Efficient Distribution Estimation and Uncertainty Quantification for Elliptic Problems on Domains with Stochastic Boundaries

Jehanzeb H Chaudhry∗ Nathanial Burch† Donald Estep‡

July 17, 2018

Abstract

We study the problem of uncertainty quantification for the numerical solution of elliptic partial differential equation boundary value problems posed on domains with stochastically varying boundaries. We also use the uncertainty quantification results to tackle the efficient solution of such problems. We introduce simple transformations that map a family of domains with stochastic boundaries to a fixed reference domain. We exploit the transformations to carry out a prior and a posteriori error analyses and to derive an efficient Monte Carlo sampling procedure.

1 Introduction

In this paper, we study uncertainty quantification and efficient solution of boundary value problems for elliptic partial differential equations (PDEs) posed on domains with stochastically perturbed boundaries. The problem of stochastic boundaries occurs for a variety of reasons, e.g. from physical stresses, manufacturing deficiencies, and uncertainty in measurements of a fixed geometry. Specific applications are found in transport in tubes with rough boundaries [28], aerodynamic studies in the design of wind turbines [10], heat diffusion across irregular and fractal-like surfaces [6, 7], structural analysis studies [26], acoustic scattering on rough surfaces [27, 30], seismology and oil reservoir management [4], various civil and nuclear engineering studies [3], chemical transport in rough domains [9], and electromechanical studies for nanostructures [1].

This paper focuses on two key issues that arise in such problems:

• Since the geometric properties of the domain have a strong effect on solution behavior and smoothness, significant variation in solution behavior for different realizations of the domain is to be expected. Correspondingly, significant variation in the error arising from discretization and sampling is also to be expected;

• Each realization of a domain nominally requires construction of a new discretization mesh, at a significant computational cost. Hence, solving such problems using a Monte Carlo approach is computationally intensive.

We deal with these issues using two ideas. First, motivated by the technique of isoparametric finite elements \[12\], we describe a family of simple, locally determined, well-behaved transformations that map a given elliptic problem posed on a family of stochastic domains \(\{\Omega(\theta)\}_{\theta \in \Theta}\) to an elliptic problem with stochastic coefficients posed on a fixed reference domain \(\Omega\). We then construct finite element approximations for the solution of sample elliptic problems on the reference domain and use these to formulate a Monte Carlo method to compute the sample cumulative distribution function for a specified Quantity of Interest (QoI). We carry out a full a priori analysis of the finite element method. Second, we carry out an uncertainty quantification by deriving a posteriori error estimates both for a QoI computed from a numerical solution that take into account all sources of deterministic and stochastic errors and for the approximate cumulative distribution function computed from the QoI. The estimate is sufficiently detailed that we can efficiently balance computational work, e.g., mesh resolution versus sample numbers, to achieve a desired accuracy. This provides a way to tackle computational efficiency by describing an efficient adaptive strategy that leads to a mesh that produces acceptable accuracy for all realizations of the problem.

The analysis of elliptic problems posed on stochastic domains has received much less attention than elliptic problems with stochastic coefficients. An approach that has received substantial attention is based on postulating global transformations between a reference domain and the random domains that satisfy certain regularity conditions and the use of Karhunen-Loeve expansions, stochastic Galerkin methods, stochastic collocation, etc., to compute numerical approximations. Some of the earlier references are \[28, 30, 31, 1, 27\], which considers elliptic problems posed on a domain whose boundary is parameterized by a stochastic process. Some of the key technical issues were analyzed in subsequent work, e.g., \[20, 11, 21, 22\].

The mathematical analysis of the method considered in this paper and the methods studied in \[28, 30, 31, 1, 27, 20, 11, 21, 22\] deal with similar technical challenges since all the methods employ transformations between random domains and a reference domain. However, the method analyzed in this paper has several fundamental differences to these other methods. The great difficulty involved in constructing smooth global transformations between two domains places constraints on the formulation of the random domain problem. The method analyzed in this paper avoids construction of global transformations between the random domain realizations and a fixed reference domain, instead employing simple, easily computed transformations confined to a neighborhood of the random boundary. This makes the method well-suited for the class of problems where data describing the boundary of each realization of the random domain is given, e.g., determined through physical measurement. Some of the analysis is focused on dealing with the technical issues that arise from the use of a localized transformation. With the goal of accurately computing a sample cumulative distribution function as opposed to a couple of statistics, we employ Monte Carlo sampling, and we consider the issue of increasing the efficiency of this approach. Finally, in addition to a priori convergence analysis, we present and implement a posterior error analysis as well as an adaptive method based on the estimates.

Of course, transforming a domain of a given elliptic problem to another domain is a classic analytic approach, e.g., Schwarz-Christoffel transformations \[14, 29\] provide a global and smooth map. However, conformal maps involve significant complications in practice, e.g., the resulting maps may introduce complications such as singularities at boundaries of a domain and they are difficult and expensive to compute. This motivates the very simple transformations studied in this manuscript.

The rest of the paper is organized as follows. In Section 2 we present the problem formulation and modeling assumptions. We construct a piecewise-smooth transformation to a deterministic domain \(\Omega\), provide details for the finite element method, formulate the adjoint problem and an error estimate in Section 3. The estimate is
extended to analyze Lions domain decomposition on a transformed domain in Section 4. A posteriori estimates of the various sources of errors for each realization and for the empirical distribution function are obtained in Section 5. Section 6 discusses the construction of a finite element mesh suitable for all realizations of \( \theta \). Numerical experiments are performed and presented throughout the paper.

## 2 Problem formulation

### 2.1 Stochastically perturbed domains

We describe the domains with stochastic boundaries as random perturbations of a nominal deterministic reference domain \( \Omega \). The reference domain \( \Omega \) is a convex polygonal domain in \( \mathbb{R}^2 \) with sides formed by straight edges joining a collection of nodes \( \{ \hat{v}_j \}^J_{j=1} \). To define the stochastic perturbations, we let \( \{ \hat{\theta}_j \}^J_{j=1} \) denote a collection of random vectors \( \hat{\theta}_j \in \mathbb{R}^2 \) such that \( \hat{\theta}_j \sim (\Lambda_j, \mathcal{F}_j, P_j) \), where \( (\Lambda_j, \mathcal{F}_j, P_j) \) is a probability space with compact domain \( \Lambda_j \subset \mathbb{R}^2 \), \( \sigma \)-algebra \( \mathcal{F}_j \), and probability measure \( P_j \). We abuse notation to let \( \theta = \{ \hat{\theta}_j \}^J_{j=1} \) and let \( \theta \in \Theta \) denote the set of admissible perturbation vectors. The stochastic perturbation \( \Omega(\theta) \) is the polygonal domain with boundaries defined by straight edges connecting nodes \( \{ \hat{v}_j + \hat{\theta}_j \}^J_{j=1} \); see Fig. 1. We note that \( \Omega(\theta) \to \Omega \) as

![Figure 1: Left: Stochastic perturbation of a boundary node. Middle: A collection of perturbed boundary nodes. Right: A collection of stochastic perturbations of the nominal domain.](image)

\[ ||\theta|| = \max ||\hat{\theta}_j|| \to 0, \text{ where } ||\ |\ || \text{ in the second quantity denotes the Euclidean norm.} \]

To enforce the assumption that the domains \( \Omega(\theta) \) share the same gross shape, we let \( \Omega^* \) and \( \Omega_* \) denote convex polygonal domains with \( J \) boundary nodes and nonzero volume obtained by scaling \( \Omega \) so that \( \Omega_* \subseteq \Omega \subseteq \Omega^* \). We assume that for all \( \theta \),

\[ \Omega_* \subseteq \Omega(\theta) \subseteq \Omega^*, \quad \forall \theta \in \Theta, \]

see Fig. 1. As we demonstrate, the solution technique described below can be applied to relatively large perturbations and to nonconvex domains. However, there are well known analytic difficulties associated with elliptic problems on non-convex polygonal domains with "sharp" inset angles. By reducing the volume of \( \Omega^* \setminus \Omega_* \), we can limit the degree of non-convexity in \( \Omega(\theta) \) that may occur.

We emphasize that the numerical method does not depend on identifying a "true" nominal domain \( \Omega \). Under these assumptions, given a collection of sample domains \( \{ \Omega(\theta^n) \} \) corresponding to a collection of samples \( \{ \theta^n \} \),
we can simply choose one sample domain to use as a reference domain. As we discuss, some choices may yield improved numerical accuracy.

2.2 The elliptic problem

In defining the elliptic problem, we wish to avoid situations in which there is a radical change in material properties from one domain to the next. So, we assume that the coefficients and right-hand side of the elliptic equation are defined in the largest domain \( \Omega^* \). The elliptic problem on \( \Omega(\theta) \) is: Find \( w \) satisfying

\[
\begin{cases}
-\nabla \cdot (a(x)\nabla w(x; \theta)) = f(x), & x \in \Omega(\theta), \\
w(x; \theta) = 0, & x \in \partial \Omega(\theta),
\end{cases}
\]

(2.1)

where \( a \) is a \( 2 \times 2 \) symmetric positive definite matrix with coefficients that are continuous functions on \( \Omega^* \) such that there is a constant \( a_0 > 0 \) with \( w^\top a w \geq a_0 \| w \|^2 \) for all \( w \in \mathbb{R}^2 \) and \( x \in \Omega^* \) and \( f \) is continuous on \( \Omega^* \). We assume that both \( a \) and \( f \) are independent of \( \theta \), though extensions to the cases when \( a \) and \( f \) are also stochastic [16, 17]. Having obtained the solution, we evaluate the quantity of interest (QoI),

\[
Q(w; \theta) = \int_{\Omega(\theta)} w(x; \theta) \psi(x) \, dx,
\]

(2.2)

where \( \psi \in L^2(\Omega^*) \). By standard results \( w(x; \theta) \) depends continuously on \( \theta \). Hence, \( Q(w; \theta) \) is a random variable and the stochastic version of (2.1) and (2.2) is to compute the probability distribution of \( Q(w; \theta) \),

\[
P(t) = \Pr(Q(w; \theta) \leq t).
\]

Since we are dealing with a collection of domains, there are some restrictions on possible QoIs. For example, it is inappropriate to choose the value at a point that is not in all the sample domains. Some choices of QoI vary as the domain varies, e.g., \( \psi = 1 \).

2.3 Basic properties of the elliptic problem

The variational formulation of (2.1) reads: Find \( w \in H^1_0(\Omega(\theta)) \) such that

\[
B_{\Omega(\theta)}(w, v) = F_{\Omega(\theta)}(v), \quad \forall v \in H^1_0(\Omega(\theta)),
\]

(2.3)

where the bilinear form

\[
B_{\Omega(\theta)}(w, v) = \int_{\Omega(\theta)} a(x)\nabla w \cdot \nabla v \, dx
\]

is bounded and coercive for all \( \theta \in \Theta \), i.e.,

\[
|B_{\Omega(\theta)}(w, v)| \leq C_1(\theta) \| w \|_{H^1_0(\Omega(\theta))} \| v \|_{H^1_0(\Omega(\theta))}, \quad \forall w, v \in H^1_0(\Omega(\theta)),
\]

\[
B_{\Omega(\theta)}(w, w) \geq C_2(\theta) \| w \|^2_{H^1_0(\Omega(\theta))}, \quad \forall w \in H^1_0(\Omega(\theta)),
\]

and the linear form

\[
F_{\Omega(\theta)}(v) = \int_{\Omega(\theta)} f(x)v(x) \, dx
\]
is bounded, i.e.,
\[ |F_{\Omega}(\theta)(v)| \leq C_3(\theta)\|v\|_{H^1_0(\Omega(\theta))}. \]
We assume uniform boundedness and coercivity with respect to \( \theta \), i.e., there are constants \( C_1, C_2, C_3 \) with
\[ C_1(\theta) \leq C_{1,\max} < \infty \quad C_2(\theta) \geq C_{2,\min} > 0, \quad C_3(\theta) \leq C_{3,\max} < \infty. \tag{2.5} \]
The Lax-Milgram lemma \([23]\) grants a unique weak solution \( w \) to (2.3) for all \( \theta \in \Theta \). Moreover, by (2.5),
\[ \sup_{\theta \in \Theta} \|w\|_{H^1_0(\Omega(\theta))} \leq \frac{1}{C_{2,\max}} \|f\|_{L^2(\Omega^*)}. \]
Under the convexity assumption, the standard regularity result holds, i.e.,
\[ \|w\|_{H^3_0(\Omega(\theta))} \leq C(\theta)\|f\|_{L^2(\Omega(\theta))}. \]

3 Transformed Problem

The problem is transformed by mapping \( \Omega(\theta) \) back to the reference domain \( \Omega \) using a piecewise affine map. As mentioned, we can choose any sample domain to be the reference domain. To create the map, we partition \( \Omega \) into \( D \) triangular subdomains \( \{\Omega_d\}_{d=1}^D \) such that \( \overline{\Omega} = \bigcup_{d=1}^D \overline{\Omega}_d \). The subdomains in the partition are chosen so that they are non-intersecting and the vertices of subdomains do not intersect interiors of edges of other subdomains or interiors of boundary edges. Under these assumptions, there is a corresponding partition \( \{\Omega_d(\theta)\}_{d=1}^D \) of each \( \Omega(\theta) \) that is obtained by perturbing only the nodes of the partition \( \{\Omega_d\}_{d=1}^D \) that lie on the boundary of \( \Omega \) by \( \theta \).

There are many choices of such partitions but some choices yield better numerical results than others. In particular, we use the partition to make a domain decomposition formulation of the original elliptic problem and the difficulty in obtaining accurate numerical solutions is affected by the shape of the subdomains. Consequently, the angles in the subdomains and number of subdomains impact the convergence of the domain decomposition iteration and the condition numbers of the resulting linear systems. Likewise, the properties of the transformations affect the accuracy of the finite element approximation. We illustrate some of the issues with an example in 3.6.

3.1 Random samples

We select \( N \) independent realizations \( \{\theta^n\}_{n=1}^N \), which corresponds to a set of sample domains \( \{\Omega(\theta^n)\} \).

3.2 Transformation to a reference domain

Rather than discretizing the elliptic problem on each sample domain \( \Omega(\theta^n) \) directly, we first apply a piecewise affine map \( \varphi : \Omega(\theta^n) \to \Omega \). The map is determined by \( D \) invertible affine maps \( \varphi_d(\theta^n) = \varphi^n_d : \Omega_d(\theta^n) \to \Omega_d, \) \( 1 \leq d \leq D \). Let \( y \in \Omega_d \) denote the image of \( x \in \Omega_d(\theta^n) \) under the map \( \varphi^n_d \) and let \( J^n_d \) denote the Jacobian matrix of \( \varphi^n_d \). We denote the three vertices of \( \Omega_d(\theta^n) \) by \( r^n_{d,1}, r^n_{d,2}, \) and \( r^n_{d,3} \) and the three corresponding vertices of \( \Omega_d \) by \( s_{d,1}, s_{d,2}, \) and \( s_{d,3} \), see Fig. 2. The transformation is defined,
\[ \varphi^n_d(x) = J^n_d (x - r^n_{d,1}) + s_{d,1}, \tag{3.1} \]
where
\[ J^n_d = \begin{pmatrix} s_{d,2} - s_{d,1} & - (s_{d,3} - s_{d,1}) \end{pmatrix} \begin{pmatrix} r^n_{d,2} - r^n_{d,1} & -(r^n_{d,3} - r^n_{d,1}) \end{pmatrix}^{-1} = S_d(R_d)^{-1}. \]
Both $S_d$ and $R_d^n$ are invertible since $\Omega_d(\theta^n)$ and $\Omega_d$ are non-degenerate triangles.

We constrain the partitions $\{\Omega_d(\theta^n)\}_{d=1}^D$ so that for constants $M_*, M^*$,

$$0 < M_* \leq \min_{n,d} |\det(J^n_d)| \leq \max_{n,d} |\det(J^n_d)| \leq M^* < \infty,$$

uniformly for all samples $\{\theta^n\}$. We note that (3.2) implies uniform bounds on $|J_d^n|$ and $|J_d^n|^{-1}$.

### 3.3 Transformation of the problem

We next reformulate the elliptic problem by applying the transformation $\varphi$. Let $n_d$ denote the outward pointing normal vector to the boundary of $\Omega_d(\theta^n)$, $a|\Omega_d \equiv a_d$ and $f|\Omega_d \equiv f_d$. Then, for $1 \leq d \leq D$, compute $w_d$ on $\Omega_d(\theta^n)$ solving,

$$\begin{cases}
-\nabla \cdot (a_d(x)\nabla w^n_d(x; \theta^n)) = f_d(x), & x \in \Omega_d(\theta^n), \\
w^n_d(x; \theta^n) = 0, & x \in \partial \Omega(\theta^n) \cap \partial \Omega_d(\theta^n), \\
w^n_d(x; \theta^n) = w^\prime_d(x; \theta^n), & x \in \partial \Omega_d(\theta^n) \cap \partial \Omega_d(\theta^n), \
n_d \cdot (a_d(x)\nabla w^n_d(x; \theta^n)) = -n_d \cdot (a_d(x)\nabla w^\prime_d(x; \theta^n)), & x \in \partial \Omega_d(\theta^n) \cap \partial \Omega_d(\theta^n),
\end{cases}$$

(3.3)

where $d'$ is the set of $\{1, \ldots, D\} \setminus \{d\}$ such that $\Omega_d(\theta^n)$ and $\Omega_{d'}(\theta^n)$ share a boundary. The last two lines in (3.3) are interface conditions guaranteeing continuity of the solution and normal flux across the boundaries. The analysis of the existence, uniqueness, and regularity of the solution of (3.3) is discussed in [2, 5, 8, 24, 25]. We have $w|\Omega_d \equiv w_d$.

Using (3.1) in (3.3), we obtain the transformed problem on $\Omega$,

$$\begin{cases}
-\nabla \cdot (A^n_d(y; \theta^n)\nabla u^n_d(y; \theta^n)) = F^n_d(y; \theta^n), & y \in \Omega_d, \\
u^n_d(y; \theta^n) = 0, & y \in \partial \Omega \cap \partial \Omega_d, \\
u^n_d(y; \theta^n) = u^n_d(y; \theta^n), & y \in \partial \Omega_d \cap \partial \Omega_d, \
(n_d \cdot (A_d(y; \theta^n)\nabla u^n_d(y; \theta^n))) = (n_d \cdot (A^n_d(y; \theta^n)\nabla u^n_d(y; \theta^n))), & y \in \partial \Omega_d \cap \partial \Omega_{d'}, \forall d \in d',
\end{cases}$$

(3.4)
where \( u_d(y; \theta^n) = u_d((\varphi^n_d)^{-1}(y); \theta^n) \).

\[ A^n_d(y; \theta^n) = |\det J^n_d|^{-1} J^n_d \circ_a ((\varphi^n_d)^{-1}(y)) (J^n_d)^\top, \]

and, \( F^n_d(y; \theta^n) = |\det J^n_d|^{-1} f_d((\varphi^n_d)^{-1}(y)) \).

Equivalently, we can write (3.4) in compact form as,

\[
\begin{aligned}
&\left\{ \begin{array}{ll}
-\nabla \cdot (A^n(y; \theta^n) \nabla u^n(y; \theta^n)) = F^n(y; \theta^n), & y \in \Omega, \\
\quad u^n(y; \theta^n) = 0, & y \in \partial \Omega \cap \partial \Omega,
\end{array} \right.
\]

where \( u^n(y; \theta^n) = u^n_d(y; \theta^n) \), \( A^n(y; \theta^n) = A^n_d(y; \theta^n) \) and \( F^n(y; \theta^n) = F^n_d(y; \theta^n) \) for \( y \in \Omega_d \). We note that (3.11) implies that \( A^n_d \) and \( F^n_d \) can be computed without constructing \( \Omega(\theta^n) \) explicitly.

The QoI in terms of the transformed variables becomes,

\[ Q(u^n; \theta) = \int_{\Omega} u^n(y; \theta) \tilde{\psi}(y) \, dy, \]

where \( \tilde{\psi}(y) = \psi((\varphi^n_d)^{-1}(y)) |\det J^n_d|^{-1} \) for \( y \in \Omega_d \).

### 3.3.1 Weak form of the transformed problem

For the variational formulation of (3.5), we let \( V = H^1_0(\Omega) \) and seek \( u \in V \), we have,

\[ \int_{\Omega} A^n(y; \theta^n) \nabla u^n \cdot \nabla v \, dy = \int_{\Omega} F^n(y; \theta^n) v \, dy, \]

for all \( v \in V \). The matrix \( A^n \) is symmetric, positive definite.

We now show that the bilinear form \( \int_{\Omega_d} A^n(y; \theta^n) \nabla u^n \cdot \nabla v \, dy \) is continuous and coercive. Let \( \kappa_d := \text{diam}(\Omega_d), \rho_d := \sup \{ \text{diam}(S) | S \subset \Omega_d \}, \kappa_d(\theta^n) := \text{diam}(\Omega_d(\theta^n)), \rho_d(\theta^n) := \sup \{ \text{diam}(S) | S \subset \Omega_d(\theta^n) \} \). We utilize the following properties of the Jacobians \( J^n_d \) [12],

\[ \|J^n_d\| \leq \frac{\kappa_d}{\rho_d(\theta^n)}, \quad \|(J^n_d)^{-1}\| \leq \frac{\kappa_d(\theta^n)}{\rho_d}. \]

Further,

\[ |\det J^n_d| = \frac{\text{meas}(\Omega)}{\text{meas}(\Omega(\theta^n))}. \]

and

\[ \pi \rho_d(\theta^n)^2 \leq \text{meas}(\Omega_d(\theta^n)) \leq \pi \kappa_d(\theta^n)^2, \quad \pi \rho_d^2 \leq \text{meas}(\Omega_d) \leq \pi \kappa_d^2, \]

where \( \text{meas} \) denotes the Lebesgue measure on \( \mathbb{R}^2 \).

We have from (3.9) and (3.10),

\[ \frac{\rho_d^2}{\kappa(\theta^n)^2} \leq |\det J_d| \leq \frac{\kappa_d^2}{\rho_d(\theta^n)^2}. \]

**Lemma 1.** The bilinear form

\[ B_{\Omega}(u^n, v) = \int_{\Omega} A^n(y; \theta^n) \nabla u^n \cdot \nabla v \, dy \]
is bounded and coercive, i.e.,
\[ B_\Omega(u^n, v) \leq C_{1,n} \|u^n\|_{H^1_0(\Omega)} \|v\|_{H^1_0(\Omega)}, \quad \forall u^n, v \in H^1_0(\Omega), \quad (3.12a) \]
\[ B_\Omega(u^n, u^n) \geq C_{2,n} \|u^n\|^2_{H^1_0(\Omega)}, \quad \forall u \in H^1_0(\Omega), \quad (3.12b) \]
where the constants \(C_{1,n}\) and \(C_{2,n}\) depend on the transformations \(\varphi_d(\theta^n)\).

Proof. Let \(\lambda_{n,d,max}\) and \(\lambda_{n,d,min}\) denotes the largest and smallest eigenvalues of \(J^n\) and \(a_{max}\) and \(a_{min}\) be the ones for the symmetric positive definite matrix \(a\). Then,
\[ B_\Omega(u^n, v) \leq \max_d \left( |\det J_d^{-1}| \lambda_{n,d,max}^2 \right) a_{max} \|u^n\|_{H^1_0(\Omega)} \|v\|_{H^1_0(\Omega)}. \quad (3.13) \]
By (3.8)
\[ \lambda_{n,d,max}^2 = \|J_d^n(J_d^n)^\top\| \leq \|J_d^n\|^2 \leq \frac{\kappa_d^2}{\rho_d(\theta^n)^2}. \quad (3.14) \]
Combining (3.11), (3.13) and (3.14) we have,
\[ B_\Omega(u^n, u^n) \geq a_{min} \max_d \left( \frac{\kappa_d^2 \kappa_d(\theta^n)}{\rho_d \rho_d(\theta^n)} \right) \|u^n\|^2_{H^1_0(\Omega)}, \quad (3.15) \]
which proves (3.12a) with
\[ C_{1,n} = a_{max} \max_d \left( \frac{\kappa_d \kappa_d(\theta^n)}{\rho_d \rho_d(\theta^n)} \right)^2. \]
Now we prove coercivity of the bilinear form. We have,
\[ B_\Omega(u^n, u^n) \geq \gamma \min_d \left( |\det J_d^{-1}| \lambda_{n,d,min}^2 \right) a_{min} \|u^n\|^2_{H^1_0(\Omega)} \quad (3.16) \]
where \(\gamma\) is the constant arising from Poincaré’s inequality. By (3.8),
\[ \lambda_{n,d,min}^2 = \frac{1}{\|J_d^{-1}(J_d^-1)\|^{-1}} \geq \frac{1}{(\|J_d^n\|^{-1})^2} \geq \frac{\rho_d^2}{\kappa_d(\theta^n)^2}. \]
Combining this with (3.11) and (3.16),
\[ B_\Omega(u^n, u^n) \geq a_{min} \gamma \min_d \left( \frac{\rho_d \rho_d(\theta^n)}{\kappa_d \kappa_d(\theta^n)} \right) \|u^n\|^2_{H^1_0(\Omega)}, \quad (3.17) \]
which proves (3.12b) with
\[ C_{2,n} = \gamma a_{min} \min_d \left( \frac{\rho_d \rho_d(\theta^n)}{\kappa_d \kappa_d(\theta^n)} \right)^2. \]
A similar argument shows that the linear form \(\int_{\Omega_d} F^n(y; \theta) v_d(y) \, dy\) is bounded.
3.4 Finite element discretization

We next discretize each transformed problem (3.5) using a standard finite element method corresponding to a triangulation of \( \Omega \). We let \( T_h \) denote a triangulation of \( \Omega \) that is a refinement of the partition \( \{ \Omega_d \} \), that is \( T_h \) is a collection of non-overlapping triangular elements \( \{ K_m \}_{m=1}^M \) that is constructed by starting with \( \{ \Omega_d \} \) and refining into smaller triangles such that no node of one \( K_m \) intersects and interior edge of another \( K_m' \) and \( \Omega = \bigcup_m K_m \). We let \( h_K \) denote the length of the maximum side of element \( K \), define the mesh function \( h(x) = h_K \) for \( x \in K \), and set \( h = \max h_K \) for all \( K \in T_h \). We let \( \alpha_K \) denote the maximum of the interior angles in element \( K \), and assume there is a constant \( \alpha < \pi \) such that \( \alpha_K < \alpha \) for all \( K \in T_h \). The maximum angle condition insures that the finite element solution corresponding to the mesh converges at the expected rate. We let \( V_h(\Omega) \) denote the space of continuous piecewise linear functions on \( T_h \). We note that the restriction of \( V_h(\Omega) \) is a subset of \( V \). The finite element discretization reads: Compute \( U^n \in V_h(\Omega) \) such \( \forall v \in V_h(\Omega) \),

\[
\int_\Omega A^n(y; \theta^n) \nabla U^n \cdot \nabla v \, dy = \int_\Omega F^n(y; \theta^n) v \, dy.
\]

3.5 Convergence properties

The restriction on the partitions \( \Omega_d \) in (3.2), along with the maximum angle condition implies that the finite element approximation converges at a first order rate in the energy norm and a second order rate in the \( L^2(\Omega) \) norm uniformly with respect to \( \theta^n \). However, the choice of partitioning has a significant effect on the magnitude of the error, even if the mesh satisfies the maximum angle condition which can be observed by consideration of the constants in the convergence for the \( H^1(\Omega) \) norm. A standard result from finite element analysis is that the \( H^1(\Omega) \) norm is bounded by,

\[
||u^n - U^n||_{H^1(\Omega)} \leq \sqrt{C_{1,n}} \min_{v \in V_h(\Omega)} ||u^n - v||_{H^1(\Omega)}, \tag{3.19}
\]

where \( C_{1,n} \) and \( C_{2,n} \) are the continuity and coercivity constants for the transformed problem, see Lemma[1]. The factor \( \min_{v \in V_h(\Omega)} ||u^n - v||_{H^1(\Omega)} \) depends on the order of the polynomials used in constructing \( V_h(\Omega) \) as well as the properties of the triangulation \( T_h \). This term is well understood and here we focus on the effect on the error due to the transformation. Substituting the values of the constants \( C_{1,n} \) and \( C_{2,n} \) from the proof of Lemma[1] we have,

\[
||u^n - U^n||_{H^1(\Omega)} \leq \sqrt{a_{max} \gamma a_{min}} \max_d \left( \frac{\kappa_d \rho_d(\theta^n)}{\kappa_d \rho_d(\theta^n)} \right) \cdot \left( \min_d \left( \frac{\rho_d \rho_d(\theta^n)}{\rho_d \rho_d(\theta^n)} \right) \right)^{-1} \min_{v \in V_h(\Omega)} ||u^n - v||_{H^1(\Omega)}
\]

\[
= \sqrt{a_{max} \gamma a_{min}} \max_d \left( \frac{\kappa_d \rho_d(\theta^n)}{\rho_d \rho_d(\theta^n)} \right)^2 \min_{v \in V_h(\Omega)} ||u^n - v||_{H^1(\Omega)} \tag{3.20}
\]

If we assume that we have the same domain \( \Omega \) with partitions \( \Omega_d \) for the transformed domain, then the bound (3.20) indicates that the error is adversely affected by the shape of the random domain \( \Omega(\theta) \). In particular, sliver-like partitions, that is partitions which have a large \( \kappa_d(\theta)/\rho_d(\theta) \) ratio, reflect a boundary geometry that can have large impact on the accuracy of the finite element approximation.

3.6 Construction of the transformation and a numerical example

As indicated, there is a great deal of flexibility in the construction of the transformations to a reference domain. We choose transformations that are the identity except for a neighborhood of the boundary. We construct the sub-
domains $\Omega_d$ using a uniform partition of $\Omega$. The affine maps $\varphi_d^n$ are defined to be the identity for the subdomains which do not intersect with the boundary of the domain, that is, the subdomains $\Omega_d(\theta^n)$ and $\Omega_d$ coincide in this case. This effectively localizes the domain transformation to a neighborhood of the boundary. The maps $\varphi_d^n$ for the subdomains which intersect the boundary are specified by the the formula (3.1). Thus as the points on the boundary change, the subdomains $\Omega_d(\theta^n)$ which intersect with the boundary and the maps $\varphi_d^n$ change while the corresponding subdomains $\Omega_d$ remain fixed. We illustrate in Figure 3.

Figure 3: The random domains $\Omega(\theta^1)$ and $\Omega(\theta^2)$ and the reference domain $\Omega$ to which they are mapped. The transformations are the identity on the cells in the grey shaded region.

The random domain $\Omega(\theta^1)$ is sliver like and $\max_d \left( \frac{\kappa_d(\theta^1)}{\rho_d(\theta^1)} \right) = 32.3$. The random domain $\Omega(\theta^2)$ is more regular and $\max_d \left( \frac{\kappa_d(\theta^2)}{\rho_d(\theta^2)} \right) = 4.8$.

Reflecting boundary geometry, a transformation may have a strong effect on the difficulty in obtaining an accurate approximation. We illustrate by solving an elliptic problem with $a = 1$, $f(x, y) = 200x(1 - x) + 200y(1 - y)$ on the two random domains $\Omega(\theta^1)$ and $\Omega(\theta^2)$ shown in Figure 3. For the QoI, we choose $\psi = \chi_{10xy}$ in (2.2) where $\chi$ is the characteristic function of $[0.50, 0.75] \times [0.50, 0.75]$.

We compute numerical approximations for both $\theta^1$ and $\theta^2$ using the transformed problem formulation on $\Omega$ in Figure 3. The mesh for $\Omega$ has 681 vertices and was generated using Gmsh. The numerical solutions are computed using the standard space of piecewise linear continuous functions.

The plots of the transformed numerical solutions, $U^1$ and $U^2$, corresponding to $\theta^1$ and $\theta^2$ respectively are shown in Figure 4. The effects of sliver like subdomains present in $\Omega(\theta^1)$ are apparent in the plot of $U^1$ while the plot of $U^2$ exhibits a much smoother solution. The error in the QoI for $U^1$ is $8.6E - 3$ whereas the error in the QoI for $U^2$ is $7.4E - 3$. These errors are approximated by using more accurate reference values of the QoI computed using piecewise quadratic continuous elements on a refined mesh of the untransformed domain. The error in the QoI for $U^1$ is greater than the error in the QoI for $U^2$. The large error for $U^1$ is expected since the ratio $\max_d \left( \frac{\kappa_d(\theta^1)}{\rho_d(\theta^1)} \right)$ is quite large and hence the error is adversely affected in light of (3.20).
3.7 A posteriori analysis of the transformed problem

We derive an accurate, computable a posteriori error estimate for the QoI computed from a numerical solution. The estimate employs computable residuals and a generalized Green’s function satisfying an adjoint equation. The Green’s function quantifies the effects of stability in the accumulation, cancellation and propagation of the errors in the QoI. The strong form of the adjoint problem corresponding to the transformed problem (3.5) is,

\[
\begin{cases}
-\nabla \cdot (A_n(y; \theta^n) \nabla \eta_n(y; \theta^n)) = F_n(y; \theta^n), & y \in \Omega, \\
\eta_n(y; \theta^n) = \tilde{\psi}(y), & y \in \partial \Omega \cap \partial \Omega,
\end{cases}
\]

(3.21)

where \(\tilde{\psi}(y)\) is given as in (3.6).

**Theorem 1** (Error Representation for the Transformed Problem). Let \(e^n = u^n - U^n\). Then we have the error representation,

\[
Q(e^n; \theta^n) = \int_{\Omega} F_n \eta_n \, dy - \int_{\Omega} A_n \nabla U^n \cdot \nabla \eta^n \, dy.
\]

(3.22)

**Proof.** The proof is standard, e.g. see Section 8.1 in [15]. \(\square\)

3.7.1 Numerical Example for error estimate of the transformed problem

In the earlier numerical example in §3.6, the errors in the QoI corresponding to the solutions \(U^1\) and \(U^2\) were \(Q(e^1; \theta^1) = 8.6E - 3\) and \(Q(e^2; \theta^2) = 8.6E - 3\) respectively. We now estimate the error using the error estimate obtained from (3.22). The adjoint solution is computed using the standard space of piecewise quadratic continuous functions. The error estimate obtained for \(Q(e^1; \theta^1)\) is \(8.06E - 3\) while for \(Q(e^1; \theta^1)\) is \(7.2E - 3\). These have effectivity ratios of 0.93 and 0.97 and hence are quite accurate.
4 Lions Non-overlapping Domain Decomposition

Equation (3.18) yields a large coupled system of discrete equations for the finite element approximation. Following [16, 17], it is natural to solve the discrete equations using a non-overlapping domain decomposition iteration. In this case, the a posteriori error analysis must be extended to include the effects of the iterative solution of the accuracy of the approximation. For notational simplicity, we drop the superscript \( n \) indicating the sample number. In particular, (3.7) is rewritten as,

\[
\int_{\Omega} A(y; \theta) \nabla u \cdot \nabla v \, dy = \int_{\Omega} F(y; \theta) v_d \, dy,
\]

(4.1)

The non-overlapping domain decomposition solution is formed by employing the Lions domain decomposition algorithm [25]. The continuous Lions problem is to find an iterative solution \( u^{(i)}_d \), where the superscript \( (i) \) refers to the approximation at iteration \( i \). That is, given an set of initial guesses \( \{u^{(0)}_d, d = 1, \ldots, D\} \) for the \( D \) subdomains, we solve for \( i = 1, 2, \ldots \),

\[
\begin{cases}
-\nabla \cdot A_d \nabla u^{(i)}_d = F_d, & y \in \Omega_d, \\
\lambda u^{(i)}_d + n_d \cdot A_d \nabla u^{(i)}_d = \lambda u^{(i-1)}_d - n_d \cdot A_d(y) \nabla u^{(i-1)}_d, & y \in \partial \Omega_d \cap \partial \Omega_i, \\
u_d = 0, & y \in \partial \Omega_d \cap \partial \Omega_i,
\end{cases}
\]

(4.2)

where \( n_d = -n_{\tilde{d}} \) is the unit normal and \( \lambda \) is some constant. Lions proved that as \( i \to \infty \), \( u^{(i)}_d(y) \to u(y) \) [25].

The discrete analog of Lions domain decomposition involves finding a numerical solution for a finite number of iterations \( I \). We let the restriction of \( T^d_h \) on \( \Omega_d \) be \( T^d_h \) and define \( V^h(\Omega_d) \subset H^1(\Omega_d) \) as the set of continuous piecewise linear functions on \( T^d_h \). That is, given an set of initial guesses \( \{u^{(0)}_d, d = 1, \ldots, D\} \) for the \( D \) subdomains and fixed \( \lambda \geq 0 \), we solve for \( u^{(i)}_d \in V^h(\Omega_d), i = 1, 2, \ldots, I, \)

\[
(A_d \nabla U^{(i)}_d, \nabla v)_d + \sum_{d \neq d'} \lambda (U^{(i)}_d, v)_{d \cap d'} = (F_d, v)_d + \sum_{d \neq d'} \left( \lambda (U^{(i-1)}_d, v)_{d \cap d'} - (n_d \cdot A_d \nabla U^{(i-1)}_d, v)_{d \cap d'} \right)
\]

(4.3)

for all \( v \in V^h(\Omega_d) \) where,

\[
(f, g)_d = \int_{\Omega_d} f(y) g(y) \, dy \quad \text{and} \quad (f, g)_{d \cap d'} = \int_{\partial \Omega_d \cap \partial \Omega_d} f(y) g(y) \, dy.
\]

4.1 A posteriori analysis of Lions Domain Decomposition

We denote the numerical solution after \( i \) iterations as \( U^{(i)} \) so that \( U^{(i)}|_{\Omega_d} = U^{(i)}_d \). Then the computed value of the QoI at iteration is obtained from (3.6) as,

\[
Q(U^{(i)}) = \int_{\Omega} U^{(i)} \psi \, dy = \sum_{d=1}^{D} \int_{\Omega_d} U^{(i)}_d \psi \, dy = \sum_{d=1}^{D} (U^{(i)}_d, \psi)_d.
\]

(4.4)
**Theorem 2.** Let $s^{(i)} = u - U^{(i)}$. Then the error in the QoI at iteration $i$ of Lion’s domain decomposition algorithm is represented as,

$$Q(u - U^{(i)}) = DE^{(i)} + IE^{(i)} + CE^{(i)},$$

where $DE^{(i)}$, $IE^{(i)}$, $CE^{(i)}$ represent the discretization, iteration and transformation contributions to the total error and are given as,

$$DE^{(i)} = \sum_{d=1}^{D} \left[ (F, \eta)_d - (A_d \nabla U_d^{(i)}, \nabla \eta)_d + \sum_{d' \in d'} \left( -\lambda U_d^{(i)} + \lambda U_{d'}^{(i-1)} - n_{d'} \cdot A_{d'} \nabla U_{d'}^{(i-1)}, \eta_{d'} \right)_{d' \cap d} \right],$$

$$IE^{(i)} = \sum_{d=1}^{D} \sum_{d' \in d'} \left( (\lambda U_d^{(i)} - \lambda U_{d'}^{(i-1)}, \eta)_{d' \cap d} + (n_{d'} \cdot \nabla U_{d'}^{(i-1)} - n_d \cdot \nabla U_d^{(i)}, \eta)_{d' \cap d} \right),$$

$$CE^{(i)} = \frac{1}{2} \sum_{d=1}^{D} \sum_{d' \in d'} \left( n_d \cdot A_d \nabla U_d^{(i)} - n_{d'} \cdot A_{d'} \nabla U_{d'}^{(i)} - n_d \cdot \nabla U_d^{(i)} - U_{d'}^{(i)} \right)_{d' \cap d}.$$ 

**Proof.** Multiplying (3.21) by $e^{(i)}_d$ and integrating by parts on $\Omega_d$ yields,

$$(e^{(i)}, \psi)_d = (A_d \nabla e^{(i)}_d, \nabla \eta)_d - \sum_{d' \in d'} (n_{d'} \cdot A_{d'} \nabla \eta, e^{(i)}_d)_{d' \cap d}.$$ (4.6)

Summing (4.6) over all domains, and noting that since $u$ is the true solution, we have $\langle n_d \cdot A_d \nabla \eta, u \rangle_{d' \cap d} = -\langle n_{d'} \cdot A_{d'} \nabla \eta, u \rangle_{d' \cap d}$,

$$Q(e^{(i)}) = \sum_{d=1}^{D} \left[ (F, \eta)_d - (A_d \nabla U_d^{(i)}, \nabla \eta)_d + \sum_{d' \in d'} (n_d \cdot A_d \nabla \eta, U_d^{(i)})_{d' \cap d} \right].$$ (4.7)

where we also used (3.7). Now consider,

$$\sum_{d=1}^{D} \sum_{d' \in d'} (-\lambda U_d^{(i)} + \lambda U_{d'}^{(i-1)}, \eta)_{d' \cap d} = \sum_{d=1}^{D} \sum_{d' \in d'} (\lambda U_d^{(i)} - \lambda U_{d'}^{(i-1)}, \eta)_{d' \cap d}.$$ (4.8)

Also,

$$\sum_{d=1}^{D} \sum_{d' \in d'} (n_d \cdot A_d \nabla U_d^{(i-1)}, \eta)_{d' \cap d} - (n_d \cdot A_d \nabla U_d^{(i)}, \eta)_{d' \cap d} = \sum_{d=1}^{D} \sum_{d' \in d'} (n_d \cdot A_d \nabla U_d^{(i-1)}, \eta)_{d' \cap d} - (n_d \cdot A_d \nabla U_d^{(i)}, \eta)_{d' \cap d}.$$ (4.9)

$$= \sum_{d=1}^{D} \sum_{d' \in d'} (n_d \cdot A_d \nabla U_{d'}^{(i-1)}, \eta)_{d' \cap d} - (n_d \cdot A_d \nabla U_{d'}^{(i)}, \eta)_{d' \cap d} + \frac{1}{2} (n_d \cdot A_d \nabla U_{d'}^{(i)} + n_{d'} \cdot A_{d'} \nabla U_{d'}^{(i)}, \eta)_{d' \cap d},$$

$$= \sum_{d=1}^{D} \sum_{d' \in d'} (n_d \cdot A_d \nabla U_{d'}^{(i-1)}, \eta)_{d' \cap d} - \frac{1}{2} (n_d \cdot A_d \nabla U_{d'}^{(i)} + n_d \cdot A_d \nabla U_{d'}^{(i)}, \eta)_{d' \cap d},$$
where we used \( n_d = -\tilde{n}_d \) in the last step. Similarly,

\[
\sum_{d=1}^{D} \sum_{d' \in d'} (n_d \cdot A_d \nabla \eta, U_d^{(i)} \rho_d^{(i)}) = \frac{1}{2} \sum_{d=1}^{D} \sum_{d' \in d'} (n_d \cdot A_d \nabla \eta, U_d^{(i)} - U_d^{(i)} \tilde{n}_d) \rho_d^{(i)} \tag{4.10}
\]

Combining (4.8), (4.9), (4.10) with (4.7) and grouping terms proves the theorem. \( \square \)

### 4.1.1 Numerical Example of Lions Domain Decomposition

The setup is similar to 3.6 corresponding to the parameter \( \theta^1 \). Lions domain decomposition is carried out on the transformed problem on \( \Omega \). The parameter \( \lambda = 5.0 \) is used.

The results are shown in Table 4.1.1.

| \( i \) | Comp. Err | Eff. Rat. | \( DE^{(i)} \) | \( IE^{(i)} \) | \( CE^{(i)} \) |

5 A posteriori error analysis for Cumulative Distribution Function (CDF) computations

In this section, we construct a posteriori error estimates of the error in the computed distribution of a given QoI. The estimate takes into account stochastic sources of error arising from finite sampling and deterministic sources arising from discretization of the differential equation.

#### 5.1 Approximating the CDF

The solution \( u \) depends implicitly on a random vector \( \theta \) and hence the QoI, \( Q(u) \), is a random variable. We approximate the CDF,

\[
P(t) = P\{\theta : Q(u^\theta) \leq t}\}
\]

\( = P(Q \leq t), \)

\]
using a finite number of approximate sample values \( \{Q(U^n)\}_{n=1}^{N} \):

\[
P_N(t) = \frac{1}{N} \sum_{n=1}^{N} I(Q(U^n) \leq t),
\]

where \( I \) is the indicator function. The formal Monte Carlo solution algorithm is given in Algorithm 1.

**Algorithm 1: Formal Monte Carlo algorithm**

1. Draw samples \( \{\theta^n\}_{n=1}^{N} \) from the distribution of \( \theta \)
2. for \( n = 1, \cdots, N \) (number of samples) do
   1. Compute solutions \( \{U^n\} \) to produce samples \( \{Q(U^n)\} \)
3. Approximate the output distribution using a standard nonparametric technique, e.g. via binning

### 5.2 Motivating examples

In general, there is a balance between the error arising from finite sampling and discretization that should be struck for efficiency. The results are often surprising in the sense that despite the slow convergence of the Monte Carlo method, numerical discretization error is often the most significant source of error. We refer to [16, 17] for further discussion. For the case of uniform refinement, we define the normalized mesh parameter, \( \tilde{h} \) as the ratio: (\( h \) of given mesh / \( h \) of coarsest mesh). In the numerical examples \( \tilde{h} = 1.0 \) corresponds to a mesh with 249 vertices while \( \tilde{h} = 0.5 \) corresponds to a mesh of 945 vertices.

#### 5.2.1 Poisson Equation

We illustrate with an the Poisson equation from §3.6 with \( a = 1 \) and \( f(x, y) = 200x(1-x) + 200y(1-y) \). For the QoI, we choose \( \psi = \chi_{10xy} \) in (2.2) where \( \chi \) is the characteristic function of \([0.50, 0.75] \times [0.50, 0.75] \). The nominal reference domain is a unit square \([0, 1] \times [0, 1] \). The boundary points are perturbed according to a uniform distribution \([-0.08, 0.08] \times [-0.08, 0.08] \) centered around each boundary point. The random perturbations are graphically illustrated in Figure 5(a), where each boundary point is sampled uniformly in the square around each boundary point. Examples of two perturbed domains are shown in Figures 5(b) and 5(c).

Two mesh configurations are used, a coarse mesh with normalized mesh parameter \( \tilde{h} = 1.0 \) and a finer mesh with \( \tilde{h} = 0.5 \). The ranges of the 2-norm condition numbers of the linear systems arising from the finite element discretizations are \([70.65, 275.97] \) and \([318.378, 1466.17] \) corresponding to \( \tilde{h} = 1.0 \) and \( \tilde{h} = 0.5 \) respectively. To approximate the true error, we compute a reference distribution using a fine discretization with \( \tilde{h} = .25 \) and 10,000 samples. We plot the distributions obtained using fewer samples, \( N = 100 \) and \( N = 1000 \), and coarser meshes, \( \tilde{h} = 1 \) and \( \tilde{h} = 0.5 \) in Fig. 6.

These results demonstrate that the discretization and finite sampling can result in significant bias and variance in the estimated distributions. Variance can be reduced effectively by increasing \( N \), while reducing bias involves refining the mesh for the differential equation solve. The a posteriori error estimate provides a way to quantify the contributions of finite sampling and discretization to the error in the computed distribution.
Figure 5: (a) Random domains are obtained by perturbing the boundary points uniformly 0.08 in each direction as indicated by the squares around each point. (b) and (c) Two randomly perturbed domains.

5.2.2 Convection-Diffusion Equation

We consider the equation,

\[
\begin{cases}
-\nabla \cdot (a(x)\nabla w(x; \theta)) + b(x) \cdot \nabla w = f(x), & x \in \Omega(\theta), \\
w(x; \theta) = 0, & x \in \partial\Omega(\theta).
\end{cases}
\]

Here \(b\) is a convective vector field while rest of the variables have the same meaning as in (2.1). The transformed problem reads,

\[
\begin{cases}
-\nabla \cdot (A^\theta_n(y; \theta^n)\nabla u^\theta_n(y; \theta^n)) + \hat{b}^\theta_n(y; \theta^n) \cdot \nabla u^\theta_n(y; \theta^n) = F^\theta_n(y; \theta^n), & y \in \Omega, \\
u^\theta_n(y; \theta^n) = 0, & y \in \partial\Omega.
\end{cases}
\]

Here \(\hat{b}^\theta_n(y; \theta^n) = \hat{b}_d^\theta_n(y; \theta^n)\) for \(y \in \Omega_d\) defined by,

\[
\hat{b}_d^\theta_n(y; \theta^n) = |\det J_d^\theta_n|^{-1} J_d^\theta_n b(\varphi_d^n)^{-1}(y), \quad y \in \Omega_d
\]

while rest of the variables have similar definitions as in §3.3.

We choose \(b = [-80, 0]^T\) is the convection vector field. Other parameters are set as \(a = 1\), \(f(x, y) = 200\sin(2\pi x)\sin(2\pi y)\). For the QoI, we choose \(\psi = \chi 10xy\) in (2.2) where \(\chi\) is the characteristic function of \([0.50, 0.75] \times [0.50, 0.75]\). We plot the distributions obtained using \(N = 100\) and \(N = 1000\) samples, and \(\hat{h} = 1\) and \(\hat{h} = 0.5\) in Fig. 7. The ranges of the 2-norm condition numbers of the linear systems arising from the finite element discretizations are \([12.8628, 46.1225]\) and \([51.654, 224.635]\) corresponding to \(\hat{h} = 1.0\) and \(\hat{h} = 0.5\) respectively. The reference distribution is computed using 4000 samples and \(\hat{h} = 0.125\).

These results numerically demonstrate the claim that numerical error in CDF computations is dominated by discretization errors. Refining the spatial mesh once has a huge impact on reducing the error in the computed CDF, whereas increasing the samples has a relatively minor effect in computing a more accurate CDF.
Figure 6: The reference distribution (dashed line) plotted with several approximate empirical distributions. The normalized mesh parameters are $\tilde{h} = 1$ (left) and $\tilde{h} = 0.5$ (right). The number of samples are $N = 100$ (top) and $N = 1000$ (bottom).
Figure 7: The reference distribution (dashed line) plotted with several approximate empirical distributions. From left to right, distributions are computed using $\tilde{h} = 1$, $\tilde{h} = 0.5$, The number of samples are $N = 100$ (top) and $N = 1000$ (bottom).
5.3 A posteriori error analysis for a computed distribution function

We approximate \( P(t) \) by the approximate sample distribution function,

\[
\hat{P}_N(t) = \frac{1}{N} \sum_{n=1}^{N} 1_{(-\infty,t]}(Q(\tilde{U}^n; \theta^n)),
\]

where \( \{\tilde{U}^n\} \) are the solutions corresponding to samples \( \{\theta^n\}_{n=1}^{N} \) and \( 1_S \) denotes the indicator function for the set \( S \). For the purpose of error analysis, we introduce the "nominal" sample distribution using exact model solves by,

\[
P_N(t) = \frac{1}{N} \sum_{n=1}^{N} 1_{(-\infty,t]}(Q(u; \theta^n)),
\]

and decompose the error into contributions arising from finite sampling and discretization of the differential equation,

\[
P(t) - \hat{P}_N(t) = (P(t) - P_N(t)) + (P_N(t) - \hat{P}_N(t)).
\]

This decomposition is used to derive the following error bound

**Theorem 3** ([16] [17]). For \( 0 < \varepsilon < 1 \),

\[
|P(t) - \hat{P}_N(t)| \leq \left( \frac{\hat{P}_N(t)(1 - \hat{P}_N(t))}{N \varepsilon} \right)^{1/2} + \frac{2}{N} \sum_{n=1}^{N} 1_{[-|E^n|,|E^n|]}(t - Q(\tilde{U}^n; \theta^n)) + \frac{1}{2N \varepsilon},
\]

with probability greater than or equal to \( 1 - \varepsilon \), where \( E^n \) is an error estimate for the QoI computed from the sample numerical solution, i.e.,

\[
E^n \approx Q(u^n; \theta^n) - Q(\tilde{U}^n; \theta^n).
\]

The first term on the right of (5.3) is a standard bound on error arising from finite sampling. There is a discussion of such bounds in [16] [17] as well as computations illustrating its accuracy. The second term quantifies bias in the computed distribution arising from numerical error as "shifts" in the distribution function. Evaluating the second term requires a computational error estimate for each sample value.

5.4 Numerical experiments

5.4.1 Poisson Equation

We present a numerical experiment showing the behavior of the complete error estimate as the number of samples is increased and the finite element mesh is refined. Figure 8(a) shows the error bound and the actual error in the CDF for the example in §5.2.1 with \( \epsilon = 0.05 \). The error bound is around six times larger than the actual error. Figure 8(b) shows the stochastic and the discretization contributions. Increasing the number of samples or refining the mesh both decrease the error in the CDF as observed in Figure 9. The figure also indicates that adding more samples decreases the variance, making the CDF smoother, while refining the mesh primarily targets the discretization contribution.
Figure 8: (a) Actual error and bound for distribution computed using $\tilde{h} = 1$, $N = 100$. (b) The solid, dashed and dotted lines indicate the total error bound, the discretization contribution and the stochastic contributions.

Figure 9: Actual error and bound. From left to right, distributions are computed using $\tilde{h} = 1$, $N = 1000$ and $\tilde{h} = 0.5$, $N = 100$. 
5.4.2 Convection-Diffusion Equation

A similar experiment is performed for the convection-diffusion problem in §5.2.2. The weak form of the adjoint equation to (5.2) is

\[ \int_{\Omega} A^n \nabla \eta^n \cdot \nabla v + \hat{b}^n \cdot \nabla v \eta^n \, dy = \int_{\Omega} \psi, v \, dy, \quad \forall v \in H^1_0(\Omega) \]

The corresponding error representation (compare to (3.22)) is

\[ Q(e^n; \theta) = \int_{\Omega} F^n \eta^n \, dy - \int_{\Omega} A^n \nabla U^n \cdot \nabla \eta^n \, dy - \hat{b}^n \cdot \nabla U^n \eta^n. \tag{5.5} \]

Figure 10(a) shows the error bound and the actual error in the CDF. The error bound is around six times larger than the actual error. Figure 10(b) shows the stochastic and the discretization contributions.

6 Adaptive Mesh Refinement

We note that the use of a different triangulation \( T^n_\theta \) for each sample \( \theta^n \) is indicated in situations in which the solution behavior - and therefore numerical accuracy - depends on the shape of the domain \( \Omega(\theta^n) \). On the other hand, meshing is often a computationally demanding aspect of discretization, so there is incentive to employ one mesh for all samples. As an alternative to the use of a computationally inefficient heavily refined uniform mesh, we now describe an adaptive algorithm that attempts to optimize across samples.

A posteriori error estimates are well-suited to guide adaptive mesh refinement algorithms [18]. The general approach is iterative: Start with a coarse mesh, compute the solution, evaluate the estimate, use the estimate to select elements for refinement, refine the mesh, and then iterate.

Nominally, a straightforward adaptive algorithm based on the a posteriori error estimate would require computing a sequence of adaptive meshes for each sample computation. This would appear to be inefficient however.
We describe a “greedy” adaptive algorithm that seeks to find an adaptive mesh that works for all realizations at the cost of some loss of efficiency. The idea is to construct an adapted mesh for the first realization. We use the adapted mesh as the initial mesh for the computation of the second realization. The initial mesh is refined (but not coarsened) as necessary to control the error in the second sample. This repeats, where at each step the mesh is further refined and is described in Algorithm 2. In practice, we find that within 10-50 iterations, the algorithm constructs a mesh that works for all subsequent realizations.

Algorithm 2: Constructing a universal finite element mesh

Start with an initial (uniform) mesh $T_h^0$

for $n = 1, \ldots, M$ (loop through the set of $M$ test problems) do

- $T_h^n = T_h^{n-1}$
- Compute solution $U^n$ and error estimate $E^n$

while $|E^n| > TOL$ do

- Refine the mesh, i.e., $T_h^n = \text{refine}(T_h^n)$
- Compute solution $U^n$ and error estimate $E^n$

end

end

Algorithm 2 is demonstrated for the problem in §5.4.2. The per element error indicator $E_K$ measures the error on element $K$ and is defined as

$$E_K = \left| \int_K F^n \eta^n - A^n \nabla U^n \cdot \nabla \eta^n \, dy - \hat{b}^n \cdot \nabla U^n \eta^n \right|. \quad (6.1)$$

The Dörfler strategy is used for marking elements with large elemental error indicators [13]. If the QoI error at a parameter value is above a specified tolerance, which is taken to be 0.0004 for this example, then the mesh is adapted for that parameter till the error falls below the tolerance, TOL. The mesh is only refined for four parameter values, and after iteration 28, there is no further refinement for the remaining 972 iterations as shown in Figure 11. The refinement pattern indicates that the mesh is refined around the region $[0.50, 0.75] \times [0.50, 0.75]$ where the support of the QoI function $\psi$ lies and to the right of this region. The mesh is not refined around all the boundary nodes even though they are all perturbed. This is because the error indicator (6.1) describes the sensitivity of the QoI to different parts of the domain and for this example the refined region contributes the most to the error. The results may be explained heuristically by noting that the direction of the vector field $b$ is from right to left, and hence the QoI is affected the most from the region to its right.

The CDF computed using the adaptive algorithm with 1000 samples is plotted in Figure 12(a). This CDF compares well with the CDF computed a twice uniformly refined mesh corresponding to $\hat{h} = 0.25$ with 4000 samples (labeled “Actual” in the plot). The adaptive algorithm is carried out on a mesh of 992 vertices (after 41 iterations) compared to 945 vertices for the mesh corresponding to $\hat{h} = 0.5$. Although the number of vertices in the meshes are similar, and hence the computational effort is similar, the CDF computed using the adaptive method is significantly more accurate. The dramatic increase in the accuracy of the CDF is explained by observing the error contributions in Figure 12. Now the discretization contribution is significantly than the CDF computed with no refinement, e.g. see Figure 10(b).

7 Summary

We study elliptic partial differential equation boundary value problems for which the domain where the equations are posed is uncertain. In order to model this uncertainty, we formulate a class of problems that are posed
Figure 11: In panel (a) The number of vertices in the finite element mesh is plotted against parameter number. Panels (b) and (c) show the initial mesh and the final refined mesh respectively.

Figure 12: (a) CDF computed using adaptive refinement with 1000 samples (solid line) against the CDF computed using $\tilde{h} = 1, N = 1000$, $\tilde{h} = 0.5, N = 1000$ and “Actual” CDF computed thrice uniformly refined mesh ($\tilde{h} = 0.125$) and 4000 samples. (b) Error bound and contributions.
on stochastic domains. Of particular interest is the nonparametric density estimation problem for a quantity of interest. We introduce a piecewise transformation of the domain to a deterministic reference domain and exploit for efficiency the transformation in a Monte Carlo sampling procedure so that many samples can be obtained to approximate the distribution at a reasonable cost. We present an a posteriori error analysis for each sample and for the empirical distribution function obtained from the samples, which reflect the various deterministic and statistical sources of error. The estimate is sufficiently detailed that we can efficiently balance computational work, e.g. mesh resolution versus sample numbers, to achieve a desired accuracy. An interesting issues that arises in the context of numerical solution is that each realization of a domain nominally requires construction of a new discretization mesh, at a significant computational cost. We address computational efficiency by describing an adaptive strategy that leads to a mesh that produces acceptable accuracy for all realizations of the problem and describing an iterative solution algorithm in which the number of matrix inversions is independent of the number of samples.
