclusion by comparing the properties of the mid-IR Spitzer/IRS spectra of IR-bright and IR-weak quasars. Therefore, IR-bright quasars might represent a transition phase to the evolution to classical optical quasars.

The paper is organized as follows. Section 2 describes the samples of IR-bright galaxies and quasars. Section 3 gives details on the new and existing mid-IR observations used in this work. Section 4 presents the analysis of the mid-IR spectroscopy, whereas Section 5 discusses the mid-IR AGN and nuclear star formation properties of local IR-bright galaxies and the comparison sample of quasars. In Section 6, we investigate the possible evolutionary connection between the mid-IR AGN properties and nuclear star formation activity of IR-bright galaxies and quasars. Finally in Section 7, we present our conclusions. Throughout this work, we use the following cosmology: $H_0 = 73$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_M = 0.27$, and $\Omega_L = 0.73$.

2 THE SAMPLES
Our sample of IR-bright galaxies contains 14 local systems with IR luminosities in the range $log L_{IR} = 11.4 – 12.5 L_{\odot}$ (see Fig. 1 and Table 1), hosting an AGN and with available high-angular resolution ($\sim 0.3–0.4$ arcsec) ground-based mid-IR spectroscopy (see Section 3). All but one are part of our GTC/CanariCam mid-IR survey of local AGN (see Alonso-Herrero et al. 2016, for details). According to their IR luminosities, seven systems are LIRGs and seven are ULIRGs. We selected our sample of IR-bright galaxies to cover mostly close (projected nuclear distances of <10 kpc) interaction and merger phases. Using the morphological classification of Veilleux et al. (2002), we have (see Table 1) six close interacting galaxies termed class IIIb, five mergers termed class IV, and one old merger termed class V. Mrk 1073 is part of the Perseus cluster and probably paired with UGC 2612 (Levenson, Weaver & Heckman 2001) at a projected distance greater than 10 kpc, so likely in the IIIa class. Finally, the ULIRG/IR-bright quasar IRAS 13349+2438 (see Low et al. 1989, and below) has no morphological classification but it shows a compact appearance which probably indicates a merger. The projected nuclear separations between the nuclei of galaxies classified as IIIb are as follows, 6.1 kpc for IRAS 08572+3915, 5.5 kpc for IRAS 14348–1447,
The sample of local IR-bright galaxies.

Notes. Dist is the luminosity distance taken from NED for $H_0 = 73$ km s$^{-1}$ Mpc$^{-1}$, $Ω_Λ = 0.27$, and $Ω_M = 0.73$. The IR luminosity is in the 8–1000 $\mu$m range. The morphology class follows the criteria defined by Veilleux, Kim & Sanders (2002): IIa: wide binary (nuclear separation > 10 kpc); IIIb: close binary (nuclear separation < 10 kpc); IVa: diffuse merger; IVb: compact merger; V: old merger; Pair: in a pair. The references are for the optical class except for Mrk 478 and IZw1 which is for the IR luminosity: GM06: García-Marín et al. (2006), Y10: Yuan et al. (2010), W09: Wu et al. (2009), GM07: García-Marín (2007), V95: Veilleux et al. (1995), E06: Evans et al. (2006).
Figure 2. The upper panel is the Spitzer/IRAC 8 µm image of Arp 299 shown in a square root scale to emphasize the diffuse emission. The white squares represent the approximate FoV of the GTC/CanariCam images shown in the lower panels of the two galaxies in the system: IC 694 or Arp 299A (left), and NGC 3690 (right). The nuclear region of NGC 3690 is the B1 source. B2 is a bright optical source, whereas C and C’ are bright star-forming regions in the overlapping region of the two galaxies. The CanariCam images were obtained with the Si-2 filter (λc = 8.7 µm). We smoothed the CanariCam images using a Gaussian function with σ = 0.6 pixels. The orientation of the images is north up, east to the left, and are shown in a linear scale.

Martinez-Paredes et al. (in preparation). These quasars were chosen to match bolometrically the luminosities of our sample of IR-bright galaxies (see fig. 1 of Alonso-Herrero et al. 2016, for the 2–10 keV luminosities of the PG quasars). We list the properties of the sample of quasars in Table 2. The median luminosity distance of the quasar sample is 319 Mpc.

Although the IR luminosities of six of the 10 optically selected quasars would put them in the (U)LIRG class (see Table 2 and Fig. 1), they are IR-weak quasars (see Low et al. 1989), based on their IR to optical B-band luminosity ratios (typically ratios LIR/L_B between 1 and 3, as calculated using total B-band magnitudes from NASA/IPAC Extragalactic Database, NED). Among the IR-bright galaxies in our sample, there are also four optically selected quasars (IZw1, Mrk 1014, Mrk 478, and IRAS 13349+2439), of which three are in the PG catalogue (see Table 1). These are, however, IR-bright quasars based on their observed IR to B-band ratios (LIR/L_B ratios between 4 and 11). Our IR-bright and IR-weak quasar classifications are consistent with the far-IR strong and weak classes of Netzer et al. (2007) based on the observed 60–150 µm ratios of PG quasars. Finally, Mrk 231 is also considered the nearest quasar (Boksenberg...
Figure 3. Top panels: GTC/CanariCam image (right, shown in a linear scale) at 8.7 µm of the central region of NGC 1614, which clearly resolves the nucleus (marked with a black cross) and the circum-nuclear ring of star formation (see Pereira-Santaella et al. 2015, for a detailed study of this galaxy). The Spitzer/IRAC 8 µm image (left, shown in a square root scale) shows a larger FoV with the white square representing the approximate FoV of the right-hand panel and also the approximate size of the Spitzer/IRS SL slit width (3.7 arcsec). The orientation of the images is north up, east to the left. Middle panels: same as upper panels but for NGC 6240. The GTC/CanariCam 8.7 µm image (right) of the nuclear region of NGC 6240 clearly resolves the two nuclei of this interacting system (see Alonso-Herrero et al. 2014, 2016, for more details). Bottom panels: same as the upper panel but for IRAS 17208−0014. The nearly nuclear point source seen in the IRAC 8 µm image (left) is clearly resolved in the GTC/CanariCam image (right). We tentatively identify the western nucleus with the peak of the 8.7 µm emission. The projected separation of the two nuclei (∼0.24 arcsec ∼CanariCam 3 pixels; see Medling et al. 2014, 2015), shown as black crosses, is slightly smaller than the FWHM of the CanariCam image (0.26 arcsec; see Alonso-Herrero et al. 2014).
et al. 1977) and has a dusty broad absorption line region obscuring the continuum source and the standard broad absorption line region (Veilleux et al. 2013). Thus, Mrk 231 might be a bona fide emerging IR-bright quasar in the local Universe.

3 OBSERVATIONS

3.1 New GTC/CanariCam imaging observations

We obtained new mid-IR high-angular resolution imaging observations of the interacting LIRG Arp 299 with GTC/CanariCam on the night of 2016 January 26 in queue mode. These observations were part of our GTC/CanariCam AGN guaranteed time programme (PI: C. Telesco). We used the Si-2 filter which has a central wavelength of $\lambda_c = 8.7$ $\mu$m and a width of $\Delta \lambda_{cut} = 1.1$ $\mu$m, at 50 per cent cut-on/off. The CanariCam 320 pixel $\times$ 240 pixel Si:As detector has a plate scale of 0.0798 arcsec pixel$^{-1}$ which provides a field of view (FoV) of 26 arcsec $\times$ 19 arcsec. We therefore required two pointings to cover the nuclei and bright star-forming regions of Arp 299. The mid-IR spectroscopy of the bright nuclei of Arp 299 was presented in Alonso-Herrero et al. (2013b).

The observations were taken using the standard mid-IR chopping technique with on-source integration times of 608 s for each of the two pointings. We also obtained an image of a standard star with the same filter to perform the photometric calibration and assess the image quality of the observations. We reduced the data using the CanariCam pipeline REDCAN (González-Martín et al. 2013) that includes for imaging observations stacking of the individual observations, rejection of bad images and flux calibration. Fig. 2 shows the fully reduced image of the two galaxies of Arp 299. Using the image of the standard star, we measured an image quality of the observations of 0.48 arcsec (full width at half-maximum, FWHM). The GTC/CanariCam Si-2 filter imaging data of the rest of the IR-bright galaxies in the sample are presented in Alonso-Herrero et al. (2016), except for I Zw1 which is in the sample of optically selected quasars analysed by Martínez-Paredes et al. (in preparation).

3.2 Existing high-angular resolution mid-IR spectroscopic observations

We compiled high-angular resolution (image quality of $\sim 0.3$–0.4 arcsec, FWHM) mid-IR $\sim 7.5$–$13$ $\mu$m spectroscopy of the sample of 14 local IR-bright systems listed in Table 1 and the comparison sample of 10 IR-weak quasars in Table 2. These data were obtained with ground-based instruments on 8–10 m class telescopes. The majority of systems in both samples were observed with the CanariCam instrument on the GTC in spectroscopic mode with a spectral resolution of $R = \lambda / \Delta \lambda \sim 175$ as part of the CanariCam AGN guaranteed time programme, an ESO/GTC large programme (ID: 182.B-2005; Alonso-Herrero et al. 2016) or through the GTC Mexican open time (see Martínez-Paredes et al., in preparation). The ULIRG I Zw1 and the PG quasar Mrk 509 were observed in the mid-IR using VLTI Imager and Spectrometer for mid infrared (VISIR) (Lagage et al. 2004) on the Very Large Telescope (VLT) by Burscher et al. (2013) and Hönig et al. (2010), respectively, with a spectral resolution of $R \sim 300$ and similar image quality to the CanariCam spectra. We reduced all the CanariCam imaging and spectroscopic data using the REDCAN pipeline (González-Martín et al. 2013). We refer the reader to Alonso-Herrero et al. (2016) and Martínez-Paredes et al. (in preparation) for full details on the CanariCam observations, including the extraction of the spectra, the correction for possible slit losses, and their photometric calibration.

The GTC/CanariCam and VLT/VISIR mid-IR spectroscopic observations were taken with similarly sized slit widths of 0.52 and 0.75 arcsec, respectively. At the median distances of the IR-bright galaxy sample and the IR-weak quasar sample (see Section 2), the physical sizes probed by our ground-based slits range between 112 and 1396 pc, and between 248 and 1376 pc, respectively.

3.3 Archival Spitzer/IRAC and IRS observations

For both samples, we obtained fully reduced Spitzer/IRS low-spectral resolution ($R \sim 60$–120) spectra from the Cornell Atlas of Spitzer/IRS Sources (CASSIS; Lebouteiller et al. 2011, version LR7), except for the nuclear regions of Arp 299 for which we used the spectra of Alonso-Herrero et al. (2009). In this work, we only used the spectral range covered by the short-low (SL) mode, $\sim 5$–$15$ $\mu$m, as this is the range used by the spectral decomposition tool (see Section 4.1) and the spectra with optimal extraction regions. The slit width of the SL spectra is 3.7 arcsec.

We also retrieved from the Spitzer archive fully calibrated Infrared Array Camera (IRAC; Fazio et al. 2004) images at 8 $\mu$m rebinned to a pixel size of 0.6 arcsec. The FWHM of the IRAC images is approximately 2.2 arcsec. In Figs 2 and 3, we show a few examples in the IR-bright galaxy sample comparing the Spitzer/IRAC 8 $\mu$m morphologies and the nuclear morphologies resolved by our GTC/CanariCam 8.7 $\mu$m images. These figures emphasize the gain in angular resolution of the ground-based mid-IR observations.

The GTC/CanariCam 8.7 $\mu$m images of Arp 299 show emission stemming not only from the bright mid-IR sources (A, B1, B2 and C’), but also from H II regions in the spiral arms of the eastern component and to the north-west of B1, as well as extended emission around B1 (see Fig. 2 and Alonso-Herrero et al. 2009). The IRAC 8 $\mu$m image of IRAS 17208–0014 shows a bright nearly point source, which is clearly resolved and extended in the east-west direction in the GTC/CanariCam 8.7 $\mu$m (see Fig. 3, bottom panels). The projected separation of the two nuclei identified in this galaxy (see Medling et al. 2014, 2015) is approximately the same as the FWHM of the image (0.26 arcsec) and cannot therefore be resolved. However, based on the nuclear Br $\gamma$ (Medling et al. 2014) and Pa $\alpha$ (Piqueras López et al. 2012) morphologies of this system and the similarity between hydrogen recombination line and 8 $\mu$m morphologies of local LIRGs (Díaz-Santos et al. 2008), we tentatively identify the peak of the CanariCam emission with...
the western nucleus of IRAS 17208−0014. García-Burillo et al. (2015) proposed that this nucleus hosts an obscured (i.e. Compton-thick; see González-Martín et al. 2009) AGN which is responsible for the energetic outflow detected in molecular gas in this system. We note that the extraction aperture used for the GTC/CanariCam spectra includes emission from the two nuclei. NGC 1614 and NGC 6240 were discussed in detail in Pereira-Santaella et al. (2015) and Alonso-Herrero et al. (2014), respectively.

4 ANALYSIS

4.1 Deriving the AGN mid-IR properties

Even on sub-arcsecond resolution, the mid-IR emission of local (U)LIRG nuclei can have a significant contribution from star formation activity, as revealed by the detection of polycyclic aromatic hydrocarbon (PAH) features, in particular, the 11.3 µm PAH feature (see e.g. Soifer et al. 2002; Díaz-Santos et al. 2010; Alonso-Herrero et al. 2014, 2016; Mori et al. 2014; Pereira-Santaella et al. 2015). To study the AGN mid-IR emission of local (U)LIRG nuclei, we need to disentangle it from that due to star formation. Spectral decomposition methods have been proven effective in doing so for local (U)LIRGs (see e.g. Nardini et al. 2008, 2010; Alonso-Herrero et al. 2012; Martínez-Paredes et al. 2015) and have been mostly applied to Spitzer/IRS spectra.

We use the DEBLENDIRS tool (Hernán-Caballero et al. 2015) to do the spectral decomposition of the ground-based mid-IR spectra of the two samples. DEBLENDIRS is an IDL/GDL-based routine that uses Spitzer/IRS observational spectral templates to decompose the mid-IR 5–15 µm spectra of galaxies into AGN, interstellar (PAH), and stellar (STR) components. Although DEBLENDIRS was originally designed to be used with IRS spectra, it can be easily adapted to do the spectral decomposition of ground-based spectroscopy by setting the adequate spectral range. We note, however, that this routine uses templates taken with IRS. We are therefore assuming that the mid-IR emission associated with star formation activity on kpc scales resembles that taking place in the vicinity of the AGN. DEBLENDIRS provides the best-fitting model to the data and it also gives the probability distribution functions (PDFs) of the fitted AGN, PAH and STR fractional components to the 5–15 µm spectral range and within the slit. For the fitted AGN fractional contribution at 12 µm within the slit, mid-IR 5–15 µm spectral index and strength of the silicate feature, we give the median value and in brackets the 16 per cent and 84 per cent percentiles of the PDFs.

The listed χ² values are reduced ones. For the AGN rest-frame 12 µm luminosities, those galaxies marked with (*) denote the corresponding AGN rest-frame 12 µm monochromatic luminosity, L_{12}(µm), the strength of the silicate feature, we give the median value and in brackets the 16 per cent and 84 per cent percentiles of the PDF, the median value of the AGN mid-IR spectral index and 1σ confidence intervals, and the median value of the strength of the silicate feature and its 1σ confidence interval. We calculated the AGN rest-frame 12 µm monochromatic luminosity, νL_{ν}(12µm), using the best-fitting AGN component at that wavelength.

In Appendix A, we show two examples of the graphical output from DEBLENDIRS for an IR-bright galaxy with AGN-dominated mid-IR emission (Mrk 463E) and an IR-bright galaxy with a star formation-dominated nuclear mid-IR spectrum (IRAS 17208−0014). In Tables 3 and 4, we list the results from the DEBLENDIRS spectral decomposition of the nuclear spectra of the IR-bright galaxies and comparison quasars, respectively. We provide for each galaxy the reduced χ² value of the best-fitting model, the rest-frame 12 µm monochromatic AGN luminosity, the best-fitting value of the AGN, PAH and stellar contributions in the 5–15 µm spectral range within the slit, the median value of the AGN fractional contribution at rest-frame 12 µm and 1σ confidence interval. The median values of the AGN mid-IR spectral index and 1σ confidence interval, and the median value of the strength of the silicate feature (positive values indicate that the feature is in emission and negative values in absorption) and 1σ confidence interval. Since the AGN spectral templates are flatter than those accounting for the stellar and interstellar emission (i.e. STR and PAH templates, see fig. 2 of Hernán-Caballero et al. 2015), the contribution from the AGN at long wavelengths is generally lower than the integrated values for the entire 5–15 µm range.
templates, reproduces its extremely deep silicate absorption. We refer the reader to Appendix A for a more detailed discussion on fits of sources with deep silicate features and high values of $\chi^2$. Deep silicate features are believed to be related to additional extinction due to either dust lanes in the host galaxy or the merger process (see Goulding et al. 2012; González-Martín et al. 2013, and also Section 6.1). We finally note that for sources with $S_{\text{Si}} < -2$, both the AGN fraction and AGN luminosity should be considered as upper limits, because the ‘obscured AGN’ templates could be composite sources.

Finally, we also performed the spectral decomposition of the Spitzer/IRS spectra of the IR-bright galaxy and quasar samples. In Appendix 2, we show the comparisons between the derived AGN spectral index and strength of the silicate feature for the IRS and ground-based spectra using DEBLENDIRS. We demonstrate that the results are compatible for the majority of the sources. We, however, use the DEBLENDIRS AGN results obtained from the ground-based mid-IR spectra because they allow us to compare them with the star formation activity on nuclear scales (see Sections 4.2 and 6.2).

4.2 Measuring the 11.3 $\mu$m PAH feature

The PAH features and, in particular, the 11.3 $\mu$m PAH emission are good proxies for deriving the SFR in starburst galaxies, LIRGs and ULIRGs (Brandl et al. 2006; Farrah et al. 2007; Alonso-Herrero et al. 2013a) as well as in Seyfert galaxies and other AGN (Netzer et al. 2007; Shi et al. 2007; Diamond-Stanic & Rieke 2012). To measure the 11.3 $\mu$m PAH feature from both the high angular resolution and the Spitzer/IRS spectra, we fitted a local continuum on both sides of the feature (rest-frame 10.75–11.0 $\mu$m and 11.65–11.9 $\mu$m) and integrated the feature within the spectral range $\lambda_{\text{rest}} = 11.05–11.55$ $\mu$m. We refer the reader to Hernán-Caballero & Hatziminaoglou (2011) for more details on this method and to Esquej et al. (2014) for its implementation for ground-based mid-IR spectroscopy. We estimated the uncertainties in the flux and equivalent width (EW) of the feature by performing Monte Carlo simulations using the calculated dispersion around the measured fluxes and EWs in 100 simulations of the original spectrum. For the CanariCam spectra, we used the random noise distributed as the fluxes and EWs in 100 simulations using the calculated dispersion around the measured equivalent width (EW) of the feature by performing Monte Carlo fits of sources with deep silicate features and high values of $\chi^2$. Thus, for these four nuclei in Table 5, we give the measurement value plus 1σ uncertainty as upper limits.

5 NUCLEAR MID-IR EMISSION OF QUASARS AND IR-BRIGHT GALAXIES

5.1 AGN rest-frame 12 $\mu$m luminosities and contribution to IR luminosity

Using the results from DEBLENDIRS, we derived the monochromatic rest-frame 12 $\mu$m luminosities of the AGN in the samples of the IR-bright galaxies and IR-weak quasars. For those nuclei where the observed ground-based $\sim$7.5–13 $\mu$m spectra did not cover the rest-frame 12 $\mu$m (marked in Tables 3 and 4), we derived the luminosities by extrapolating the best-fitting AGN component. Tables 3 and 4 list the derived rest-frame 12 $\mu$m AGN luminosities for the IR-bright galaxy and quasar samples, respectively, and Fig. 4 shows the corresponding histograms.

As can be seen from this figure, the median values of the AGN luminosities (using the 12 $\mu$m AGN luminosity as a proxy, see e.g. Asmus et al. 2014, 2015, and references therein) of the local IR-bright galaxies are slightly lower than those of the IR-weak quasars. However, the IR-bright galaxy AGN show a broader distribution. Their faint luminosity end ($\log L_{12}\mu$m $\sim$ 10$^{43}$ erg s$^{-1}$) still corresponds to typical values of local Seyfert galaxies (Asmus et al. 2014; Alonso-Herrero et al. 2016) even for those nuclei optically classified as L, C and H II (see Table 1). The high end of the 12 $\mu$m AGN luminosity distribution ($\log L_{12}\mu$m $\geq$ 10$^{45}$ erg s$^{-1}$) of the sample of local IR-bright galaxies is contributed by two IR-bright quasars (e.g. Mrk 1014 and IRAS 13349+2438) as well as the emerging quasar Mrk 231. Based on the observed distribution of the 12 $\mu$m AGN luminosities of the PG quasars in our sample, we consider that AGN with monochromatic 12 $\mu$m luminosities greater than a few 10$^{44}$ erg s$^{-1}$ indicate the presence of a quasar. Therefore, in our IR-bright galaxy sample, IRAS 08572+3915N and Mrk 463E (see also Mazzarella et al. 1991), which are not identified as optical

Notes: The Spitzer/IRS SL slit covers both nuclei of NGC 6240, Mrk 463, and IRAS 08572+3915, whereas for Arp 299, the two nuclei, NGC 3690B1 and IC 694, were observed separately (see Alonso-Herrero et al. 2009). The upper limits to the size of the emitting region indicate that the mid-IR nuclear emission appeared unresolved at the observed angular resolution of the ground-based spectroscopy (see Alonso-Herrero et al. 2016) and correspond to the slit width. The nuclear to IRS ratios refer to the luminosity ratios. The nuclear SFR take into account the factor of 2 needed to correct the PAH luminosities measured with a local continuum to the values obtained with ∝n^2 and use the Diamond-Stanic & Rieke (2012) calibration.

Figure 4. Distributions of the AGN rest-frame 12 µm monochromatic luminosities derived with DEBLENDIRS for the sample of IR-bright galaxies (red histogram) and the comparison sample of IR-weak quasars (blue solid histogram). The vertical lines mark the median of the distributions for the IR-bright galaxies (solid red line) and IR-weak quasars (blue dashed line).

The AGN fractional contributions within the slit (typical physical regions of a few hundred parsecs) at 12 µm and in the ~5–15 µm spectral range for the IR-bright galaxy nuclei (see Table 3) show a large variation going from 0.4 (NGC 6240N and IRAS 17208−0014) to nuclei completely dominated by the AGN emission (e.g. Mrk 1014 and IRAS 13349+2438). The median value of the AGN fractional contribution at 12 µm for the IR-bright galaxy nuclei is 0.78 (within the slit). This high value is not surprising because our sample selection required relatively compact emission and this tends to select IR-bright galaxies with AGN-dominated mid-IR fluxes within the slit (see discussion in Section 2). The nuclear (typical physical scales of hundreds of pc) mid-IR emission of the majority of quasars in our sample appears to be dominated by AGN emission (median value AGN contribution at 12 µm of 0.87), which is consistent with the AGN fractional contributions at 24 µm derived from Spitzer/IRS spectroscopy by Shi et al. (2007).

We can use the average AGN and quasar templates of Mullaney et al. (2011), which have L_{12}^{AGN}/L_{12}^{IR} = 2.3 and 1.6, respectively, to derive the IR (8–1000 µm) emission of the AGN. We find that the IR emission of the AGN contribute between 1 per cent (NGC 6240N and IRAS 17208−0014) and ~68 per cent (Mrk 463E) of the total IR luminosity of the system in our IR-bright galaxy sample with a median value of 10 per cent. This is in contrast with the AGN mid-IR dominance within the central hundred parsecs and indicates that the IR-bright galaxies in our sample have extended star formation over several kiloparsecs (see also Section 5.3). The largest AGN contributions among the IR-bright galaxies are, not surprisingly, for the IR-bright quasars. These estimates are in good agreement with the average 35–40 per cent AGN...
bolometric contribution estimated for local ULIRGs (Veilleux et al. 2009a; Nardini et al. 2010) and 5–15 per cent for local LIRGs (Petric et al. 2011; Alonso-Herrero et al. 2012) applying different methods to the Spitzer/IRS spectra. For the quasars, the AGN contribution to the IR luminosity is higher than for the IR-bright galaxies, with values in the range 30–70 per cent and a median contribution of 60 per cent.

5.2 AGN silicate feature and mid-IR spectral index

For each nucleus in the IR-bright galaxy and quasar samples, we list in Tables 3 and 4, respectively, the median values and 1σ confidence intervals of the fitted strengths of the silicate feature and mid-IR spectral index of the AGN component. As can be seen from these tables, the AGN hosted in IR-bright galaxies show a broader range of strengths of the silicate feature than the IR-weak quasars. The latter tend to have values consistent with the feature being slightly in emission, as also found by other studies using Spitzer/IRS spectroscopy (see e.g. Shi et al. 2006; Thompson et al. 2009). In terms of the AGN spectral index in the 5–15 μm range, the two samples show values that are similar to values derived for Seyfert galaxies, although some for slightly different spectral ranges (see e.g. Thompson et al. 2009; Hönig et al. 2010; Ramos Almeida et al. 2011b; Hernán-Caballero et al. 2015; Alonso-Herrero et al. 2016).

To make a statistical comparison of the derived mid-IR AGN properties of IR-bright galaxies and quasars, we combined the individual PDF of the mid-IR 5–15 μm spectral index and the strength of the silicate feature from the DEBLEND/IRS spectral decomposition for the nuclei of the samples. We show the resulting combined PDFs in Fig. 5 and the statistics in Table 6. We note that the relatively small size of our samples means that some of the observed peaks in the combined PDF are due to individual nuclei with relatively well-constrained values of the AGN $S_{\text{Sil}}$ and $\alpha_{\text{MIR}}$ (see the discussion below). However, we prefer to show the combined PDFs rather than the PDF for the individual galaxies as the PDF for some individual objects are quite broad, whereas the combined PDF contain more information.

The expectation value for $\alpha_{\text{MIR}}$ derived from the combined PDFs (median of the distribution) is similar for the samples of IR-bright galaxies and the IR-weak quasars ($\alpha_{\text{MIR}} = -1.7$ to $-1.8$). However, the distribution for the nuclei of IR-bright galaxies shows a slightly broader tail towards flatter mid-IR spectral indices. On the other hand, the distributions of the strengths of the silicate features for the AGN component are markedly different for the two samples. The IR-weak quasars show a narrow distribution centred at $S_{\text{Sil}} = 0.07$ (the silicate feature slightly in emission), whereas the distribution for the AGN hosted by IR-bright galaxies (including IR-bright quasars, but see below) is much broader with a median value of $S_{\text{Sil}} = -0.90$. These results are similar to the findings for ULIRGs and optical quasars by Veilleux et al. (2009a) based on the Spitzer/IRS spectroscopy.

We also produced the combined PDFs for the IR-bright quasars alone (six nuclei excluding IRAS 08572+3915N), see bottom panels of Fig. 5 and Table 6. The best-fitting AGN components for both IR-bright and IR-weak quasars are relatively similar (see Fig. 6), as also reflected by the median values of the combined PDFs of $S_{\text{Sil}}$ and $\alpha_{\text{MIR}}$. However, there are some slight differences in the 16–84 per cent percentiles of the combined PDF of $S_{\text{Sil}}$. There is a second peak in the distribution of the AGN $S_{\text{Sil}}$ of the IR-bright quasars at $S_{\text{Sil}} \sim -0.8$, which is due to the two ‘transitioning quasars’ in our sample, namely, Mrk 463E and Mrk 231 (the two best-fitting AGN components with the 9.7 μm silicate feature in absorption in Fig. 6). Conversely, the peak at a value $S_{\text{Sil}} \sim 0.1–0.2$ seen in the combined PDF of the IR-bright galaxy nuclei is contributed by the IR-bright quasars (IZw1, Mrk 1014, IRAS 13349+2438, and Mrk

![Figure 5. Combined probability distribution functions of the AGN mid-IR (5–15 μm) spectral index (right-hand panel) and strength of the silicate feature (left-hand panel) derived with DEBLEND/IRS. The IR-bright galaxy sample includes the IR-bright quasars and contains 16 nuclei, the IR-weak quasar sample contains 10 nuclei, and the IR-bright quasar sample contains 6 nuclei.](image-url)

### Table 6. Statistics of the combined PDF for the fitted mid-IR AGN properties.

| Sample                  | Number | AGN $S_{\text{Sil}}$ (16%, 84%) | Median | AGN $\alpha_{\text{MIR}}$ (16%, 84%) |
|-------------------------|--------|---------------------------------|--------|------------------------------------|
| IR-bright galaxies      | 16     | $-0.90$                         | $[-3.52, 0.09]$ | $-1.79$                           | $[-2.63, -0.73]$ |
| IR-weak quasars         | 10     | $0.07$                          | $[-0.24, 0.33]$ | $-1.68$                           | $[-2.40, -1.04]$ |
| IR-bright quasars       | 6      | $-0.03$                         | $[-0.68, 0.29]$ | $-1.58$                           | $[-2.39, -0.35]$ |
478), whereas the rest of the AGN components in the IR-bright galaxy sample appear to be much more obscured.

In Section 6, we will investigate further the possible evolutionary connection between IR-bright galaxies and quasars and the interaction stage of the AGN mid-IR emission.

### 5.3 Nuclear star formation activity

In this section, we use the $11.3 \, \mu m$ PAH feature emission to study the star formation activity in the nuclear regions of the IR-bright galaxy sample. Of the 13 IR-bright nuclei where the ground-based spectral range allowed measurements, we detected the $11.3 \, \mu m$ PAH feature (with a detection significance better than $2\sigma$) in 7 of them (see Table 5). The nuclear values of the EW of the $11.3 \, \mu m$ PAH feature for most of the nuclei in the IR-bright galaxy sample are below the typical values of star-forming galaxies ($\sim 0.5 – 1 \, \mu m$; see for instance, Hernán-Caballero & Hatziminaoglou 2011) because of the increased AGN fractional contribution at 12 $\mu m$ when using high-angular resolution data. For the $11.3 \, \mu m$ PAH non-detections, there still can be a small contribution from star formation activity in the nuclear region. Our upper limits show that sources with undetected $11.3 \, \mu m$ PAH features could still have $11.3 \, \mu m$ PAH luminosities of a few $10^{41} \, erg \, s^{-1}$. This shows that detecting PAH emission may be difficult when the AGN continuum dominates the emission at 12 $\mu m$ unless the spectrum has a high S/N ratio. In galaxies with deep silicate features (e.g. IRAS 08572+3915N in our sample), it is possible that the $11.3 \, \mu m$ PAH emission is obscured by the same foreground absorber that obscures the AGN continuum (see also discussion by Veilleux et al. 2009a). In fact, for IRAS 08572+3915N, the 100 per cent AGN contribution in the mid-IR is because this galaxy is fitted with an ‘obscured AGN’ template which might be suffering from the same effect.

Since we also measured the $11.3 \, \mu m$ PAH feature in the Spitzer/IRS spectra, we computed the ratios between the nuclear and the IRS $11.3 \, \mu m$ PAH luminosities (fifth column of Table 5). The ratios for the IR-bright galaxy sample indicate that there is a large fraction with extended PAH emission from the nuclear physical scales probed with the ground-based data (hundreds of parsecs) to the few kpc scales probed by the IRS slit. The two nuclei in the IR-bright galaxy sample with the most extended $11.3 \, \mu m$ PAH emission (nuclear to IRS ratios of 0.08 and $\sim 0.1$) are the two components of Arp 299 (see Fig. 2), as also revealed by the deep GTC/CanariCam imaging at 8.7 $\mu m$ with the Si-2 filter. The rest have ratios of between 0.1 and 0.5. For the nuclear spectra with only upper limits to the $11.3 \, \mu m$ PAH feature ratios are consistent with compact emission (ratios 0.5–1).

For the five IR-weak quasars where the ground-based spectra covered the $11.3 \, \mu m$ PAH feature (see Table 5), we only detected the feature in Mrk 509 (see also Honig et al. 2010) with an EW of $0.011 \pm 0.004 \, \mu m$. This lack of detections is not surprising as the EW of the $11.3 \, \mu m$ PAH feature, measured from the Spitzer/IRS spectra for the PG quasars in our sample, are in the range $0.068 \pm 0.002 \, \mu m$ for Mrk 509 and $0.090 \pm 0.002 \, \mu m$ for Mrk 335. The $11.3 \, \mu m$ PAH feature of PG0804+761 remained undetected even in the IRS spectrum. Since the ground-based slits are about $\sim 7$ times narrower than the IRS SL one, higher AGN contributions within the smaller slits would produce even smaller EW of the PAH features. As can be seen from Table 5, three quasars have formally nuclear upper limits to the $11.3 \, \mu m$ PAH fluxes larger than the IRS one due to the S/N ratio of the CanariCam spectra. Clearly, the nuclear to IRS ratios have to be lower than one.

In Fig. 7, we plot the nuclear $11.3 \, \mu m$ PAH feature luminosities from ground-based data against those measured from the Spitzer/IRS spectra for the IR-bright galaxy sample. From the slit widths and angular resolution, we estimate that if the emission was uniformly distributed, we would expect a ratio between the two luminosities for the GTC/CanariCam spectra for approximately 50. In this figure, for NGC 1614, we plot the nuclear (central $\sim 150$ pc) $11.3 \, \mu m$ PAH luminosity estimated by Pereira-Santaella et al. (2015) rather than our 160 pc extraction, which leads to a nuclear to IRS ratio of approximately 0.1. As can be seen from this figure, the $11.3 \, \mu m$ PAH emission of the majority of the IR-bright galaxies, while extended over several kpc, is not uniformly distributed. It does not appear to be very compact either (approximately ratios of less than a few tenths), except perhaps for some of nuclei with nuclear upper limits and NGC 6240S. If the $11.3 \, \mu m$ PAH emission traces the recent star formation activity in IR-bright galaxies, this indicates that star formation is extended over several kiloparsecs and not taking place uniformly distributed. Indeed, near-IR HST and ground-based hydrogen recombination line observations show that in local (U)LIRGs, star formation takes place in high-surface brightness H II regions (see e.g. Alonso-Herrero et al. 2006; Arribas et al. 2012; Piqueras López et al. 2016). The morphologies traced by the GTC/CanariCam 8.7 $\mu m$ imaging observations of those IR-bright galaxies in our sample with clearly resolved nuclear regions (see Figs 2 and 3, and also Díaz-Santos et al. 2008, for other lower IR luminosity LIRGs) also confirm this.

---

Figure 6. The thick colour lines are the DEBLENDIRS best-fitting AGN components of the ground-based mid-IR spectra of the IR-weak quasars (upper panel) and IR-bright quasars (lower panel), normalized at 12 $\mu m$.  

---

2 This relatively narrow mid-IR filter probes the emission from the 8.6 $\mu m$ PAH feature, see fig. 4 of Díaz-Santos et al. (2008).
Taking into account the estimated nuclear SFR per unit area in our sample of IR-bright galaxies and the AGN contributions to the nuclear emission, we suggest that NGC 1614, IC 694 and NGC 6240 would be potentially good candidates for starburst-driven powerful outflows based on the observed correlation between SFR per unit area and outflow velocity (Arribas et al. 2014; Heckman et al. 2015). Indeed, Feruglio et al. (2013) and García-Burillo et al. (2015) have confirmed the presence of starburst-driven outflows in the southern nucleus of NGC 6240 and the nuclear region of NGC 1614, respectively, using molecular gas data.

6 EVOLUTIONARY SEQUENCE OF MID-IR PROPERTIES BETWEEN IR-BRIGHT GALAXIES AND QUASARS?

6.1 Nuclear obscuring material

In this section, we look for evidence for an evolution of the obscuring material around the AGN between the IR-bright galaxies, IR-bright quasars and IR-weak quasars. To do so, we use the derived mid-IR AGN properties, namely, the spectral index, the strength of the silicate feature, and the fractional contribution to the mid-IR emission. With regards to the AGN properties, Haas et al. (2003) predicted an evolutionary change of the mid-IR slope towards flatter indices from ‘warm’ ULIRGs (those dominated by AGN emission) to young quasars, evolved quasars and finally dead quasars. ‘Cool’ ULIRGs, even those hosting an AGN, are dominated by star formation, and emit most of their energy in the far-IR. In ‘cool’ and ‘warm’ ULIRG systems, the dust is distributed in a more spherical configuration and as the system evolves to a quasar, the dust distribution is predicted to develop a disc or torus-like configuration. From their fig. 12, we can see that their predictions for the shape of the IR emission encompasses physical scales of less than 1 kpc which compare well with the physical sizes probed by our ground-based spectroscopy. Moreover, in the context of the predictions from clumpy torus models, the mid-IR slope and the strength of the silicate feature provide information about the radial distribution of the clouds and the number of clouds along the equatorial direction in the torus (Hönig et al. 2010; Ramos Almeida et al. 2014). Fig. 8 compares the AGN mid-IR spectral index to the AGN strength of the silicate feature for the IR-bright galaxies and quasars as derived with DEBLEND/IRS. The sources are colour-coded by the fractional AGN contribution at 12µm and the IR-bright galaxies are shown with their interaction class given in Table 1. Most of the IR-weak quasar sample and the IR-bright quasars (the latter recognized as having high AGN fractional contributions and IV or V morphologies) are located in the region around $S_{sil} = 0$ (see also Fig. 9) but span the same range of mid-IR spectral indices as the rest of the IR-bright galaxy sample. This indicates that, in general, the nuclear mid-IR emission of type 1 quasars can be explained with tori with a relatively low number of clouds along the equatorial direction (see Mor et al. 2009, Martínez-Paredes et al., in preparation for detailed modelling of the nuclear IR emission of PG quasars).

As we also showed in Section 5.2 for the combined PDF of $S_{sil}$ and $a_{sil}$, the shapes of the AGN mid-IR emission of IR-bright and IR-weak quasars do not differ significantly (see also Fig. 6). This seems to imply that the predicted evolution of the dust distribution around these two types of quasars is taking place in short timescales which cannot be resolved with our data. This agrees with the observational result that red quasars make up only 15–20 per cent of the quasar population (see e.g. Glikman et al. 2012). Moreover, our...
classification between IR-bright and IR-weak quasars is based on the IR-to-optical ratios which is likely reflecting different levels of star formation activity in their host galaxies as their far-IR emission is dominated by this process (Netzer et al. 2007). Finally, as discussed in Section 2, our sample of quasars is likely mid-IR-bright and thus, it is possible that we are missing more evolved quasars with different mid-IR spectral shapes.

One exception in this mid-IR view might be the transition quasar Mrk 231 in our sample whose AGN silicate feature is intermediate between those of non-AGN dominated IR-bright galaxies and quasars suggesting the presence of extra dust components. In Mrk 231, the nuclear silicate feature (measured on physical scales of <400 pc) would indicate an extinction of $A_V \sim 10$ mag, using a foreground dust screen, which is compatible with the value derived by Veilleux et al. (2013) for the obscuration of the broad absorption line region through which the broad-line region is observed. The AGN in the other two candidates to buried quasars (Mrk 463E and IRAS 08572+3915N) have strengths of the silicate features which are not compatible with those measured in optically identified quasars, with IRAS 08572+3915N showing, in fact, the most extreme absorption feature in our sample of IR-bright galaxies and in general the local (U)LIRG population (Spoon et al. 2007). These three quasars could be perhaps just before the blowout phase of the quasar evolution (Hopkins et al. 2006).

As can be seen from Fig. 8, a large fraction of non-quasar IR-bright galaxies (8 out of 10) occupy a different region from that of the quasars, especially in terms of the silicate feature as we saw from the combined PDFs (see Fig. 5). There is no clear trend of the AGN 5–15 $\mu$m spectral index with the AGN fractional contribution for the IR-bright galaxy sample (see Fig. 9, lower-right panel). This would be expected if the AGN fractional contribution were to give an indication of the evolutionary stage of the AGN. On the other hand, there is a tendency for the AGN component of IR-bright galaxy nuclei with low (<10 per cent) AGN fractional contributions to the total IR luminosity of the system to show deeper silicate features (Fig. 9, lower-left panel). These have a mean value of $S_{\text{Sil}} = -1.7$, whereas the nuclei with AGN fractional contributions above 10 per cent have a mean value of $S_{\text{Sil}} = -0.1$. This is similar to the trend found by Veilleux et al. (2009a) for H II-like optically classified ULIRGs to have deeper silicate features. As pointed out by many works (Levenson et al. 2007; Alonso-Herrero et al. 2011; González-Martín et al. 2013; Hatziminaoglou et al. 2015; Alonso-Herrero et al. 2016), deep silicate features ($S_{\text{Sil}} < -1$) cannot be reproduced by clumpy torus models (see e.g. Nenkova et al. 2008; Hönig & Kishimoto 2010), indicating either extended dust components in the host galaxies (see Goulding et al. 2012) and/or deeply embedded sources in more spherical configurations. This is consistent with Haas et al. (2003) evolutionary prediction of a more embedded dust distribution surrounding the AGN for the ‘cool’ (i.e. star formation dominated) ULIRG phase.

We do not find any clear trends of the AGN mid-IR properties in terms of the interaction stage (see Fig. 8) or the projected nuclear separation (see the upper panels of Fig. 9). For instance, the three AGN in the IR-bright galaxy sample with the deepest silicate features are in interacting galaxies which are not fully merged (that is classified as IIIb, with projected nuclear separations between the individual nuclei of less than 10 kpc). However, the LIRG NGC 7469 (not plotted here), which is classified as IIIa (its companion is IC 5283, located at a projected distance greater than 10 kpc) has an AGN silicate feature flat or slightly in emission (Hönig et al.
A. Alonso-Herrero et al.

Figure 9. Comparison between the derived AGN mid-IR spectral index $\alpha_{\text{MIR}}$ and strength of the silicate feature $S_{\text{Sil}}$ and the projected nuclear separation (upper panels) and the ratio between the AGN IR luminosity and total IR luminosity of the system (bottom panels) for IR-bright galaxies (only those not classified as quasars, 10 nuclei), IR-bright quasars and IR-weak quasars. The fully merged IR-bright systems and IR-weak quasars are plotted at projected nuclear separations of 0.1 and 0.08 kpc for clarity.

2010), which is similar to the values measured in the (fully merged) quasars in our sample and other Seyfert 1 nuclei (Thompson et al. 2009; Hönig et al. 2010; Alonso-Herrero et al. 2016). The other non-quasar IR bright nuclei whose AGN is fitted with a deep silicate feature is UGC 5101 which is believed to be fully merged.

In summary, since the AGN mid-IR spectral index and the silicate feature trace the properties of the obscuring material around the AGN (approximately, the radial distribution of clouds and number of clouds in the context of the clumpy dusty torus, respectively, see Hönig & Kishimoto 2010) the only clear trend is for both IR bright IR-weak quasars to show less obscuration than the rest of the nuclei in the IR-bright galaxy sample which tend to have lower AGN fractional contributions. We find no apparent relationship of these properties with the interaction class of the host galaxy or the projected nuclear separation between the nuclei. This confirms that there is not a single evolutionary path for the local IR-bright galaxies into AGN-dominated systems, as already discussed in previous works (Rigopoulou et al. 1999; Farrah et al. 2009; Veilleux et al. 2009a).

6.2 Nuclear star formation versus AGN luminosity

In the last part of this work, we investigate the relation between the nuclear star formation activity and the AGN luminosity for our sample of local IR-bright galaxies. Numerical simulations for major gas-rich mergers (Hopkins et al. 2008) predict a relation between these two quantities with the correlation becoming more tightly coupled on smaller physical scales (Hopkins & Quataert 2010). However, dynamical delays between the peaks of star formation activity and AGN activity are also predicted and are also a function of the physical scales where the star formation is measured (Hopkins 2012). From the observational point of view, this
correlation has been observed for local Seyferts in the Revised Shapley–Ames (RSA) sample for nuclear SFR measured on circum-nuclear scales (radius of $r = 1 \text{kpc}$; Diamond-Stanic & Rieke 2012) and on 100-pc nuclear scales (Esquej et al. 2014). Also, Netzer et al. (2007) found a similar correlation for PG quasars using the 7.7 $\mu$m PAH feature as measured from Spitzer/IRS spectra and probing several kpc scales.

Fig. 10 shows the AGN rest-frame 12 $\mu$m monochromatic luminosity against the nuclear 11.3 $\mu$m PAH luminosity as proxies for the AGN luminosity and nuclear SFR, respectively, for the IR-bright galaxy and quasar samples. Symbols and colours as in Fig. 7. The 11.3 $\mu$m PAH luminosities and AGN 12 $\mu$m fractional contributions are from the ground-based mid-IR spectroscopy except for IC 694 and NGC 3690B (see the text for more details).

The filled star symbols are IR-weak quasars with detections or upper limits of the 11.3 $\mu$m PAH feature. The inverted triangles are RSA Seyferts for which the mid-IR spectroscopy probes physical scales of a few hundred parsecs. The shaded area indicates the locus of normal AGN, as defined by the location of the RSA Seyferts and assuming they follow a linear relation (see the text for details).

Figure 10. AGN rest-frame 12 $\mu$m monochromatic luminosity against the nuclear 11.3 $\mu$m PAH luminosity for IR-bright and IR-weak quasars. Symbols and colours as in Fig. 7. The 11.3 $\mu$m PAH luminosities and AGN 12 $\mu$m fractional contributions are from the ground-based mid-IR spectroscopy except for IC 694 and NGC 3690B (see the text for more details).

Summary and Conclusions

The evolutionary connection between IR-bright galaxies associated with gas-rich mergers and quasars was proposed nearly 30 yr ago. We used ground-based mid-IR imaging and spectroscopy of a sample of 14 local (16 individual nuclei) IR-bright galaxies ($\log L_{\text{IR}} \geq 11.4\, L_\odot$) and a comparison sample of 10 optical quasars to investigate this connection. Among the IR-bright galaxies, which are mostly in interacting or merger systems, five are classified as IR-bright quasars based on their IR luminosity to optical $B$-band ratios. We took advantage of the high angular resolution (0.3–0.4 arcsec) afforded by mid-IR instruments on 8–10 m-class telescopes to study nuclear physical scales of hundreds of parsecs in both samples with an improvement of almost a factor of 10 with respect to Spitzer/IRS. This allows us to probe nuclear scales where the black hole growth and star formation activity are believed to be more tightly coupled.

Using the DEBLEND/IRS spectral decomposition tool, we isolated the mid-IR emission due to dust heated by the AGN from that due to nuclear star formation for both samples. This allowed us to derive AGN mid-IR properties such as, the $5–15\,\mu$m spectral index ($\alpha_{\text{MIR}}$), the strength of the 9.7 $\mu$m silicate feature ($S_{\text{Sil}}$), and the AGN rest-frame $12\,\mu$m monochromatic luminosities, which provide information about the nuclear dust distribution and the AGN contribution to the IR luminosity. We also measured the 11.3 $\mu$m PAH feature emission on nuclear and kiloparsec scales, the latter from Spitzer/IRS spectroscopy, as proxies for the star formation activity in both IR-bright galaxies and quasars.

Our main results are as follows.

(i) IR-bright galaxies and quasars show similar high AGN mid-IR contributions (median $\sim 80$–$90\%$ per cent) within the slits. However, the AGN IR contribution to the total IR luminosity of IR-bright galaxies is significantly lower (between 1 per cent and 70 per cent, median 10 per cent) than in quasars (median 60 per cent) indicating that the former have significant contributions from star formation activity.

(ii) The shapes of the AGN mid-IR emission of IR-bright and IR-faint quasars do not differ significantly, as demonstrated by the similarity of the combined PDF of the derived AGN $5–15\,\mu$m spectral indices (medians $\alpha_{\text{MIR}} = -1.6$ and $-1.7$) and strength of the 9.7 $\mu$m silicate feature (medians $S_{\text{Sil}} = -0.03$, that is, feature...
slightly in emission and $S_{\text{Sil}} = 0.07$, feature slightly in absorption). This suggests that the predicted evolution of the nuclear dust distribution around these two types of quasars is taking place in short time-scales and the differences in terms of IR to $B$-band ratios are likely due to different levels of star formation activity in their host galaxies. However, our sample of quasars is likely to be mid-IR-bright and therefore miss some of the more evolved quasars.

(iii) Based on the observed nuclear silicate features, IR-bright and IR-weak quasars are likely to contain less nuclear obscuring material than the rest of the nuclei in the IR-bright galaxy sample (median $S_{\text{Sil}} = -0.90$). For the far-infrared galaxies, we found no clear trend of the AGN mid-IR properties ($S_{\text{Sil}}$ and $S_{\text{MIR}}$) with the interaction class of the host galaxy or the projected nuclear separation. This confirms that there is not a single evolutionary path for the evolution of the dust distribution around the AGN hosted by local IR-bright galaxies.

(iv) From the comparison of the 11.3 $\mu$m PAH fluxes between nuclear scales (ground-based spectroscopy) and kiloparsec scales (Spitzer/IRS spectroscopy), we concluded that star formation in many local IR-bright galaxies is extended over several kiloparsecs and not uniformly distributed but rather taking place in individual bright star-forming regions. The nuclear SFR of the IR-bright galaxies in our sample range between $0.6 M_{\odot} \text{yr}^{-1}$ for IC 694 and $7.6 M_{\odot} \text{yr}^{-1}$ for NGC 6240S. For the physical sizes covered by the ground-based slits, these translate into nuclear SFR per unit area between $18 M_{\odot} \text{yr}^{-1} \text{kpc}^{-2}$ for IRAS 17208$-$0014 and $160 M_{\odot} \text{yr}^{-1} \text{kpc}^{-2}$ for NGC 6240S.

(v) IR-bright and IR-weak quasars have more luminous AGN (using the AGN 12 $\mu$m luminosity as a proxy) and higher nuclear (a few hundred parsecs) SFR (using the 11.3 $\mu$m PAH luminosity as a proxy) than local Seyferts. For their luminosities and compared to local Seyferts, the nuclear star formation activity of some local quasars is already dimming, as predicted by numerical simulations of major mergers. Some of the other IR-bright galaxy nuclei, however, show enhanced nuclear star formation at a given AGN $\nu L_\nu(12\mu\text{m})$ compared to local Seyferts, indicating that they are in an earlier star formation-dominated phase of the interaction process. However, this excess nuclear star formation activity is observed in both fully merged IR-bright galaxies as well as individual nuclei of close interacting systems.

The results of this paper highlight the evolutionary complexity of the AGN and star formation energetics in the nuclear regions of local IR-bright galaxies and quasars. The integral field unit of the mid-IR MIRI instrument (Rieke et al. 2015; Wright et al. 2015) on the James Webb Space Telescope will produce sensitive observations with similar angular resolutions to the ground-based data analysed here while providing a broad spectral range ($5-28.5 \mu$m) and high spectral resolution ($R \sim 1500-3500$). This will allow us to observe direct indicators of the presence of an AGN (i.e. detection of high-excitation emission lines), probe the nuclear star formation activity with different tracers, and obtain the kinematics of the nuclear regions of local IR-bright galaxies and quasars.

APPENDIX A: EXAMPLES OF SPECTRAL DECOMPOSITION WITH DEBLENDIRS

Even though DEBLENDIRS was initially designed to perform the spectral decomposition of Spitzer/IRS spectra, it can also be used with ground-based data covering the approximate spectral range 7.5–13 μm. We only needed to change the spectral range in the DEBLENDIRS configuration file to reflect that covered by the ground-based data. Additionally, from the list of AGN templates, we removed those in our sample selected as such (see Hernán-Caballero et al. 2015, for more details). We note, however, that the mid-IR fractional contributions of the STR, PAH, and AGN components and the mid-IR spectral index $\alpha_{\text{MIR}}$ are for the 5–15 μm spectral range.

We show in Fig. A1 examples of the DEBLENDIRS graphical output of the spectral decomposition of the GTC/CanariCam spectra of two Local infrared bright galaxies
Figure A1. Examples of the graphical output of DEBLENDIRS for the spectral decomposition of the GTC/CanariCam 8–13 μm nuclear spectra of an AGN-dominated IR-bright galaxy: Mrk 463E (right-hand panel) and a star formation-dominated IR-bright galaxy IRAS 17208−0014 (left-hand panel). The top panels show the GTC/CanariCam spectrum in rest frame (note that the label says ‘IRS spec’), together with the best-fitting model (orange) and the stellar, PAH and AGN components in green, red, and blue. The PDF in the lower panels are for the STR, PAH and AGN emission fraction (within the slit) in the 5–15 μm spectral range rSTR, rPAH, and rAGN, respectively; the strength of the AGN silicate feature S_{Sil}; the starburst and AGN fractional contribution at 12 μm (within the slit) L_{12} SB and L_{12} AGN, respectively; the AGN fractional contribution at 6 μm but since the rest-frame 6 μm is not covered by the CanariCam spectra the PDF of L_{6} AGN fraction is meaningless; the AGN α_{MIR} spectral index derived for the 5–15 μm spectral range. For all the PDF, the shaded regions represent the 1σ confidence interval, that is, the 16 per cent and 84 per cent percentiles, whereas the solid and dashed lines are the expectation value and the best-fitting model value of the distributions, respectively.

IR-bright galaxy nuclei in our sample, one dominated by the AGN emission (Mrk 463E) and one dominated by star formation (IRAS 17208−0014).

In Section 4.1, we remarked that based on the reduced χ^2 values, the majority of the ground-based spectra of the IR-bright galaxies and the quasars were well fitted with DEBLENDIRS using IRS templates. However, there are a few cases with relatively high χ^2 values, so we need to determine if this is due to the lack of appropriate spectral templates in the DEBLENDIRS data base to fit deep silicate features. In Fig. A2, we plot the reduced χ^2 value of the best fit against the derived strength of the silicate feature of the AGN component. As can be seen from this figure, there is a tendency for worsening χ^2 for deeper silicate features cod nuclei with χ^2 > 10 having the deepest silicate feature (S_{Sil} < −2). This might be, in part, due to the limited number of ‘obscured AGN’ templates (22) in the DEBLENDIRS data base versus the rest of ‘bona fide AGN’ templates (159; see Hernán-Caballero et al. 2015, for further details). Also, the χ^2 value does not only depend on the appropriateness of the templates but also the S/N ratio of the spectra.

In objects with very deep silicate absorption features, the flux near the silicate minimum at 9.7 μm is very weak and can be a factor of ~100 lower than in the wings at 8 and 13 μm. The larger IRS aperture may admit substantially more diffuse emission from the host galaxy than the slits of the ground-based instruments, which can partially fill in the silicate absorption minimum and change the...
shape of the apparent silicate profile. This effect can be seen in the comparison of the IRS and ground-based TReCS spectra of NGC 4418 in Roche et al. (2015), where the absorption feature in the IRS spectrum is broader than the profile measured with the ground-based instrument TReCS because contributions from extra-nuclear emission flatten the minimum and broaden the wings of the silicate profile whilst enhancing the PAH emission. The same effects can be seen in the fit to IRAS 08572+3915N in Fig. A3. As more and
higher quality ground-based spectra become available, it may be possible to employ them as templates, but the broader wavelength coverage available from space missions would not be available. In the same figure, we also show the other two IR-bright nuclei whose fits have \( \chi^2 > 10 \). IC 694 might suffer from the same problem with the silicate feature as IRAS 08572+3915N but it is not as extreme. Also the high value of \( \chi^2 \) is due to the relatively poor fits of the PAH features. In any case, both nuclei have small 1\( \sigma \) uncertainties in the derived AGN \( S_{\text{Sil}} \) value due the above mentioned small number of 'obscured AGN' templates. For NGC 6240S, the high value of \( \chi^2 \) is likely caused by a bad atmospheric correction around 9.4–9.8 \( \mu \)m and at the edges of the spectrum. We conclude that for most objects in our sample, the IRS templates are appropriate for the spectral decomposition of the nuclear mid-IR spectra.

**APPENDIX B: COMPARISON OF DEBLENDIRS RESULTS FOR SPITZER/IRS AND HIGH-ANGULAR RESOLUTION GROUND-BASED SPECTRA**

In this appendix, we compare the AGN 5–15 \( \mu \)m spectral index \( \alpha_{\text{MIR}} \) and the strength of the silicate feature \( S_{\text{Sil}} \) derived with DEBLENDIRS using Spitzer/IRS SL spectroscopy (3.7 arcsec slit width) and high-angular resolution ground-based spectroscopy (slit widths between 0.52 and 0.75 arcsec) for the samples of IR-bright galaxies and quasars. As done for the ground-based data, for the Spitzer/IRS spectra, we only fitted the approximate spectral range 8–12.5 \( \mu \)m with DEBLENDIRS. We show the comparison between the derived AGN \( \alpha_{\text{MIR}} \) and \( S_{\text{Sil}} \) in Fig. B1. As can be seen from this figure, the agreement between the derived AGN properties is good within the derived 1\( \sigma \) uncertainties. While the 1\( \sigma \) uncertainties of the derived AGN \( \alpha_{\text{MIR}} \) and \( S_{\text{Sil}} \) for the quasars are similar for the ground-based and IRS spectra, in some IR-bright nuclei, especially those with low AGN fractional components, the IRS uncertainties are slightly smaller probably due to the higher S/N ratio of the IRS spectra. The most discrepant points correspond to some of the IR-bright nuclei with deep silicate features and/or for which the Spitzer/IRS spectroscopy could not isolate the individual nuclei (e.g. NGC 6240 and IRAS 14348–1447).
