Competition between Allowed and First-Forbidden $\beta$ Decay: The Case of $^{208}$Hg $\rightarrow ^{208}$Tl

Introduction.—Shell structure naturally arises for interacting multiparticle quantum systems. The concept has been successfully used in atomic physics [1], nuclear physics [2], and for metallic clusters [3]. In the case of atomic nuclei, the neutron magic numbers play an essential role in the nucleosynthesis of elements heavier than iron. Both in the slow ($s$) and rapid ($r$) neutron-capture processes, the neutron magic numbers play an essential role in the nucleosynthesis of elements heavier than iron. In the case of neutron-capture processes, these magic numbers have a significant impact on the relative stability of the nuclei involved. The $s$ abundance is the sum of the $s$-capture abundance and the $s$-capture neutron-capture abundance. The $r$ abundance is the sum of the $r$-capture abundance and the $r$-capture neutron-capture abundance. The $s/r$ ratio is the ratio of the $s$ abundance to the $r$ abundance. The $s/r$ ratio is a useful tool for understanding the nucleosynthesis of heavy elements.

The $\beta$ decay of $^{208}$Hg into the one-proton hole, one neutron-particle $^{209}$Tl nucleus was investigated at CERN-ISOLDE. Shell-model calculations describe well the level scheme deduced, validating the proton-neutron interactions used, with implications for the whole of the nucleosynthesis of heavy nuclei in the rapid neutron capture process. Furthermore, the observation of the parity changing $0^+ \rightarrow 0^-$ decay where the daughter state is core excited is unique, and can provide information on mesonic corrections of effective operators.
the abundances of nuclei with magic neutron numbers are enhanced. Thus the $\Lambda \sim 195$ r-process abundance peak is the consequence of the $N = 126$ neutron shell closure. $\beta$-decay half-lives are basic nuclear physics input in r-process calculations. While half-lives of a large number of fission products were recently measured [4,5], the $N = 126$ r-process path nuclei are experimentally unreachable [6,7], and we have to rely on theoretical calculations. In this context the nuclei in the $N = 126$ region are of particular interest [8] because first-forbidden ($FF$) $\beta$ decays successfully compete [9–15] with allowed Gamow-Teller (GT) and Fermi decays, and this impacts on the calculations of r-process nucleosynthesis abundances [16]. However, the calculation of $FF$ $\beta$ decay is notoriously difficult and subject to debate.

An ideal nucleus to study the competition between $FF$ and allowed $\beta$ decay should have a small number of both negative and positive parity levels below the $Q_\beta$ value, with simple and well-understood wave functions. The $\beta$ decay of $^{208}\text{Hg}$ into the one-proton-hole, one-neutron-particle $^{208}\text{Tl}$ nucleus with a $Q_\beta = 3.48$ (3) MeV [17] provides this ideal testing ground. $Q_\beta$ is low due to the vicinity of the stability line, and the wave functions are simple due to the small number of valence nucleons outside the doubly magic $^{208}\text{Pb}$ core. Furthermore, states with spin $I = 0$ and $I = 1$ of both positive and negative parities are available by combining a neutron above the $N = 126$ core with a proton hole below $Z = 82$. In addition, $^{208}\text{Tl}$, with one proton hole and one neutron outside $^{208}\text{Pb}$, provides directly the neutron-proton two-body matrix elements for the shell-model calculations [18]. Therefore the understanding of excited states in $^{208}\text{Tl}$ is essential for the successful prediction of properties of nuclei in the little studied $N > 126$, $Z < 82$ region [19]. In this region excited states were observed in only a handful of nuclei: $^{208}\text{Tl}$ [20] and $^{209}\text{Tl}$ [21–23], and more recently, with the advent of radio-active-beam facilities, $\gamma$-ray spectroscopy following internal decays provided information on the yrast structures of $^{208}\text{Hg}$ [24], $^{209}\text{Tl}$ [24], and $^{210}\text{Hg}$ [25]. Single-neutron states in $^{207}\text{Tl}$ [26] and $\gamma$-ray transitions in $^{211,213}\text{Tl}$ [27] were also identified.

In this Letter we present results from the $\beta$ decay of $^{208}\text{Hg}$ into $^{208}\text{Tl}$, providing information on the competition between allowed and first-forbidden $\beta$ decay and validating the proton-neutron interaction ‘south-east’ of $^{208}\text{Pb}$.

Experimental details.—Experiments to measure the $\beta$ decay of $^{208}\text{Hg}$ to $^{208}\text{Tl}$ were performed at the ISOLDE decay station (IDS) at CERN. $^{208}\text{Hg}$ nuclei were produced by impinging 1.4 GeV protons on a molten lead target. These were extracted using a FEBIAD VADIS ion source [28], accelerated to 30–50 keV, mass selected with a dipole magnet, and finally implanted in a tape at the IDS. Two experiments were performed [29] in 2014 and 2016. In both cases the IDS consisted of plastic scintillation detectors for $\beta$-particle detection surrounding the implantation point, and five composite Ge detectors for $\gamma$-ray measurements. In 2014 four Clover Ge and one Miniball Cluster detector were used, while in 2016 five clover Ge detectors were employed. The $\gamma$-ray detection efficiency at 1 MeV was 8% and 4% in 2014 and 2016. The $\beta$-particle detection efficiencies were $\sim 30\%$ in 2014 and $\sim 85\%$ (with a $\sim 4\pi$ detector placed in the vacuum chamber) in 2016. Data were time stamped to a precision of 10 ns and recorded using a triggerless data acquisition system. Correlations between detectors were made in software using the GRAIN software package [30].

Results.—The rate of $^{208}\text{Hg}$ delivery to the implantation position was $\sim 5$ and 25 Hz in 2014 and 2016, respectively. Better statistics on the $^{208}\text{Hg} \rightarrow ^{208}\text{Tl}$ decay were obtained in 2016, although the data were dominated by the $\beta$ decays of $^{208}\text{At}$ to $^{208}\text{Po}$ [31]. The 2014 data were cleaner, so the spectra presented here are from the 2014 measurement, while the intensities and lifetimes are from 2016.$\gamma$-ray spectra, with and without $\beta$ coincidence requirements, are shown on Fig. 1. \end{align*}

The theoretical

\begin{align*}
&\text{configurations of the individual states see Fig. 2.}
\end{align*}

Almost all of the \( \gamma \) rays assigned to \( 208 \)Tl are in prompt coincidence with \( \beta \) particles. The exceptions are the 221 and 1314 keV transitions originating from the excited state at 1807 keV. By examining the \( \beta-\gamma \) time spectrum, shown in Fig. 3, a lifetime of \( T_{1/2} = 1.3(1) \mu s \) was obtained for the 1807 keV level.

By comparing the intensity of the 453 keV \( M1 \) transition with that of the 157 keV in the 936 keV gated spectrum, the electron conversion coefficient of the 157 keV line was obtained as \( \alpha = 2.1(3) \). This proves its \( M1 \) character \( \left[ \alpha_{\text{theor}}(M1) = 2.38 \right] \). Consequently, the excited states at 1429 and 1586 keV have the same parity. In addition, the sum (\( \gamma \) plus conversion electron) intensity of the 221, 1314, 374, and 533 keV transitions cannot be larger than the total intensity reaching the ground state. This requires that the electron conversion coefficients of all the above listed \( \gamma \) rays are small. This rules out \( M1 \) character for the 221 keV transition \( \left[ \alpha_{\text{theor}}(M1) = 0.92 \right] \). \( E2 \) is favored by the isomerism as \( E1 \) yields the extreme hindrance of \( 10^{-8} \) W.u.

Two rather different values have been published for the lifetime of the \( 208 \)Hg ground state. \( T_{1/2} = 41^{+3}_{-5} \) min was reported from the earlier mentioned \( \beta \)-decay measurements \[36,37\], but recently a much shorter value of 132(50) s was published following a projectile fragmentation experiment \[7,38\]. We measured the half-life by implanting \( 208 \)Hg nuclei for a fixed time, than observing their decay. After removing the activity with the tape system, we repeated this sequence several times. In our first experiment in 2014 we aimed to be sensitive to 30 min lifetime. The nonobservation of the \( 208 \)Hg decay indicated that its lifetime is much shorter than 30 min. In 2016, we measured the half-life

\end{table}
of $^{208}$Hg, from the time profile shown in Fig. 3, to be $T_{1/2} = 135(10)$ s. This is in good agreement and more accurate than the recently reported value obtained at GSI. We used our new lifetime value for the log $ft$ calculations.

The spin parities of the excited states are restricted by $\beta$-decay considerations. There are three directly fed states at 2119, 1960, and 1807 keV with relative feedings of 25(4)%, 8(3)%, and 66(5)%. The corresponding log $ft$ values are 5.5(1), 6.0(2), 5.2(1), respectively. This restricts the spin of these states to 0 or 1, based on the log $ft$ systematics of Ref. [39]. Lower-lying levels need to have increasing spins as they decay towards the $5^+$ ground state. Ultimately the spin parities of the three states fed directly in $\beta$ decay are assigned by comparison with shell-model calculations.

Discussion.—In order to understand the structure of $^{208}$Tl, shell model calculations have been performed, using the OXBASH [40] code. Level energies and transition rates were calculated in the $\pi (0g_{9/2}, 1d, 2s1/2, 0h_{11/2}) \nu (0i_{13/2}, 1g, 2d, 3s1/2, 0j_{15/2})$ model space using the Kuo-Herling interaction [41] for $\pi \nu$ and $\nu \nu$ and H7B [42] for $\pi \nu$. For $^{208}$Tl this reduces to H7B only. The calculations were done in particle-particle mode relative to a hypothetical $^{132}$Sn core. In an extended model space neutron particle-hole ($ph$) excitations from the $2p_{1/2}$ and $2p_{3/2}$ orbits across the $N = 126$ shell closure were considered to account for the $2p2h$ content in the $(0–1)^-$ states and $\gamma$-ray transitions between them. The other transitions were calculated in the valence space only. The inclusion of the core breaking excitation is needed in order to account for the $1/2^-$ state with $\nu p_{1/2}^1g_{9/2}^0$ configuration at the relatively low energy of 2149 keV in $^{208}$Pb [23]. $\gamma$-decay transition rates were calculated using effective operators $e_\pi = 1.5 e$, $e_\nu = 0.85 e$ for $E2$ transitions and $g_{\pi} = 0.7 g_{\pi}^{\text{rest}}$ for $M1$ transitions. No $E1$ transitions are allowed in this model space.

In $^{208}$Tl, the level density is rather low at low excitation energies. Figure 4 shows the theoretical level scheme featuring relevant states with leading $ph$ configuration

![Fig. 3](image-url)  
**FIG. 3.** (a) Lifetime of the isomeric state at $E_x = 1807$ keV in $^{208}$Tl. The time difference between the $\beta$ particle and any of the 221–453 and 221–936 keV $\gamma$-ray pairs is shown. (b) Lifetime of the $^{208}$Hg ground state determined both from the accumulation and decay phases. Since the former one assumes a constant implantation rate, the value obtained during the exponential decay phase is adopted.

![Fig. 4](image-url)  
**FIG. 4.** Comparison of experimentally observed states with shell-model calculations. The horizontal lines indicate the theoretical values. The experimental values are denoted by circles (for states observed in the present experiment) and triangles (states from Ref. [20]). Levels with the same dominant configurations are connected. Positive (negative) parity states are shown in red (blue). Black is used for core-excited negative-parity states.

$\nu (g_{9/2}, i_{13/2}, s, d) \pi (s, d)$ and $\nu j_{15/2} h_{11/2}$ for even parity and $\nu (g_{9/2}, i_{13/2}) h_{11/2}$ for odd parity below the $Q_\beta$ value. In addition, the core excited $2p2h F^\pi = (0, 1)^- \pi h_{11/2}^2, g_{9/2}^0$ states are also shown. Note that the used model space does not allow for the prediction of collective octupole states [43,44]. These are negative parity states with spin parities ranging from $1^- (4^+ \otimes 3^-)$ to $8^- (5^+ \otimes 3^-)$, expected (at $\sim 2.6$ MeV) several hundreds of keV above the highest level observed here.

The calculations indicate that the only possible isomer at $\sim 2$ MeV excitation energy is the $0^-$ state with $\nu p_{1/2}^{-1}g_{9/2}^0\pi s_{1/2}^{-1}$ character. Accordingly we associate this with the 1807 keV level. The other member of the multiplet is predicted to be the lowest lying $1^-$ state, therefore we assign this to the 1960 keV state. These assignments are supported by a comparison to the $^{206}$Tl ground state and 305 keV excited state with $hh$ configuration $\nu p_{1/2}^{-1}h_{11/2}^{-1}$. The $^{208}$Tl states have the structure $^{208}$Tl$(0,1^-) = ^{206}$Tl$(0,1^-) \times ^{208}$Pb$(0^-)$. This manifests itself in similar log $ft$ values in $^{206,208}$Hg $\beta$ decays, namely, 5.41(6) and 5.24(10) in $^{208}$Tl $F^\pi = 0^-$, 1$^-$ [45] vs 5.2(1) and 6.0(2) in the $^{206}$Tl analogs. The relatively low excitation energy of the core excited states in $^{208}$Tl is readily explained by the strong $\nu g_{9/2}^0$ pairing which partially compensates the $N = 126$ shell gap.

The configurations of the low-energy states, below 1 MeV, are established as given on Fig. 4. We associate the 2119, 1586, 1429, and 1347 keV levels with the $1^-\rightarrow 4^-$ members of the $\nu g_{9/2} h_{11/2}^{-1}$ multiplet. As expected, these states are connected by strong M1 transitions, with decreasing energies. These compete with weak, but high-energy $E1$ transitions.
There is good agreement between the experimental and theoretical level schemes (see Fig. 4). The small discrepancy for negative parity states is due to omission of the octupole phonon coupled to the low-lying positive-parity states, which by mixing would lower the energies of the yrast states. The highly retarded transition strengths of the $\gamma$ rays depopulating the $0^-$ isomer are also well reproduced. The experimental transition strengths $B(E2) = 6.8(12) \times 10^{-3}$ and $B(E3) = 11.5(20) \times 10^{-3}$ W.u. for the 221 and 1314 keV transitions, respectively, compare well with the theoretical values of $B(E2) = 1.8 \times 10^{-3}$ and $B(E3) = 7.9 \times 10^{-3}$ W.u. The experimental branching ratios are in good agreement with the theoretical values, as shown in Table I. While the model space does not allow for $E1$ transitions, their reduced transition strengths can be estimated based on the experimental branching ratios and the theoretical $B(M1)$ and $B(E2)$ values of the competing $M1$ and $E2$ transitions. $B(E1)$ values of all observed transitions are of the order of $10^{-5} - 10^{-6}$ W.u. All possible, but not observed $E1$ transitions have strengths of $B(E1) < 3 \times 10^{-5}$ W.u.

While we assign negative parity to all three states directly populated by $\beta$ decay, we examined other scenarios. In particular we looked into the possibility that the directly populated states are of positive parity $0^+$ with $\nu s_{1/2}\pi s_{1/2}^{-1}$ configuration or $1^+$ with $\nu s_{1/2}\pi s_{1/2}^{-1} \nu s_{1/2}\pi d_{3/2}^{-1}$, and $\nu d_{5/2}\pi d_{3/2}^{-1}$ (see Fig. 4). None of the scenarios, with the exception of that presented in Fig. 2 is compatible with the shell model calculations.

We now examine the $\beta$ decay of $^{208}$Hg. First-forbidden $\beta$ decays populate negative parity states in $^{208}$Tl. These correspond to $\nu h_{9/2} \rightarrow \pi h_{11/2}$ and $\nu i_{11/2} \rightarrow \pi h_{11/2}$ decays. The measured log $ft$ values in the range of 5.2–6.0 are in line with those observed for first-forbidden decays in this mass region [20,46]. We refrain from a shell model calculation of rank $L = 0, 1$ $FF$ $0^+ \rightarrow (0, 1)^-$ transitions as a consistent treatment requires full inclusion of $\Delta l = 1$ $\pi$ orbitals in $1p1h$ core excitations, i.e., $2p2h$ states in $^{208}$Tl [47,48]. We note that the shell-model calculations available for the $\beta$ decay of $N = 126$ nuclei [9,10] do not consider neutrons above the 126 shell closure, therefore cannot provide reliable estimates for the decay of $^{208}$Hg.

Positive parity states could be populated by the allowed $\beta$ decay. For neutrons above $N = 126$ there are neither allowed Gamow-Teller (GT) nor Fermi transitions to protons below $Z = 82$. This is because the number of nodes between the corresponding orbitals change ($\Delta n = 1$), and hence the orthogonality of the radial wave functions zeroes the GT matrix element as its operator contains no radial dependence [49,50]. Besides, the Fermi operator does not act on the radial part of the wave functions. For $N > 126$ the only allowed transition is the GT $\nu i_{11/2} \rightarrow \pi i_{13/2}$, which requires at least $1p1h$ proton core excitations. For $N < 126$ the allowed GT/Fermi transitions are $\nu h_{9/2} \rightarrow \pi (h_{11/2}, h_{9/2})$, $\nu (f_{5/2}, f_{7/2}) \rightarrow \pi (f_{5/2}, f_{7/2})$, $\nu i_{13/2} \rightarrow \pi i_{13/2}$, and $\nu (p_{3/2}, p_{1/2}) \rightarrow \pi (p_{3/2}, p_{1/2})$. The $\nu h_{9/2} \rightarrow \pi h_{9/2}$ GT decay would populate $1p1h$ neutron core excitations at $E_x \sim 8$ MeV, higher than the aforementioned $\nu i_{11/2} \rightarrow \pi i_{13/2}$. All others need $2p2h$ core excitations, consequently lying even higher in energy, well outside the $\beta$-decay window and beyond the neutron separation energy, therefore they cannot be populated in $\beta$ decay. The several $1^+$ and $0^+$ states expected in $^{208}$Tl to lie below the $Q_\beta$ value (see Fig. 4) could be mixed with the lowest same spin GT resonances. Specifically, $\pi^{-} \nu i_{13/2} \nu i_{11/2}$ states, if mixed with the lower lying $1^+$ and $0^+$ configurations, could act as a “doorway” to populate them in (weak) GT, while their $\gamma$ decay will proceed via their main configurations. The experimental log $ft$ values would correspond to an estimated 1% core-excited admixture in the wave functions. The inclusion of only one-particle one-hole proton or neutron core excitation into the shell model calculations does not provide the required mixing for these decays. However, calculations including one-particle one-hole core excitations for both protons and neutrons are not feasible for $^{208}$Tl.

The $FF0 \rightarrow 0$ transition, despite its unique core excited nature [51] with a $\nu (g_{9/2})^0$ spectator, exhibits a log $ft = 5.2(1)$ similar to the corresponding $p_{1/2} \leftrightarrow s_{1/2}$ transitions in $^{206}$Hg $\rightarrow ^{206}$Tl($0^+ \rightarrow 0^-$) and $^{206}$Tl $\rightarrow ^{206}$Pb($0^+ \rightarrow 0^-$) [45]. This is in-line with the previously established 30% underestimate of the theoretical mesonic exchange correction [47].

In summary, the $\beta$ decay of $^{208}$Hg was studied. The level scheme of the single proton-hole single neutron-particle $^{208}$Tl nucleus was established, providing the first direct test of the proton-neutron residual interaction in the $N > 126$, $Z < 82$ quadrant. $^{208}$Hg provides a unique testing ground of the competition between allowed and first-forbidden $\beta$ decay. However, with a half-life of $135(10)$ s, it populates only directly negative parity states via first-forbidden decays. The strongest branch establishes a $0^+ \rightarrow 0^-$ decay to a core excited daughter state. This is the first such $\beta$ decay observed and provides information on meson corrections of effective operators. The present data provide important constraints on theoretical models addressing the competition between allowed and first-forbidden $\beta$ decays, important for the detailed understanding of the nucleosynthesis of heavy $r$-process elements.
