We study the relativistic orbit of binary black holes in systems with small mass ratio. The trajectory of the smaller object (another black hole or a neutron star), represented as a particle, is determined by the geodesic equation on the perturbed massive black hole spacetime. The particle itself generates the gravitational perturbations leading to a problem that needs regularization. Here we study perturbations around a Schwarzschild black hole using Moncrief’s gauge invariant formalism. We decompose the perturbations into $\ell$–multipoles to show that all $\ell$–metric coefficients are $C^0$ at the location of the particle. Summing over $\ell$, to reconstruct the full metric, gives a formally divergent result. We succeed in bringing this sum to a generalized Riemann’s $\zeta$–function regularization scheme and show that this is tantamount to subtract the $\ell \to \infty$ piece to each multipole. We explicitly carry out this regularization and numerically compute the first order geodesics. Application of this method to general orbits around rotating black holes would generate accurate templates for gravitational wave laser interferometric detectors.

I. INTRODUCTION

The computation of the gravitational radiation generated by binary black holes is of great theoretical and observational interest. On one hand these binary systems are among the best candidates to be detected by the new generation of gravitational wave detectors. On the other hand the theoretically very interesting two body problem in General Relativity remains an unsolved task for full numerical approaches. An appropriate astrophysical model to compute gravitational radiation coming from the capture of stars by massive black holes at the center of galaxies is provided by the perturbative approach applied to binary systems where one black hole is much more massive than the other. In the perturbative regime, linearized Einstein equations can be brought to two simple wave equations for the two polarizations of the gravitational field \( \psi_+ \) and \( \psi_\times \). This problem has been recently revisited to include initial data into the formulation in order to be able to start numerical integrations from finite separations of the holes \( \psi_\times \). It also proved to be an excellent arena where to test the accuracy of the longitudinal-conformally flat ansatz to solve the initial value problem for binary black holes \( \psi_+ \). In order to answer questions like what is the the displacement of the innermost stable circular orbit (ISCO) and the rate of increase of the characteristic gravitational frequency due to inspiralling orbits, it is important to go beyond the leading approximation. Technically, one has to compute the geodesic trajectory of a particle in the perturbed black hole spacetime generated by the particle itself. Taking this effect into account will make otherwise particle’s bounded orbits actually to inspiral towards the bigger black hole. This consistent description of the first order perturbative approach opens the door to second order perturbative studies which allow to compute gravitational radiation from binary black holes with much higher accuracy and for systems with not so small mass ratio. Such studies would teach us about new nonlinear physical effects as well as to produce accurate templates to analyze the forthcoming data from ground (and space) based laser interferometric detectors.

Recent work on gravitational radiation reaction prompted a renewed theoretical interest on this problem. The approach we will develop here privileges its direct computational implementability. Throughout this paper we will use results and techniques of Ref. \#1. There it was computed the gravitational radiation generated by the collision of two non-spinning black holes, one much less massive than the other, starting from rest at a finite distance. The extreme mass ratio allowed to describe the problem of gravitational radiation as perturbations about the Schwarzschild metric. Hence, instead of working with all ten metric perturbations, seven even parity and three odd parity (that identically vanish for our axially symmetric problem), the relevant perturbative information is organized into (one in the even parity case, two in general) the Moncrief waveform \( \psi \).

\[
\psi_\ell(r,t) = \frac{r}{\lambda + 1} \left[ K^t + \frac{r - 2M}{\lambda r + 3M} \left\{ H_\ell^t - r\partial K^t/\partial r \right\} \right]
\]

where we have used Zerilli’s normalization for \( \psi \) and
notation for \( \lambda \equiv (\ell + 2)(\ell - 1)/2 \).

One of the advantages of working with \( \psi_\ell \) is its gauge invariance under first order diffeomorphisms. This allows us to choose any convenient gauge, like the Regge-Wheeler gauge \([5]\), to make computations. \( \psi_\ell \) satisfies a single (in general two, with the odd parity case) wave equation

\[
- \frac{\partial^2 \psi_\ell}{\partial t^2} + \frac{\partial^2 \psi_\ell}{\partial r^2} - V_I(r)\psi_\ell = S_I(r, t), \tag{2}
\]

where \( r^* \equiv r + 2M \ln(r/2M - 1) \), \( V_I \) is the Zerilli potential, and \( S_I(r, t) \) is the source term generated by the small hole, given in Ref. \([3]\). The smaller hole is described as a point particle of proper mass \( m_0 \), its stress energy tensor given by

\[
T^{\mu\nu} = m_0 U^\mu U^\nu \frac{\partial^2 \Omega}{\partial r \partial t^2} \delta(r - r_p(t)) \delta^2[\Omega], \tag{3}
\]

where \( U^\mu \) is the particle 4-velocity. The two dimensional delta function \( \delta^2[\Omega] \) gives the angular location of the particle \( (\theta_p, \phi_p) \). Since \( T^{\mu\nu} \), and hence \( S_I(r, t) \) are already proportional to \( m_0 \), to first perturbative order, the geodesic trajectory \( r_p(t) \), follows from the geodesic equation in the background geometry (Schwarzschild’s here). There are situations when one wants to know the trajectory of the small hole to the next order. In the computation of the gravitational radiation to second perturbative order one needs to know the source term to second order, hence the trajectory of the hole on the first order metric (background plus first order perturbations). Even within first order perturbation theory one would also like to go further in order to compute secular effects like the particle’s bounded orbit decay around a much bigger black hole.

For the sake of simplicity we will treat here the radial infall of a particle into a nonrotating hole. This problem contains many of the relevant features that occur for more general orbits. To first perturbative order, the trajectory of the particle is given by a geodesic on the first order metric (Schwarzschild plus first order perturbations). This is so because the only "forces" acting on the particle are gravitational. The time component of the particle’s four-momentum, \( P_t = m_0 g_{tt}(dt/d\tau) = -m_0 E \), is no longer a conserved quantity along the trajectory. We then have to deal with the radial and time (here the only nontrivial ones) components of the geodesic equation. We combine these two equations into a single equation of motion for \( r(t) \) by eliminating the dependence on the geodesic parameter. Linearization of the resulting equation and subtraction of the zeroth order geodesic gives the deviation of the trajectory \( \Delta r_p(t) \) from the zeroth order one \( r_p(t) = \partial_0 z_p = -(1 - 2M/z_p)\sqrt{2M/z_p - 2M/z_0}/(1 - 2M/z_0) \), directly in terms of Schwarzschild coordinates, ready for further applications

\[
\Delta r_p = A \Delta r_p + B \Delta \dot{r}_p + C \tag{4}
\]

where

\[
A = \frac{2M}{r^3} \left[ 3 - \frac{3M}{r} - (1 - 3M/r)^2 \right] \frac{1}{(1 - 2M/r)^2},
\]

\[
B = \frac{6Mr_p}{r^2(1 - 2M/r)},
\]

\[
C = \frac{1}{\Gamma_{\ell\ell}^t} \left[ \Gamma_{\ell\ell}^t \dot{r}_p^3 + (2 \Gamma_{t\ell}^t - \Gamma_{\ell\ell}^r) \dot{r}_p^2 + (\Gamma_{tt}^t - 2 \Gamma_{t\ell}^t) \dot{r}_p \right] - \frac{1}{\Gamma_{\ell\ell}^r} \sum_{i=0}^\infty C_i. \tag{5}
\]

The (numerical) integration of this expression gives the trajectory of the particle correct to first perturbative order, \( (m_0/M) \). Since the metric perturbations generated by a particle seem to involve radial delta functions (and derivatives of them) evaluated at the location of the particle (see Eqs. \([3]\) below), the first problem to face here is to evaluate the connection coefficients at \( r_p \). We will next show explicitly that the metric is actually \( C^0 \) at the location of the particle. Connection coefficients have a finite jump and they can be computed as the average of its values at \( r_p \pm \epsilon \) with \( \epsilon \to 0 \). While this accounts for the terms coming from the radial Dirac delta in Eq. \([3]\), as we will see, the angular delta needs to be explicitly regularized by a different method.

II. CONTINUITY OF METRIC COEFFICIENTS

The \( tt \) component of Einstein’s equations give us the Hamiltonian constraint. In the Regge-Wheeler gauge \( (h_1 = h_0 = G = 0) \) it is given by Zerilli’s \([5]\) Eq. (C7a). Only two metric coefficients \( (K^\ell, H^\ell_2) \) appear in this equation and none of its time derivatives. We recall here that metric coefficients have an explicit multipole index \( \ell \) since we have decomposed their angular dependence into tensor harmonics. Consequently \( K^\ell \) and \( H^\ell_2 \) are only functions of \( t \) and \( r \). Taking the Regge-Wheeler gauge as an intermediate step, the definition of \( \psi_\ell \), and the Hamiltonian constraint we can express these two metric coefficients in terms of \( \psi_\ell \) only (and source terms)

\[
K^\ell = \frac{6M^2 + 3M\lambda r + \lambda(\lambda + 1)r^2}{r^2(\lambda r + 3M)} \psi_\ell + \left( 1 - \frac{2M}{r} \right) \partial_r \psi_\ell - \frac{\kappa}{(\lambda + 1)(\lambda r + 3M)r} \delta(r - r_p), \tag{6}
\]

and

\[
H^\ell_2 = -\frac{9M^3 + 9\lambda M^2 r + 3\lambda^2 M r^2 + \lambda^2(\lambda + 1)r^3}{r^2(\lambda r + 3M)^2} \psi_\ell + \frac{3M^2 - \lambda M r + \lambda^2 r^2}{r(\lambda r + 3M)} \partial_r \psi_\ell + (r - 2M)\partial_r^2 \psi_\ell + \frac{\kappa U^0(1 - 2M/r)|\ell^2 r^2 + 2M r - 3Mr + 3M^2|}{(\lambda + 1)(\lambda r + 3M)^2} \delta(r - r_p)
\]
\[
-kU_0^0(r - 2M)^2 \frac{1}{\lambda + 1}(\lambda r + 3M) \delta[r - r_p].
\] (7)

Integration over \( r \) of the Hamiltonian constraint tells us that the leading behavior is given by

\[
\partial_t \psi_t \sim kU_0^0(r - 2M)\delta[r - r_p]/(\lambda + 1)/(\lambda r + 3M).
\] (8)

This can be used to prove that the metric coefficients at the location of the particle are actually \( C_0^0 \), by taking up to second derivatives and using the equation above to cancel derivatives of the Dirac’s delta. The same \( C_0^0 \) behavior at \( r_p \) can be proven for \( H^0_1 \), we now consider the \( t \) and \( \theta \) (or \( t \phi \)) components of the Einstein equations that give us the momentum constraint. In the Regge-Wheeler gauge they are given by Zerilli’s [2] Eqs. (C7b) and (C7d).

We combine them to eliminate the dependence on \( H^0_1 \), and obtain after integration over \( r \) that \( \partial_r(\partial_t \psi_t) \sim -kU_0^0 \delta_p r (r - 2M)\partial_r \delta[r - r_p]/(\lambda + 1)/(\lambda r + 3M) \).

From Zerilli’s [2, Eq. (C7b)] and the expressions for \( \partial_t K^t \) and \( \partial_t H^t \) in terms of \( \partial_t \psi_t \), we find the last metric coefficient in the Regge-Wheeler gauge

\[
H^t_1 = \rho \partial_r(\partial_t \psi_t) + \frac{\lambda^2 - 3M\lambda r - 3M^2}{(\lambda + 1)(\lambda r + 3M)} \partial_t \psi_t - \frac{kU_0^0 \rho_t r (r - 2M)}{(\lambda + 1)(\lambda r + 3M)} \delta[r - r_p].
\] (9)

This equation together with \( H^t_0 = H^t_2 \) (valid for head-on collisions), [6], and [1] give us all metric perturbations on the chosen hypersurface in terms only of \( \psi_t \) and \( \partial_t \psi_t \) (and the source). We recall here that since our case has axial symmetry only even waves are generated.

### III. Regularization

In Fig 1 we plot the results of computing by means of Eq. (6) the metric coefficient \( H_2^{\text{ren}}(1 - 2M/r_p)/\sqrt{2\ell + 1}H_2^0 \) along the trajectory of the particle \( r_p(t) \). It clearly shows that it is finite at each point of the trajectory. The other notable feature is that for large \( \ell \) the curves quickly accumulate over the \( \ell \to \infty \) asymptotic curve. Since one has then to sum over all \( \ell \) contributions, this sum clearly diverges. One way of regularizing this sum is to subtract to each mode precisely the \( \ell \to \infty \) contribution, and then verify the convergence of the remanent series. The result of such regularization is shown in the lower half of Fig 4. The same qualitative results are found for the other metric coefficients \( H^t_1(r_p) \), \( K^t(r_p) \), and \( H^0_0(r_p) = H^0_2(r_p) \).

Non-radiative multipoles \( \ell = 0 \) can be found analytically and represent the mass and linear momentum contributions of the particle to the system [3]. The regularization just described is ambiguous up to a finite piece. To give a definite prescription we note that it can be brought into the generalized Riemann’s \( \zeta \)-function [10].

![Fig. 1](image-url.png)

**FIG. 1.** The upper part of the plot shows the metric coefficient \( H_2^t \) along the trajectory of the particle in units of \( m_0 \). Curves with increasing \( \ell \) quickly tend to superpose to that for \( \ell \to \infty \). The lower part of the plot represents the renormalized metric \( H_2^{\text{ren}} = H_2^0 - H_2^{\text{ren}} \). The inset figure gives the leading decay power, \( \alpha \), of \( H_2^{\text{ren}} \) at a fiducial \( r_p \).

procedure as follows. The numerical behavior of all metric coefficients shows that they can be decomposed into two pieces: One that generates the finite behavior for \( \ell \to \infty \) and the other strongly decaying for large \( \ell \) (labeled with a \( \text{ren} \) below). Thus, for instance, for the perturbed metric component \( g_{\ell \ell} \) we can write

\[
H_2(t, r, \theta, \phi) = \sum_{\ell_m} H_2^{\text{ren}}(t, r)Y_{\ell m}(\theta, \phi)
\] (10)

\[
= \sum_{\ell = 0}^{\infty} \{ (2\ell + 1 - \beta) H_2^\infty + H_2^{\text{ren}} \} \sqrt{\frac{2\ell + 1}{4\pi}} P_{\ell}(\theta)
\]

where in the second equality we made use of the axil symmetry of the problem and we have chosen the \( \beta \)-parametrization motivated by the \( D \)-dimensional extension of the conformally flat initial value problem, where \( \beta = 4 - D \). When we evaluate this metric coefficient at the location of the particle we find

\[
H_2(t, r_p(t), \theta_p = 0) = 2^{-\beta + 1/3} H_2^\infty \zeta(\beta - 1/2, -1/2) + \sum_{\ell = 0}^{\infty} \sqrt{\frac{2\ell + 1}{4\pi}} H_2^{\text{ren}}.
\] (11)

where the Riemann’s \( \zeta \)-function is \( \zeta(a, b) = \sum_{\ell = 0}^{\infty} (\ell + b)^{-a} \). Numerically, we observe that \( \beta = 1/2 \) in order to lead to the finite \( \ell \to \infty \) behavior. Since the analytically continued \( \zeta \)-function gives \( \zeta(0, 1/2) = 0 \) we must subtract to each multipole just the \( \ell \to \infty \) piece. The renormalized metric coefficients that enter into the head-on geodesic equation (\( H_0^{\text{ren}} = H_2^{\text{ren}} \)) vanish
to compute \( C \) case, also \( H \) practice) scale as \( \sim r \) trajectory

The renormalized acceleration is very small in the early stages of the trajectory. This is expected for a particle starting at rest, since the gravitational radiation is dominated by the bremsstrahlung mechanism. Then, radiation reaction effects become more important as the particle approaches the maximum of the Zerilli’s potential (around \( r_{max} \approx 3.1M \)). They tend to decelerate the particle with respect to the zeroth order (Schwarzschild) geodesics. This is what one would qualitatively expect a priori since the system is losing energy and momentum in the form of gravitational radiation. Another important feature is that the radiation reaction effect is low \( \ell \)--dominated (only after renormalization), but still the sum over large \( \ell \) give an important contribution, and one has to consider higher multipoles than one usually takes into account when computing, for instance, the total energy radiated reaching infinity.

A related approach to the one presented here has been developed independently [11] and applied to scalar radiation. It considers the large \( \ell \) dependence of the tail term of the reaction force [7], and regularizes the sum over \( \ell \) modes by subtracting the non-convergent terms plus a finite part to be determined. Applied to the equivalent case we treated here the finite part to be subtracted vanishes and both procedures coincide. Besides, this method was implemented to study static scalar and Electric fields in the Schwarzschild background [12], leading to the correct known expressions of the self force. It would be very interesting to compare the results of our procedure with still other methods of regularization in order to cross check for possible ambiguities in the determination of the remaining finite parts.

**IV. DISCUSSION**

Here we reported on a first important step to improve our ability to compute gravitational radiation from binary black holes. The next step is to apply the \( \zeta \)--function regularization method to general bounded orbits in the Schwarzschild background and compare its results with the energy and momentum balance estimates. Besides, our renormalization procedure is explicitly gauge invariant since we use Moncrief’s waveform. Another key problem to attack is the orbiting particle in a rotating black hole background. Perturbations of the Kerr metric are described by the Teukolsky equation and can be decomposed into multipoles (via spin-weighted spheroidal harmonics) in the frequency domain, i.e. after a Fourier decomposition of the time dependence. This property would still allow to apply our regularization scheme and compute the decay of bounded orbits consistently to first order. Besides, it would open the possibility to study second order perturbations [8] and obtain a remarkable improvement in our ability to compute gravitational radiation from binary systems with not so small mass ratio. This will not only be of use for LISA’s detec-
tion of gravitational radiation from black holes in the center of nearby galaxies, but also relevant for ground based interferometers, sensible to frequencies corresponding to black hole / neutron star binaries.
