Abstract
Background: The triglyceride glucose (TyG) index is closely associated with subclinical atherosclerosis. However, the association remains inconclusive among obese and nonobese individuals.

Methods: This prospective study was conducted in 5751 adults with normal carotid intima-media thickness (CIMT) at baseline. We divided the population into four groups based on the TyG index, which was calculated by the following formula: Ln (fasting triglycerides [mg/dL] × fasting glucose [mg/dL]/2). Information on CIMT was acquired by ultrasonography. Incident elevated CIMT was defined as IMT values greater than 0.9 mm at follow-up. Odds ratios (ORs) and 95% confidence intervals (CIs) of the associations between TyG index and elevated CIMT were estimated using multivariable logistic regression models.

Results: After a median follow-up of 4.3 years, 722 (12.6%) individuals had progressed to elevated CIMT. Compared with the second quartile of the TyG index, the first and fourth quartile both conferred higher risks of elevated CIMT after adjusting for potential confounders. In the total population, the ORs for the first and fourth quartile were 1.29 (95% CI, 1.00-1.66) and 1.42 (95% CI, 1.11-1.83), respectively. Restricted cubic splines demonstrated an approximately U-shaped association between TyG index and elevated CIMT among the total and nonobese adults (P for nonlinearity <.05), but not in those with general or abdominal obesity.

Conclusions: A U-shaped association was observed between TyG index and elevated CIMT only among nonobese Chinese adults.

Keywords: carotid intima-media thickness, nonlinear relationship, obesity, triglyceride glucose index

Highlights
• Many studies have reported that the triglyceride glucose (TyG) index is an inexpensive biochemical marker to assess metabolic and cardiovascular diseases.
• Our findings indicate that the TyG index is nonlinearly associated with the risk of new-onset elevated carotid intima-media thickness (CIMT) during a follow-up of 4.3 years. We further evaluated such relationship in participants by body size phenotypes. A U-shaped association between TyG index and elevated CIMT only existed among those without general or abdominal obesity.

1 | INTRODUCTION
Cardiovascular diseases (CVDs) remain the major threat to public health and the primary cause of all deaths throughout the world, among which atherosclerotic vascular diseases account for the largest part of health lost. The carotid intima-media thickness (CIMT), a surrogate indicator for the presence and progression of atherosclerosis, is associated with future cerebrovascular and cardiovascular events. Assessment of CIMT is now widely used in clinical practice.

Insulin resistance (IR) is an important pathophysiological mechanism of metabolic diseases and CVDs. The triglyceride glucose (TyG) index is a plausible and inexpensive biochemical marker to assess IR, compared with hyperinsulenic-euglycemic clamp (HIEC). Numerous studies have found that a high TyG index is closely related to type 2 diabetes mellitus, metabolic syndrome, and CVD. However, the risk is debatable at lower levels of TyG index. No significant increase in the risk of CVD is observed with a TyG index lower than 8.45 in the Vascular Metabolic CUN (VMCUN) cohort. But a J-shaped relationship of baseline TyG index with the risk of myocardial infarction exists. In addition, conclusions regarding the correlation between TyG index and the risk of CIMT are still controversial. For example, Zhao et al reported that the TyG index had no significant correlation with carotid hypertrophy (CIMT > 0.9 mm) in the Northern Shanghai Study (NSS), whereas a higher TyG index was associated with carotid atherosclerosis in patients with ischemic stroke. Moreover, obesity has a detrimental effect on the cardiovascular system and is strongly linked with CVD. A previous study found that participants with either overall or central obesity had a higher risk of elevated CIMT among physically inactive participants. Nevertheless, Hong et al showed that the risks of both incident stroke and myocardial infarction for the highest quartile of the TyG index in the subgroup of body mass index (BMI) < 25 kg/m² were even higher than in the subgroup of BMI ≥ 25 kg/m². Yet, the relationships between TyG index and CIMT among individuals with different body size phenotypes were not specified.

To address this gap, we investigated the association between TyG index and the risk of elevated CIMT based on a prospective cohort of Chinese community residents. Furthermore, we examined whether the TyG index was a risk factor for elevated CIMT in participants across different body size phenotypes.

2 | METHODS
2.1 | Study population
This population-based study was carried out among adults living in Jiading District, Shanghai, China. The study design has been described elsewhere. Briefly, during February to August 2010, 10 375 men and women aged ≥40 years were enrolled to complete a comprehensive examination of cardiometabolic health. From 2014 to 2015, we invited all eligible participants to come back for a follow-up visit. For the current analysis, participants
diagnosed with CVD (n = 850) at baseline were excluded. We further excluded participants who had missing data on CIMT measurements at both baseline (n = 74) and follow-up (n = 3618) and elevated CIMT at baseline (n = 82). Finally, a total of 5751 subjects were included in the current analysis.

The study conformed to the Institutional Review Board of the Ruijin Hospital, Shanghai Jiaotong University School of Medicine. All participants provided written informed consent.

2.2 | Data collection and clinical evaluation

At baseline and follow-up, trained staff from the local community collected data following a standard guideline. The information on sociodemographic characteristics, medical history, and behavioral factors were captured using a comprehensive questionnaire. Current smokers or drinkers were defined according to their daily habits as those who had frequently consumed cigarettes or any alcohol in the past 6 months. Body weight, height, and hip and waist circumference (WC) were measured during visits. WC was measured at the umbilical level in the standing position. BMI was calculated as the weight in kilograms divided by the height in meters squared (kg/m²). Waist-to-hip ratio (WHR) was computed by dividing the WC by hip circumference. Three systolic and diastolic blood pressure (SBP and DBP) measurements, acquired after ≥5 minutes of rest, were completed by an automated electronic device (OMRON Model HEM-752 Fuzzy; Omron Company, Dalian, China). For the analysis, the average of the three corresponding values was taken. Uniformly trained sonographers with adequate clinical experience used a high-resolution B-mode tomographic ultrasound (Esaote Biomedica SpA, Genoa, Italy) to detect and measure both sides of CIMT during two visits. The distance from the first to the second leading edge of the echogenic line was regarded as CIMT of either side. We adopted the value of maximum CIMT in the analysis.

All participants were asked to fast at least 10 hours before taking the 75-g oral glucose tolerance test. Fasting plasma glucose (FPG) and 2-hour plasma glucose concentrations were quantified by applying an autoanalyzer (Modular P800; Roche, Basel, Switzerland) and the glucose oxidase or hexokinase method at local hospitals. The level of glycated hemoglobin (HbA1c) was measured by using the method of high-performance liquid chromatography (D-10; Bio-Rad, Hercules, California). Fasting levels of triglycerides (TGs), total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), and high-density lipoprotein cholesterol (HDL-C) were also analyzed by an automated analyzer (Modular Analytics P800 and Modular E170; Roche, Basel, Switzerland).

2.3 | Definitions and diagnostic criteria

Participants with a BMI ≥ 28.0 kg/m² were defined as generally obese according to the characteristics of the Chinese population. Abdominal obesity was considered as a WC ≥ 90 cm or a WHR > 0.90 for men and a WC ≥ 80 cm or a WHR > 0.85 for women. The TyG index was calculated as Ln (fasting TGs [mg/dL] × fasting glucose [mg/dL]/2). Individuals with a CIMT greater than 0.9 mm at follow-up but a low CIMT at baseline were considered to have new-onset elevated CIMT. Diabetes was defined as FPG ≥ 126 mg/dL (7.0 mmol/L), or 2-hour plasma glucose ≥200 mg/dL (11.1 mmol/L), or HbA1c ≥ 6.5% (48 mmol/mol), or a self-reported previous diagnosis of diabetes by physicians and using insulin or taking antidiabetic medications. Hypertension was defined as SBP ≥ 140 mm Hg, DBP ≥ 90 mm Hg, the use of antihypertensive medication or previous diagnosis of hypertension by health-care professionals. The history of diagnosed liver (eg, viral or autoimmune hepatitis, cirrhosis, liver cancer, or other) and kidney (eg, kidney stone, glomerulonephritis, nephropathy, or other) diseases was self-reported.

2.4 | Statistical analysis

Baseline characteristics were presented by the quartiles of the TyG index. Continuous variables were expressed in means (standard deviations). Categorical variables were expressed as numbers (percentages). To compare the differences of baseline characteristics between groups, we conducted one-way analyses of variance and chi-square tests. In the current study, we used the TyG index at baseline (2010) to predict the subsequent risk of new-onset elevated CIMT. The odds ratios (ORs) and 95% confidence intervals (CIs) were calculated by a logistic regression model and adjusted for baseline age, sex, current smoking status, current drinking status, physical activity, HDL-C, BMI, and glucose-lowering therapy.

Stratified analyses were further performed to evaluate the above-mentioned relationships by BMI (<28 and ≥28 kg/m²), WC (<90/80 and ≥90/80 cm for males and females, respectively), and WHR (<0.90/0.85 and ≥0.90/0.85 for males and females, respectively). All tests were two sided, and a P value <.05 was considered statistically significant. All of the above statistical analyses were performed using SAS version 9.4 (SAS Institute, Cary, North Carolina).
We also used R version 4.0.5 (R Foundation for Statistical Computing, Vienna, Austria) to construct restricted cubic spline models with four knots to detect whether there was a nonlinear relationship between TyG index and the risk of elevated CIMT after full adjustment.

### RESULTS

Baseline characteristics of the 5751 participants are displayed by TyG index quartiles in Table 1. The mean TyG index quartiles were 8.02 ± 0.22, 8.48 ± 0.11, 8.86 ± 0.12, and 9.54 ± 0.45, respectively. As expected, SBP, DBP,
TGs, FPG, and CIMT were more likely to increase across the quartiles. There was no significant difference in the lifestyle factors (smoking and drinking) and education level among the four groups.

After a median follow-up of 4.3 years, 165 (11.5%), 152 (10.6%), 193 (13.4%), and 212 (14.8%) participants had elevated CIMT in four quartiles of the TyG index, respectively. As presented in Table 2, we explored the associations by quartiles of the TyG index, with the second quartile serving as the reference. After adjusting for potential confounding variables (model 3), the ORs of elevated CIMT were 1.29 (95% CI, 1.00-1.66), 1.24 (95% CI, 0.97-1.59), and 1.42 (95% CI, 1.11-1.83) for the first, third, and fourth TyG index quartile, respectively. Similar results were observed when we further adjusted for diabetes mellitus, hypertension, and liver and kidney diseases (Table S1). These results indicate a nonlinear association between TyG index and elevated CIMT.

Subgroup analyses for obese and nonobese participants are shown in Table 3. The association between TyG index and CIMT was only significant in those without general or abdominal obesity. In the multivariable model, the second quartile of the TyG index had the lowest risk of elevated CIMT among participants with BMI < 28 kg/m². Compared to the second quartile, the risk increased significantly in both quartile 1 (OR 1.96; 95% CI, 1.91 (1.37-2.86) for the first quartile, 1.56 (1.13-2.16) for the second quartile, 1.59 (1.22-2.07) for the third quartile, and 1.80 (1.39-2.33) for the fourth quartile. The ORs were 1.85 (0.85-1.45) for the second quartile, 1.89 (1.41-2.52) for the third quartile, and 1.80 (1.31-2.47) for the fourth quartile. The bold values indicated statistical significance.

### TABLE 3 Subgroup analyses for risk of elevated CIMT by TyG index

| Quartile | BMI | WC | WHR |
|----------|-----|----|-----|
|          | <28 kg/m² | <90/80 cm | <0.90/0.85 |
| Model 1  | 1.35 (1.03-1.77) | 1.56 (1.13-2.16) | 1.49 (1.03-2.16) |
| Model 2  | 1.46 (1.11-1.93) | 1.82 (1.30-2.54) | 1.75 (1.19-2.57) |
| Model 3  | 1.60 (1.20-2.15) | 1.96 (1.37-2.79) | 1.91 (1.27-2.86) |
|          | ≥28 kg/m² | ≥90/80 cm | ≥0.90/0.85 |
| Model 1  | 1.17 (0.72-1.90) | 0.90 (0.64-1.26) | 0.98 (0.73-1.31) |
| Model 2  | 1.15 (0.70-1.88) | 0.95 (0.67-1.33) | 0.99 (0.73-1.32) |
| Model 3  | 1.32 (0.79-2.19) | 1.08 (0.75-1.54) | 1.11 (0.81-1.52) |

Note: Obesity was defined as a BMI of 28.0 kg/m² or higher. Abdominal obesity was defined as WC ≥ 90 cm or WHR > 0.90 in men and WC ≥ 80 cm or WHR > 0.85 in women. Model 1 was an unadjusted model. Model 2 was adjusted for baseline age. Model 3 was adjusted for baseline age, sex, current smoking status, current drinking status, physical activity, HDL-C, BMI, and glucose-lowering therapy. The bold values indicated statistical significance.

Abbreviations: BMI, body mass index; CIMT, carotid intima-media thickness; HDL-C, high-density lipoprotein cholesterol; TyG, triglyceride glucose; WC, waist circumference; WHR, waist-to-hip ratio.
1.37-2.79) and quartile 4 (OR 1.95; 95% CI, 1.36-2.79) of the TyG index in individuals with normal WC (<90 cm in men and <80 cm in women). Similarly, the fully adjusted ORs (95% CI) for elevated CIMT among participants with normal WHR (<0.90 in men and <0.85 in women) were 1.91 (1.27-2.86) and 1.92 (1.28-2.90) in quartile 1 and quartile 4, respectively. The risk estimates did not change significantly in sensitivity analysis with further adjustments for diabetes mellitus, hypertension, and liver and kidney diseases (Table S1), whereas there was no relationship between TyG index and elevated CIMT in obese participants.

Restricted cubic splines were additionally applied to model and display the association between TyG index and elevated CIMT, with confounders adjusted (Figure 1). There was an approximately U-shaped association among the total and nonobese population. As presented in Figure 1A, the risk of elevated CIMT reached a nadir when TyG indices were within the interval of 7.95 to 8.66 in the total population. The association was negative below these values, but positive above (P for nonlinearity = .0039). In nonobese participants (Figure 1B), a marked increase in risk was observed at both low and high levels of the TyG index. Among individuals with BMI < 28 kg/m², we noticed that the risk of elevated CIMT was significantly reduced at TyG indices in the range of 7.91 to 8.60 (P for nonlinearity = .0003). Also, a strong nonlinear relationship existed in participants with WC < 90/80 cm or WHR < 0.90/0.85 (P for nonlinearity < .0001). The risk touched the bottom when the TyG index was around 8.33 and 8.31, respectively. However, no apparent association was found in the subgroups of BMI ≥ 28 kg/m², WC ≥ 90/80 cm, and WHR ≥ 0.90/0.85 (P for nonlinearity = .9475, .8846 and .9707, respectively) (Figure 1C).

FIGURE 1  The association between baseline TyG level and incident elevated CIMT based on restricted cubic splines. The solid lines represent a fitted relationship and the shadows represent the 95% confidence interval among (A) total, (B) non-obese and (C) obese population. Model was adjusted for baseline age, sex, current smoking status, current drinking status, physical activity, HDL-C, BMI and glucose-lowering therapy.

4 | DISCUSSION

In the current study, we found a nonlinear association between the baseline TyG index and risk of new-onset elevated CIMT. Moreover, the relationship was only significant among those without general or abdominal obesity. Our finding provides evidence that the TyG index is useful in identifying those at high risk of subclinical atherosclerosis, especially among nonobese individuals.

Substantial studies have reported that a high baseline TyG index is associated with elevated CIMT. Recently, a study of 631 subjects demonstrated that subclinical atherosclerosis, defined as CIMT > 0.9 mm, correlated with the TyG index. In addition, a prospective study based on the Beijing Health Management Cohort (BHMC) and the Beijing Physical Examination Cohort (BPEC) indicated that the highest quartile of the TyG index increased the risk of carotid plaque compared with those in the lowest quartile. In accordance with these studies, we also find that a higher TyG index is associated with higher risk of elevated CIMT. In addition, our finding indicates that the relationship is mostly significant in nonobese individuals.

The TyG index is a surrogate indicator of IR, which is generally recognized as the driving force of CVD events.
Endothelial cells (ECs) are the other target tissue linked to IR, as are liver and skeletal muscle. Increasing oxidative stress in ECs with significant contributions from NADPH oxidase, mitochondria, and uncoupled eNOS results in decreasing availability of NO. Impaired endothelium-derived NO might fail to inhibit both leukocyte adhesion and related promoters, driving atherosclerotic development.

Moreover, the current analysis shows that the TyG index is U-shaped associated with the risk of elevated CIMT, and those in the second quartile have the lowest risk. Numerous publications indicate that there is a nonlinear relationship between TyG index and cardiovascular mortality. Meanwhile, among the middle-aged and elderly US population in the National Health and Nutrition Examination Survey (NHANES), the second quartile of the TyG index encompasses the lowest risk of cardiovascular mortality (hazard ratio 0.62; 95% CI, 0.43-0.88) when compared with the first quartile. Lower TyG index also demonstrates higher risk.

We notice that participants in the first quartile of the TyG index with lower BMI, TGs, and FPG at baseline have higher risk of CIMT progression, compared with those in the second quartile of the TyG index. Several potential mechanisms underlying this association have been postulated. Very low levels of TGs or FPG, approximately equal to a low TyG index, may produce an adverse effect on the occurrence of CVD. It was reported previously that FPG was nonlinearly related to CVD, and lower FPG was slightly associated with increased risk of stroke and atherosclerotic CVD. Animal experiments demonstrate that repeated hypoglycemia enhances neointima formation after vascular injury, indicating that lower blood glucose predisposes elevated CIMT. Moreover, low TG levels may play a negative role on the vascular endothelium. For example, low cholesterol levels could increase the permeability of erythrocyte membranes. As determined by the two parameters, a lower TyG index may show an increased risk of elevated CIMT.

Given that adiposity substantially affects insulin sensitivity, different levels of adiposity might influence the status of IR. To explore whether there is an association between TyG index and elevated CIMT, we introduced subgroup analyses. The current study shows that higher levels of TyG index are significantly associated with the risk of new-onset elevated CIMT, but only in those without general or abdominal obesity. In other words, the TyG index may have a better predictive value in nonobese individuals. Similarly, a recent cross-sectional study of 473 postmenopausal women stratified by BMI has shown that there is an increased risk of subclinical atherosclerosis with TyG index only in lean women.

However, the association which is mainly significant in nonobese individuals has not been elucidated. Nevertheless, there are several speculations. First, the TyG index is a predictor of metabolic dysregulation and may better reflect the risk of metabolic diseases in nonobese individuals. But obese individuals, who typically have several metabolic risk factors, have a greater burden than lean participants, which would obscure the predictive role of the TyG index in elevated CIMT. Moreover, the TyG index may be more reflective of muscle-related IR and correlates strongly with homeostasis model assessment of insulin resistance (HOMA-IR) in healthy nonobese individuals, as increased intramyocellular TG accumulation would impair glucose uptake and insulin signaling in muscle. On the other hand, obese people have strong rather than muscle IR. Finally, inherited genetic factors could partly explain that the TyG index is significant in nonobese individuals. A two-stage genome-wide association meta-analysis identified a locus near insulin receptor substrate 1 (IRS1) gene that is associated with reduced body fat percentage but also with an impaired metabolic profile, including increased IR and risk of coronary artery disease.

Previous studies have pointed out that age is strongly and linearly associated with CIMT. An increase in CIMT with age can be expected. As shown in Table S2, CIMT increased during follow-up, while the risk attributed to increasing age may be similar across the four groups. Despite the fact that age has an inevitable effect on CIMT progression, the TyG index itself even works after adjustment for baseline age (Table 2).

The main strengths of this study include the prospective design, large sample size, and comprehensive assessment of covariates. In addition, the results of combined subgroup analyses can provide further information on the predictive value for certain groups. Nevertheless, we acknowledge that several limitations exist in our study. First, the statistical power might be slightly compromised due to the shorter follow-up. Second, the assessment of CIMT and TyG index is conducted at baseline and follow-up, ignoring the dynamic changes of the TyG index. Long-term investigations might address this issue. Third, although many studies have reported that CIMT measurements are useful in the evaluation of CVD risk, the effectiveness is still uncertain. Fourth, the findings could not be extended to younger populations, given our study is consisted of a Chinese population over 40 years.

In conclusion, we report that the baseline TyG index is nonlinearly associated with the risk of elevated CIMT in middle-aged and elderly nonobese Chinese adults,
suggesting that this simple index might be useful in preventing subclinical atherosclerosis.
