ABSTRACT
We report results of proper motions of 15 known Large Magellanic Cloud (LMC) old globular clusters (GCs) derived from the Gaia DR2 data sets. When these mean proper motions are gathered with existent radial velocity measurements to compose the GCs' velocity vectors, we found that the projection of the velocity vectors onto the LMC plane and those perpendicular to it tell us about two distinct kinematic GC populations. Such a distinction becomes clear if the GCs are split at a perpendicular velocity of 10 km/s (absolute value). The two different kinematic groups also exhibit different spatial distributions. Those with smaller vertical velocities are part of the LMC disc, while those with larger values are closely distributed like a spherical component. Since GCs in both kinematic-structural components share similar ages and metallicities, we speculate with the possibility that their origins could have occurred through a fast collapse that formed halo and disc concurrently.

Key words: galaxies: individual: LMC – galaxies: star clusters: general

1 INTRODUCTION
The orbital motions of the old globular clusters (GCs) in the Large Magellanic Cloud (LMC) have been described from radial velocity (RV) measurements by a disc-like rotation with no GCs appearing to have halo kinematics (Schommer et al. 1992; Grocholski et al. 2006; Sharma et al. 2010), so that it is expected that they do not cross the LMC disc. However, a closer look to the RV versus position angle (PA) diagram, tells us that although a general trend following the LMC disc rotation is visible, there are also some GCs that clearly depart from that relationship. This behaviour can be seen in the top-left panel of Fig. 1, built from RVs and PAs taken from Piatti et al. (2018). The curve for a LMC disc, rotating according to the solution found from HST proper motion measurements in 22 fields (van der Marel & Kallivayalil 2014), is also depicted with a solid line. The dotted lines represent the curves considering the quoted errors in all the parameters involved (e.g., inclination of the disc, PA of the line-of-nodes, LMC dynamical centre, disc rotation velocity, etc) and the velocity dispersion, added in quadrature.

This observational evidence, together with some speculations about their origins (e.g. Brocato et al. 1996; Piatti & Geisler 2013), their different kinematics with respect to the LMC halo field stars (Bekki 2007, and references therein), the effects on their motions because of the interaction of the LMC with the Milky Way (Bekki 2011; Carpintero et al. 2013), among others, points to the need of deriving their space velocities, so that a three-dimensional picture of their movements can be analysed. In order to obtain them, accurate proper motions are necessary. With the second data release (DR2) of Gaia mission (Gaia Collaboration et al. 2016, 2018a), this challenging goal has became to be possible for the first time. Precisely, we derive here such LMC GCs’ proper motions and from information gathered from the literature constructed their space velocity vectors. By analysing their rotational and vertical velocities, along with their relationships with the GCs’ positions in the galaxy, their ages and metallicities, we found that two groups of GCs is possible to be differentiated from a kinematics point of view.

The Letter is organised as follows: in Section 2 we describe the selection of the Gaia DR2 extracted data and the estimation of the GCs’ mean proper motions. In Section 3 we perform a rigorous transformation of RVs and proper motions in terms of the rotation in and perpendicular to the LMC plane and discuss the results to the light of possible GC formation scenarious.

2 LMC GCs’ PROPER MOTIONS

From the Gaia archive\(^1\), we extracted parallaxes (\(\pi\)) and proper motions in Right Ascension (pmra) and Declination (pmdec) for stars located within 10 arcmin from the centres of 15 known LMC GCs (see Table 1). We limited our sample to stars with proper motion errors \(\leq 0.5\) mas/yr, which correspond to \(G \geq 19.0\) mag (Gaia Collaboration et al. 2018b). Excess noise (seps\(i\)) and significance of excess of noise (epsi) in Gaia DR2 (Lindgren et al. 2018) were used to prune the data. \(D(=\text{seps\(i\)}) < 2\) and \(\text{epsi} < 1\) define a good balance between data quality and number of retained objects for our sample (see also Ripepi et al. 2018). This means that we dealt with cluster red giant stars placed above the GCs’ horizontal branches. To select cluster stars we constrained our sample to those satisfying the following criteria: i) stars located at the LMC distance, i.e., \(|\pi| < 3\sigma(\pi)\) (see Vasiliev 2018); ii) stars located within the tidal cluster radii taken from Piatti & Mackey (2018).

We then performed a maximum likelihood statistics (Pryor & Meylan 1993; Walker et al. 2006) in order to estimate the mean proper motions and dispersion for different subsets of stars, namely, those with \(\sigma(\text{pmra})=\sigma(\text{pmdec}) \leq 0.1, 0.2, 0.3, 0.4\) and 0.5 mas/yr, respectively. We optimised the probability \(L\) that a given ensemble of stars with proper motions \(\langle \text{pm}\rangle\) and errors \(\sigma_i\) are drawn from a population with mean proper motion \(\langle \text{pm}\rangle\) and dispersion \(W\), as follows:

\[
L = \prod_{i=1}^{N} \left( 2\pi \sigma_i^2 + W^2 \right)^{-\frac{1}{2}} \exp \left( -\frac{(\text{pm}_i - \langle \text{pm}\rangle)^2}{2(\sigma_i^2 + W^2)} \right)
\]

where the errors on the mean and dispersion were computed from the respective covariance matrices. We applied the above procedure for pmra and pmdec, separately.

Fig. 2 depicts the results represented by ellipses centred on the mean values and with axes equal to the derived errors. As can be seen, the larger the individual proper motion errors, the larger the derived errors of the mean proper motions, with some exception. With the aim of assuring accuracy, we constrained the subsequent analysis to the GCs’ proper motions account not only for the measured errors but also for those from the adopted system of velocities of the LMC centre of mass, propagated through the transformation equations and added in quadrature. As can be seen, the GC motions relative to the LMC centre projected onto the sky resemble that of the rotation of a disc, with some noticeable scatter and some GCs placed beyond that rotational pattern.

3 ANALYSIS AND DISCUSSION

The projection of the GC velocity vectors onto the LMC plane and that perpendicular to it provide us with a valuable tool to address the issue of the genuine rotation of them in the LMC disc and the orientation of their orbits around the LMC centre. In order to convert the vector \((\text{RV}, \text{Vra}, \text{Vdec})\) into that with components \(V_r\) and \(V_{\theta}\) in the LMC plane and \(V_z\) perpendicular to it, according to the reference system defined by van der Marel et al. (2002), see their Figure 3), we inverted the matrix \(A = B \times C\), where \(B\) is the matrix:

\[
\begin{pmatrix}
1 & 0 & 0 \\
0 & b_1 & b_2 \\
0 & b_3 & b_4
\end{pmatrix}
\]

with \(b_1, b_2, b_3\) and \(b_4\) being the coefficients of the transformation equation (9) and \(C\) the matrix defined in equation (5) of van der Marel et al. (2002), respectively, so that:

\[
\begin{pmatrix}
V_r \\
V_{\theta} \\
V_z
\end{pmatrix} = A^{-1} \begin{pmatrix}
\text{RV} \\
\text{Vra} \\
\text{Vdec}
\end{pmatrix}
\]

Hence, \(\text{Vrot} = (V_r^2 + V_{\theta}^2)^{1/2}\), while the errors \(\sigma(V_r), \sigma(V_{\theta})\) and \(\sigma(V_z)\) were computing from propagation of errors of eq. (2). The resulting values for \(\text{Vrot}\) and \(V_z\) are listed in Table 1.

The top-right panel of Fig. 1 shows the resulting relationships of \(\text{Vrot}\) and \(V_z\) as a function of the deprojected distances \(r\). At first glance, inner GCs \((r < 5 \text{ kpc})\) seem to have \(\text{Vrot}\) values in better agreement with the rotation curve of the LMC disc than those in the outer regions. However, by inspecting the \(V_z\) versus \(r\) diagram, it is possible to distinguish two groups of GCs: one group with an average velocity dispersion perpendicular to the LMC plane close to zero, and another group with \(V_z > 10 \text{ km/s}\). For the sake of the reader, we have drawn GCs with \(V_z\) smaller than 10 km/s, between 10 and 20 km/s and larger than 20 km/s with open circles and boxes and filled circles, respectively, and traced those limits.

\(^1\) http://gea.esac.esa.int/archive/
with dotted and dashed lines. Notice that, The LMC rotation curve derived from old field stars (blue line) by van der Marel & Kallivayalil (2014) does not particularly agree with GCs. Other curves (e.g. black, red, magenta lines) seem to agree better with GCs across the range of \( r \), GCs with a relatively high \( V_r \) velocity are those that globally more depart from the LMC rotation curve. For instance, the mean difference (absolute value) between the GC \( V_{rot} \) values and those for the same \( r \) values along the mean LMC disc rotation curve (magenta line) turned out to be 13.4±16.1, 24.8±21.1 and 28.3±13.0 for GCs with \( |V_r| < 10 \) km/s, \( 10 \) km/s < \( |V_r| < 20 \) km/s and \( |V_r| > 20 \) km/s (31.7±12.1 for \( |V_r| > 10 \) km/s and 18.8±12.6 for \( |V_r| < 20 \) km/s), respectively. If we consider only GCs with \( r < 5 \) kpc, we get 14.5±16.2, 15.5±28.6 and 30.0±15.3 (26.7±13.5 for \( |V_r| > 10 \) km/s and 14.7±14.2 for \( |V_r| < 20 \) km/s), respectively.

Such a kinematic distinction has also its counterpart in the spatial distribution of the GCs. The bottom-left panel shows that the farther a GC from the LMC centre, the larger its height out of the plane. Along this trend, the GCs with \( z > 10 \) km/s have occurred through a fast collapse that formed halo and spatial distribution and kinematics similar to those of the halo stars. Our analysis, based on the velocity vectors of GCs with high \( V_z \) agree very well with that theoretical result.

Finally, we analysed whether there is any link of these two phase-space GC populations with their ages and metallicities, so that some clues about their origins can be inferred. The analysis includes the two \( V_z \) cuts. The bottom-right panel of Fig. 1 shows the resultant behaviours, where ages and metallicities were taken from Piatti & Mackey (2018) and Piatti et al. (2018) (see Table 1). From a maximum likelihood analysis we found that these groups of GCs are coeval at a level of 0.4 Gyr and that they hardly differ in metallicity. This means that both GC components have formed nearly at the same time, with \( \sim 3 \) Gyr of their formation (12 \( \lesssim \) age (Gyr) \( \lesssim 14 \), Piatti et al. 2009; Wagner-Kaiser et al. 2018) and under similar chemical enrichment processes (the three groups expand similar [Fe/H] ranges). Because of these similarities in age and metallicity and the noticeable difference in their spatial distributions (thin disc and extended halo), we speculate with the possibility that their origins could have occurred through a fast collapse that formed halo and disc concurrently. The inner GCs with \( |V_r| < 10 \) km/s have remained rotating in the LMC disc since their \( in-situ \) formation. As for the formation of the GCs with higher \( V_z \) values, they could have occurred \( in-situ \) in the LMC halo and/or stripped from the Small Magellanic Cloud (SMC), where GCs with similar ages and metallicities should have formed. As suggested by Capriner et al. (2013), this could be a plausible explanation for the lack of old metal-poor GCs in the SMC. As for the time of the GC stripping, we do not have any hint: it could have happened at the early formation of both galaxies or during a later approach of the SMC by the LMC.

* a suggested GC population classification (see Section 3).
Figure 1. RVs and proper motions versus PAs diagrams of LMC GCs (top-left panel). RVs and PAs were taken from Piatti et al. (2018). We overlaid the curve representing the best-fit solution for the LMC disc rotation derived by van der Marel & Kallivayalil (2014) from HST proper motions of 22 LMC fields. The GC rotational and perpendicular velocities as a function of their deprojected galactocentric distances ($r$) are shown in the top-right panel. Open circles and boxes represent GCs with vertical velocities $|V_z| < 10$ km/s and 10 km/s $< |V_z| < 20$ km/s, respectively. The LMC rotation curves derived from HST proper motions of 22 fields, and from line-of-sight velocities of young and old stellar populations are drawn with black, red and blue solid lines, respectively (taken from Figure 7 of van der Marel & Kallivayalil 2014). The LMC disc rotation curve derived by Vasiliev (2018) is drawn with a magenta line. Relationships of the height out of the plane ($|Z|$) with $|V_z|$ and $r$ (bottom-left panel) and that of $|V_z|$ with the GCs’ ages and metallicities (bottom-right panel) (see text for details).

ACKNOWLEDGEMENTS

We thank the referee for the thorough reading of the manuscript and timely suggestions to improve it. We thanks Eugene Vasiliev his valuable comments on a draft version of this work. EJA acknowledges financial support from MINECO (Spain) through grant AYA2016-75931-C2-1-P. This work has made use of data from the European Space Agency (ESA) mission Gaia (https://www.cosmos.esa.int/gaia), processed by the Gaia Data Processing and Analysis Consortium (DPAC, https://www.cosmos.esa.int/web/gaia/dpac/consortium). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the Gaia Multilateral Agreement.
Figure 2. Vector-point diagrams of LMC GCs' mean proper motions derived using Gaia DR2 data with $\sigma$(pmra)=$\sigma$(pmdec) $\leq$ 0.1, 0.2, 0.3, 0.4 and 0.5 mas/yr, represented by black, blue, orange, magenta and red ellipses, respectively. Black points represent individual field stars located in an equal circular cluster area centred at 5 cluster radius from the cluster centre with proper motions errors $\leq$ 0.1 mas/yr (see text for details).
