**Abstract:** Due to the scarcity of fossil fuels in the world, there is increasing interest in the commercial production of biodiesel, which leads to obtaining large amounts of glycerol as a byproduct. If not disposed of properly, glycerol can generate environmental impact. One of the promises, the application of the crude glycerol is the production of citric acid by microbial fermentation. Citric acid is industrially produced by a submerged fermentation process with *Aspergillus niger*, using sucrose as carbon source, but due to increased demand for citric acid, alternative processes using renewable sources or waste materials as substrates and the cultivation of yeast strains are being studied. The aim of the study was to determine the best culture condition for maximum citric acid synthesis and lower isocitric acid production from crude glycerol through experimental design tool. For this purpose, the yeast strain *Yarrowia lipolytica* IMUFRJ-50682 was cultivated in nitrogen-limited glycerol-based media. Therefore, glycerol and yeast extract concentrations and agitation speed were evaluated as independent variables. With pure glycerol, the highest citric acid production achieved was 16.5 g/L with an isocitric acid production of 7.7% (in relation to citric acid). With crude glycerol, citric acid production reduced to 6.7 g/L because of higher biomass yield. Therefore, an increase in the initial carbon to nitrogen molar ratio from 714 to 1,561 was necessary to increase citric acid production to 9.2 g/L, reducing isocitric acid production and to achieve a yield of 0.41 g of citric acid per glycerol consumed. In this condition, less nitrogen source was used, reducing production costs.

**Key words:** *Yarrowia lipolytica*, crude glycerol, media composition optimization, citric acid, experimental design.

1. Introduction

Citric acid (CA) is industrially produced by a submerged fermentation process with *Aspergillus niger*, using sucrose as carbon source [1]. The global annual production has increased to 1.7 million tons in 2007 as estimated by Business Communications Co. (http://www.bccresearch.com), which is greater than the production of any other organic acid obtained by fermentation process [2]. This market increases at a rate of 3.5%-4% per year, because CA is widely used in food, chemical and pharmaceutical industries due to its properties as an acidifier, preservative, pH adjuster, antioxidant and sequestrant. Although the conventional process for CA production is quite attractive, it is a complex and ecologically unsafe process due to the characteristics of the raw material used. Concentrated acids and alkali are used throughout the process, and the discharge into the environment (containing cyanide and gypsum) is comparable in amount to the product [3].

Due to increased demand for CA, alternative processes involving the cultivation of yeast strains are being studied, in order to achieve a cheaper and more efficient way to produce this commodity. *Yarrowia lipolytica* has a great potential to achieve this goal, since it produces CA from raw materials [4]. The
starting point for this line of research was to gain access to n-paraffins and fatty acids that are not converted by *A. niger* as carbon sources [5]. *Yarrowia lipolytica* has been widely used for the production of organic acids through various renewable sources or waste materials as substrates, for example, glycerol from the production of biodiesel [6].

The obligatory industrial production of biodiesel has already resulted in the accumulation of high quantities of glycerol waste into the market, as the main by-product of transesterification process applied in biodiesel manufacture [7]. The bioconversion of glycerol can reduce the environmental impact caused by the biodiesel industry. Therefore, many microbial processes are being proposed to seek this by-product in its crude form [4, 8, 9]. An important way of raw glycerol valorisation is related to its biotransformation into CA [8].

The use of *Yarrowia* species presents several advantages in relation to filamentous fungi: higher tolerance to high substrate concentrations, higher yield, higher productivity and better process control because of the unicellular nature of yeasts [10]. One disadvantage is the significant amount of isocitric acid (ICA) produced during fermentation, which can reach levels of up to 50% of the total acid production thereby influencing CA yield negatively [11].

Papanikolaou et al. [6] produced 33-35 g of citric acid per liter after 236 h with high initial raw glycerol media (80-120 g/L) in buffered medium containing ammonium sulfate and yeast extract (0.5 g/L of each). *Y. lipolytica* strains and three *Candida* strains were screened for CA production from pure glycerol by Levinson et al. [11]. Ammonium sulfate, yeast extract and thiamine hydrochloride were used as nitrogen sources. *Y. lipolytica* NRRL YB-423 was the best strain producing 21.6 g of citric acid/L in 10 days with a 54% yield. Rymowicz et al. [12] studied the simultaneous production of citric acid and erythritol under nitrogen-limited conditions with crude glycerol with an acetate negative mutant of *Y. lipolytica* Wratislavia K1 in fed-batch cultivations. Maximum citric acid production (110 g/L) was obtained after 168 h of fed-batch cultivation with the initial glycerol concentration of 150 g/L. *Y. lipolytica* (IMUFJR 50682) was studied for CA production using pure glycerol [13]. A production of 2.51 g of citric acid/L was obtained in non-buffered medium. A four times increase in CA production was obtained by using a buffer medium.

Although *Y. lipolytica* have been used to produce CA from crude glycerol by several researchers [6, 11, 12], a study of the media composition optimization, regarding higher CA production as well as the reduction of ICA formation and input costs, is still lacking. Large amount of yeast extract and ammonium sulphate are still being used, which can increase the production costs. The purpose of the present investigation was to achieve the best medium composition, in relation to glycerol and yeast extract concentrations, and the best agitation speed to optimize CA production by *Yarrowia lipolytica* through experimental design technique. Pure and crude glycerol stemming from biodiesel industries were used as carbon sources.

2. Materials and Methods

2.1 Microorganism

*Yarrowia lipolytica* IMUFJR 50682 selected from an estuary in Rio de Janeiro, Brazil and identified by the Institute of Microbiology at the Federal University of Rio de Janeiro, Brazil [14] was used for all experiments. The yeast strain was maintained on YPD-agar medium, containing 1% of yeast extract (Oxoid-Hampshire, UK), 2% of peptone from casein (Oxoid-Hampshire, UK), 2% of glucose (Reagen-RJ, Brazil) and 3% of agar (Vetec-RJ, Brazil) in distilled water, and was stored at 4 ± 1 °C.

2.2 Media and Culture Conditions

Cells were cultivated in 0.5 l Erlenmeyer flasks with 0.2 l of YPD medium (% w/v: yeast extract, 1; peptone, 2; and glucose, 2) on a rotary shaker (Tecnal Digimec
BTC9090) at 28 °C and 160 rpm for 72 h. The biomass produced was used to inoculate the CA production media (0.4 l in 1 l Erlenmeyer flask) in sufficient amount for a 1 g of cells (dry weight) per litre initial concentration.

CA production was performed in a rotary shaker (Tecnal Digimec BTC9090) at 28 °C for 96 h. Agitation speed was studied. The media used contained (g/L): KH₂PO₄: 12; Na₂HPO₄: 12; MgSO₄·7H₂O: 1.5; CaCl₂: 0.15; FeCl₃·6H₂O: 0.15; ZnSO₄·7H₂O: 0.02; MnSO₄·H₂O: 0.06. Yeast extract (nitrogen source) and glycerol (carbon source) concentrations in the CA production media were studied. Pure glycerol (Vetec, RJ, Brazil) and crude glycerine (obtained through the basic (NaOH) transesterification soybean oil with ethanol and from the transesterification of soybean oil with methanol and potassium hydroxide by the research centre of Petrobras, RJ, Brazil) were evaluated.

2.3 Crude Glycerin Pretreatment

The pH of crude glycerin was adjusted with H₂SO₄ (1 N) to the range of 6-7 in order to eliminate free alkalinity. After that, it was heated (120 °C) for 1 h for ethanol elimination. The sulphate produced by the neutralization was separated by decantation in a separation funnel for 24 h.

2.4 Experimental Design

Initially pure glycerol was used as sole carbon source to assess the metabolic behavior of the strain Yarrowia lipolytica IMUFRJ 50682 and the effect of media composition in CA production.

A complete 2ᵏ factorial design, with k = 3 and two replicates at the central points, was carried out in order to identify the parameters with a significant effect on CA production. Pure glycerol and yeast extract concentrations were adopted as independent variables and the maximum citric acid production (P₀CA) was taken as the dependent variable of the experimental design. Glycerol and yeast extract concentrations ranges were 30 g/L to 50 g/L and 0.1 g/L to 0.9 g/L, respectively. The agitation ranged from 160 rpm to 250 rpm. The software statistic (version 7.0) was used for regression and graphical analyses of the data obtained.

Glycerol, yeast extract concentrations and agitation speed for the other experimental designs were selected after the results and, therefore, are described in the text.

Once the variables having the statistically significant influence on the responses were identified, a central composite design (CCD) was used to optimize the levels of these variables. The 2² factorial design was used, consisting of four assays (-1 and +1), two center points and four axial points (-1.41 and +1.41), and resulted in a total of 10 experiments.

2.5 Analytical Methods

Biomass concentration was determined in spectrophotometer (Hach DR/4000 UV-VIS) by optical density measurements at 570 nm and these values were converted to mg dry weigh (d.w.) cells/mL using a conversion factor previously established by the curve of dry weight.

Samples from the CA production medium free of cells were used for the analysis of organic acids, glycerol and pH.

The concentration of CA and ICA were determined in this cell-free sample by enzymatic kit (R-Biopharm/Boehringer Mannhein/Roche).

Glycerol was quantified by enzymatic-colorimetric method for the quantification of triglycerides (LABORLAB Kit for triglycerides) and pH of culture medium free of cells was determined using a pH meter Digimed brand, model DM-22.

2.6 Fermentation Parameters

For comparison between all trials, production parameters were determined.

Mass yield of CA from glycerol consumed (Y₀CA/g), was calculated from:

\[ Y_{CA/G} = \frac{P_{CA}}{G_f - G_i} \text{ (g/g)} \]  (1)
Biomass yield from glycerol consumed \((Y_{X/G})\), was calculated from:
\[
Y_{X/G} = \frac{X_f - X_i}{G_f - G_i} \quad \text{(g/g)}
\]  
(2)

Volumetric citric acid productivity \((Q_{CA})\), was calculated from:
\[
Q_{CA} = \frac{P_{CA}}{V \cdot t} \quad \text{(g/(L h))}
\]  
(3)

Mass ratio between CA and ICA \((R_{CA/ICA})\), was calculated from:
\[
R_{CA/ICA} = \frac{P_{CA}}{P_{ICA}}
\]  
(4)

where, indices \(i\) and \(f\) correspond to the initial and final (at the time of maximum CA concentration) quantity of elements, respectively; \(G\): Glycerol concentration; \(X\): cell concentration; \(t\): time of fermentation of citric acid maximum production; \(V\): initial volume of liquid culture.

3. Results and Discussion

In literature, no publication has been traced on optimization of culture medium together with system agitation to maximize CA production by \(Yarrowia\ lipolytica\) with glycerol as the carbon source. In preliminary trials, growth and CA production by \(Y.\ lipolytica\) IMUFRJ 50682 were studied in pure glycerol. From the best result, crude glycerol was used and a new optimization was performed.

3.1 CA Production with Pure Glycerol

Identification of the parameters influencing CA production.

In a previous work \([13]\), \(Y.\ lipolytica\) IMUFRJ 50682 produced higher CA concentrations in a buffered medium without ammonium sulphate and, therefore, these conditions were established here. It has also been reported that when sugars or glycerol are used as substrates, production of CA is induced by exhaustion of nitrogen source from the medium \([6, 15]\). Therefore, pure glycerol and yeast extract concentrations were first studied in a full factorial experimental design (FFD). Agitation speed was also considered in these trials. Table 1 shows the experimental design matrix and the results for CA production.

In this set of experiments, the maximum CA produced ranged from 0.68 g/L to 14.04 g/L. It is worth mentioning that the difference between these values is much larger than the variation between the results of the center points. This shows reproducibility of the experiments, indicating that the observed variations in the \(P_{CA}\) values are due to differences in the independent variables.

| Run | Glycerol (g/L) | Yeast extract (g/L) | Agitation speed (rpm) | C/N | \(P_{CA}^b\) (g/L) | \(X_{Max}^c\) (g d.w./L) | \(Y_{CA/G}^d\) (g/g) | \(Q_{CA}^e\) (g/(L h)) |
|-----|---------------|---------------------|-----------------------|-----|-------------------|------------------------|-------------------|---------------------|
| 1   | -1 (30)       | -1 (0.1)            | -1 (160)              | 1,260 | 1.67 (80 h)       | 6.40 (88 h)            | 0.56              | 0.02                |
| 2   | +1 (50)       | -1 (0.1)            | -1 (160)              | 2,098 | 1.46 (94 h)       | 6.82 (93 h)            | 0.03              | 0.02                |
| 3   | -1 (30)       | +1 (0.9)            | -1 (160)              | 144   | 0.69 (101 h)      | 7.61 (93 h)            | 0.23              | 0.01                |
| 4   | +1 (50)       | +1 (0.9)            | -1 (160)              | 237   | 0.68 (80 h)       | 5.76 (93 h)            | 0.01              | 0.01                |
| 5   | -1 (30)       | -1 (0.1)            | +1 (250)              | 1,260 | 14.04 (93 h)      | 4.44 (93 h)            | 0.47              | 0.15                |
| 6   | +1 (50)       | -1 (0.1)            | +1 (250)              | 2,098 | 11.40 (93 h)      | 4.73 (93 h)            | 0.23              | 0.12                |
| 7   | -1 (30)       | +1 (0.9)            | +1 (250)              | 144   | 7.89 (93 h)       | 7.04 (93 h)            | 0.26              | 0.08                |
| 8   | +1 (50)       | +1 (0.9)            | +1 (250)              | 237   | 6.35 (93 h)       | 7.44 (93 h)            | 0.13              | 0.07                |
| 9   | 0 (40)        | 0 (0.5)             | 0 (205)               | 339   | 4.69 (96 h)       | 8.81 (93 h)            | 0.12              | 0.05                |
| 10  | 0 (40)        | 0 (0.5)             | 0 (205)               | 339   | 4.91 (88 h)       | ND                     | 0.12              | 0.05                |

\(C/N\): carbon to nitrogen molar ratio in the beginning of the experiment;

\(P_{CA}\): maximum citric acid production, the time when it was obtained (in parenthesis);

\(X_{Max}\): maximum biomass obtained;

\(Y_{CA/G}\): mass yield of CA from glycerol consumed;

\(Q_{CA}\): volumetric citric acid productivity.
The best results for CA concentration were obtained in experimental run 5 and 6, i.e., when lower yeast extract concentration and major agitation speed were used. In those experiments, highest citric acid yield ($Y_{CA,Y}$) and productivity ($Q_{CA}$) were also obtained (Table 1). Tests 5 and 6 differ only by the initial concentration of glycerol, establishing initial $C/N$ molar ratio of 1,217 and 2,028, respectively. The ICA concentration detected when higher CA was produced in test 5 was 1.89 g/L, with a $R_{CA/ICA}$ of 7.43.

Several studies in literature report the effect of high initial $C/N$ molar ratio in high CA production by microorganisms. However, all tests that were performed with lower levels of agitation speed presented lower CA production (Table 1), including high initial $C/N$ molar ratio tests. Rywińska et al. [16] have also shown that the availability of oxygen to the microorganisms is essential to increase CA production. Table 1 is possible to notice that the agitation speed had more influence in CA production than the initial $C/N$ molar ratio and the highest CA production was not obtained when higher initial $C/N$ molar ratio was used (Table 1). However, runs 7 and 8, performed at 250 rpm (higher agitation speed), yielded half the CA concentration than runs 5 and 6 and promoted higher cell growth ($X_{max}$), indicating that low initial $C/N$ molar ratio is not good for this process.

The Pareto diagram in Fig. 1 shows the agitation speed as the variable with greater effect on the response variable ($\alpha = 95\%$), followed by the yeast extract concentration. These variables had opposite effects: the agitation speed had a positive effect and the yeast extract concentration had a negative effect. The results show that the dependent variable was not affected by glycerol concentration in the range studied. The interaction between yeast extract and agitation showed a statistically significant negative effect on the CA production.

### 3.2 Central Composite Rotatable Design

Based on the results of the $2^3$ FFD, a more detailed study of the influence of yeast extract and the agitation speed was performed by a central composite rotatable design (CCRD) $2^3$. Glycerol initial concentration was set at 30 g/L as it was not statistically significant in the first set of experiments. Yeast extract concentration
and agitation speed levels were also chosen by the results the FFD, fixing the best conditions at the center point (0.1 g/L of yeast extract and 250 rpm of agitation speed). The complete design matrix of the experiments used and the CA produced are shown in Table 2. CA production was relatively high for all experimental runs in this second factorial design and the highest result was obtained for run 8.

Fig. 2 shows that linear and first-order effects and interactions of variables are not statistically significant in the 95% confidence interval. The value of the coefficient of determination was low (60%). Therefore, it was not possible to perform statistical analysis and to obtain a mathematical model. Despite of that, it seems that an optimum working range was found, with good results for production, productivity, substrate conversion ($Y_{CA/G}$) and less ICA production.

It can be seen (Table 2) that the highest CA production was obtained when smaller initial C/N molar ratio was used. However, the C/N molar ratio range (714 to 4,262) was larger than the difference between CA production (9.4 g/L to 16.5 g/L) indicating that when a high C/N molar ratio is used (above 700), it does not influence much CA production. Levinson et al. [11] verified that when higher initial nitrogen concentrations (C/N molar ratio under 172) were used for Y. lipolytica NRRL YB-423, CA was utilized as substrate as incubation progressed and C/N molar ratios from 343 to 1,714 promoted CA production between 15 g/L and 21 g/L in more than 200 h of process.

The production of ICA was very low, which resulted in a maximum $R_{CA/ICA}$ of 14 (Table 2). There is not many works in literature concerning the concomitant production of CA and ICA. For Y. lipolytica NRRL YB-423, the top $R_{CA/ICA}$, when glycerol was used, was 11.3 [11].

### 3.3 CA Production with Crude Glycerol from Biodiesel Production

The experimental conditions of run 8 (Table 2) were chosen as reference to test the use of crude glycerol. When glycerine obtained from the transesterification of soybean oil with ethanol and sodium hydroxide was used (81% of purity), CA production reduced from 16.5 g/L to 6.7 g/L and the productivity decreased from 0.17 g/(L h) to 0.07 g/(L h) in comparison to pure glycerol. At this point the $R_{CA/ICA}$ was also lower (4.3 instead of 12.0). Fig. 3 presents the kinetics of both cultures, with pure and crude glycerol (Figs. 3a and 3b).

**Table 2** Coded levels and real values (in parentheses) of the central composite design (CCD) and citric acid (CA) production parameters for trials with 30 g/L of pure glycerol.

| Run | Yeast extract (g/L) | Agitation speed (rpm) | C/N$^a$ | $P_{CA}^b$ (g/L) | $R_{CA/ICA}^c$ (g/g) | $Y_{CA/G}^d$ (g/g) | $Q_{CA}^e$ (g/(L h)) |
|-----|---------------------|-----------------------|--------|-----------------|-------------------|------------------|-----------------|
| 1   | -1 (0.0500)         | -1 (210.0)            | 2516   | 12.29 (88 h)    | 14.1              | 0.41             | 0.14            |
| 2   | 1 (0.1500)          | -1 (210.0)            | 842    | 11.95 (88 h)    | 13.6              | 0.40             | 0.14            |

| 10  | 0 (0.1000)          | 1.41 (306.4)          | 1260   | 13.91 (99 h)    | 10.2              | 0.46             | 0.14            |

$^a$C/N: carbon to nitrogen molar ratio in the beginning of the experiment;  
$^b$P$_{CA}$: maximum citric acid production, the time when it was obtained (in parenthesis);  
$^c$R$_{CA/ICA}$: mass ratio between CA and ICA;  
$^d$Y$_{CA/G}$: mass yield of CA from glycerol consumed;  
$^e$Q$_{CA}$: volumetric citric acid productivity.
Experimental Design as a Tool for the Development of Citric Acid Production by Yarrowia lipolytica Using Glycerol as a Feedstock

Fig. 2  Pareto diagram for the estimated effect of each variable of the central composite design (CCD) with pure glycerol. Dependent variable: citric acid production (g/L).

It can be seen that cell growth was much higher in crude glycerol, which might happen because of the presence of oil residues present in this raw material and this yeast capability to use it as an additional substrate [17]. This fact has influenced the reduction on CA production since it diverted the metabolism to cell growth. The pH reduction was similar in those cases, especially because a buffered medium was used.

Another source of crude glycerol was tested (glycerine obtained from the transesterification of soybean oil with methanol and potassium hydroxide, 83% of purity) in the same conditions of the experimental run 8 (30 g/L glycerol, 0.1705 g/L yeast extract and 250 rpm). Biomass production was still higher than with pure glycerol ($X_{max} = 5.0$ g/L) and CA production (4.35 g/L) was even inferior to the other crude glycerol tested. It is very clear that the impurities present in crude glycerol influence CA production. It is possible that methanol residues are harmful to biomass and interfered also with CA production. Papanikolaou et al. [6] tested crude glycerol for CA production, obtained higher values (11.9 g/L), but used higher yeast extract concentration (0.5 g/L). Different yeast extract concentrations were tested with this crude glycerol in order verify if other $C/N$ molar ratios could improve CA production and the results are present in Fig. 4. It depicts that ICA production was induced and increase or decrease in yeast extract concentration did not improve CA production.

3.4 CA Production Optimization with Crude Glycerol

By the results with pure glycerol and the test with crude glycerol, an experimental design was assembled. Glycerol concentration was again included because it influences on the amount of crude glycerol used and its residues could affect CA production. Therefore, a central composite rotatable design, $2^k$, with $k = 2$, two center points and four axial points, was used to optimize the best medium composition. The agitation speed was kept constant at 250 rpm as indicated by the study with pure glycerol. Crude glycerol from the transesterification of soybean oil with ethanol and sodium hydroxide was used.

It is possible to observe in Table 3 that CA production varied from 5.50 g/L to 9.22 g/L, with the experimental design adopted. Through the change in medium composition, the CA production and its volumetric productivity reached 9.22 g/L and 0.10 g/(L h), respectively, for the trial with 45 g/L of glycerol and 0.1 g/L of yeast extract (Run 2).
Experimental Design as a Tool for the Development of Citric Acid Production by *Yarrowia lipolytica* Using Glycerol as a Feedstock

![Graph](image)

Fig. 3 Cell growth and pH kinetics of *Yarrowia lipolytica* IMUFRJ 50682 cultivated at 250 rpm with 0.1705 g/L of yeast extract and 30 g/L glycerol.

Analysing the results shown in Table 3, it is possible to observe that C/N molar ratio does not influence much CA production when crude glycerol is used, with opposite effects (Runs 2 and 3) resulting in the same CA production, productivity and yield.

Through analysis of the Pareto diagram (Fig. 5), it was observed that the effects of independent variables were not statistically significant at 95% confidence interval in the studied ranges. Therefore, it was not possible to obtain a mathematical model and to perform statistical analysis, just to identify one best condition.

Despite the fact that the conditions of Runs 2 and 3 favored the same CA production and productivity, Run 2 was performed with less yeast extract, which would be the major cost of the culture medium.

In these trials (Table 3), cell growth was inhibited in the most cases as $X_{max}$ obtained for the first trial with crude glycerol (6.7 g d.w./L) was superior than most of the values obtained, specially Run 2 (4.3 g d.w./L). Therefore, the increase in C/N molar ratio was necessary to divert the carbon flux to CA production. However, when less biomass is present, less product is

<sup>a</sup>C/N: carbon to nitrogen molar ratio in the beginning of the experiment;
<sup>b</sup><i>P</i><sub>CA</sub>: maximum citric acid production;
<sup>c</sup><i>X</i><sub>Max</sub>: maximum biomass obtained;
<sup>d</sup><i>R</i><sub>CA/ICA</sub>: Mass ratio between CA and ICA;
<sup>e</sup><i>Y</i><sub>CA/G</sub>: Mass yield of CA from glycerol consumed;
<sup>f</sup><i>Q</i><sub>CA</sub>: Volumetric citric acid productivity.

obtained. In order to verify if in the best condition (Run 2) it was possible to obtain more CA, initial cell concentration was increased and the results are shown in Table 4. Despite the increase in CA production when initial biomass was raised to 2 g d.w./L, the isocitric acid production was induced. Higher initial cell concentration reduced CA production probably because this nitrogen concentration was not enough to maintain this amount of biomass.

3.5 Comparative Analysis of the Results Obtained at Different Stages of Optimization Process

Table 5 presents the best results obtained at different stages of the optimization of CA production by Yarrowia lipolytica.

From the best result of the FFD to the best result of
Experimental Design as a Tool for the Development of Citric Acid Production by *Yarrowia lipolytica* Using Glycerol as a Feedstock

**Fig. 5** Pareto diagram for the estimated effect of each variable of the central composite design with crude glycerol. Dependent variable: citric acid production (g/L).

**Table 4** Citric acid (CA) production parameters for trials with 45 g/L of crude glycerol and 0.1 g/L yeast extract with different initial cell concentrations.

| Initial cell concentration (g d.w./L) | $P_{\text{CA}}$ (g/L) | $R_{\text{CA/ICA}}$ | $Y_{\text{CA/G}}$ (g/g) | $Q_{\text{CA}}$ (g/(L h)) |
|--------------------------------------|------------------------|----------------------|--------------------------|--------------------------|
| 1                                    | 9.22                   | 10.36                | 0.41                     | 0.10                     |
| 2                                    | 10.89                  | 4.43                 | 0.32                     | 0.12                     |
| 4                                    | 4.61                   | 1.73                 | 0.15                     | 0.05                     |
| 6                                    | 0.96                   | -                    | 0.03                     | 0.01                     |

$P_{\text{CA}}$: maximum citric acid production;  
$R_{\text{CA/ICA}}$: mass ratio between CA and ICA;  
$Y_{\text{CA/G}}$: mass yield of CA from glycerol consumed;  
$Q_{\text{CA}}$: volumetric citric acid productivity.

The CCD with pure glycerol, it was possible to increase CA production in 17% and to increase the ratio between citric and isocitric acid ($R_{\text{CA/ICA}}$) in 62%. Biomass production reduced more than 50% showing the diversion of the carbon flux to CA production.

Substituting pure glycerol for crude glycerol reduced CA production and productivity. The impurities present in crude glycerol may have diverted the metabolic pathway for cell growth, since it increased biomass production 3 times. However, with the experimental design, it was possible to increase CA production 36% with crude glycerol. This was possible with the increase of $C/N$ ratio, which diverted the carbon flux to CA production (reduction of the biomass production in 30%). The ratio between citric and isocitric acids was also increased.

Chatzifragkou et al. [8] have shown that when natural strains of *Y. lipolytica* were cultivated in conical flasks, on media containing crude glycerol in a $C/N$ initial molar ratio of 264, CA obtained was 9.4 g/L, yielding 0.11 g of CA/g of glycerol consumed. A better result was achieved in the present study (0.41 g of CA/g of glycerol consumed). Papanikolau et al. [6, 18] achieved similar yield (0.42 g and 0.40 g of CA/g of glycerol consumed, respectively) and productivity (0.14 g and 0.09 g of CA/L/h) with *Yarrowia lipolytica* but with higher nitrogen source concentrations (yeast extract: 0.5 g/L and ammonium sulphate: 0.5 g/L) than the present study (yeast extract 0.1 g/L and no ammonium sulphate). The optimization of CA production in this investigation have also taken into account the reduction of ICA production, which is not often observed in literature and this by-product is a huge problem for the CA separation process.
Table 5  Comparative analysis of the results obtained at different stages of optimization process.

| Parameters | FFD pure glycerol | CCD pure glycerol | Test with crude glycerol (Run 8) | CCD crude glycerol |
|------------|-------------------|-------------------|----------------------------------|-------------------|

4. Conclusions

The present study showed that *Yarrowia lipolytica* IMUFRI 50682 has the ability to consume pure glycerol and glycerol obtained from biodiesel production without cell growth damage. The use of the experimental design technique was effective in the study of the influence of different variables on process of obtaining of CA. Using this technique, it was possible to achieve the best concentrations of glycerol, yeast extract and agitation to optimize CA production. From the experimental designs, was possible to reduce the amount of glycerol and yeast extract, making the process of obtaining for CA more economic, and to reduce the main by-product of the process (ICA). The best initial C/N molar ratios achieved were 714 and 1,561 when pure glycerol and crude glycerol were used a carbon sources, respectively, showing the influence of carbon source on the final result.
