Nurse management of ischemic thoracic pain in hospital emergency services

Abstract

Chest pain is sometimes the reflection of mild pathologies, but in others, it is the expression of extremely serious clinical situations. This symptom has defining characteristics that help diagnose it, but performing this work in the emergency services is part of a very common challenge faced by healthcare professionals, this is because the etiology of chest pain is very diverse. For this reason, it becomes a great burden on healthcare.1

CP is defined as “a localized high sensation in the area between the diaphragm and the supraclavicular fossa”.2 Consultations for CP are very frequent, in Spain, it is estimated that between 5% and 10% of HUS consultations are for non-traumatic DT.2

Table 1 Characteristics of ischemic DT

| Location | Chest center, retrosternal. It can be seen in another area from the epigastrium to the neck, interscapular area, jaw, shoulders, arms, wrists and fingers. It is perceived as oppressive, strong, constrictive, or fiery. |
|----------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Associated Symptomatology | Vegetative courtship, fatigue, heartburn, dyspnea, diaphoresis, peripheral vasoconstriction. |
| Dt Pattern | Fixed, without variation on palpation. It is not modified when changing posture. Sudden onset and variable intensity. |
| Precipitating Factors | Stress, physical and mental, cold or any situation that requires an increase in oxygen consumption by the heart. |
| Duration | Typical angina: less than 15 minutes and begins with exercise or stressful situations. Atypical angina: 20 minutes, perceived as a stabbing discomfort. Acute myocardial infarction (AMI/IAM); greater than 30 minutes and more intense. |

Before the arrival of a patient with DT, to the emergency department, two clinical situations can be observed:

- Patient with DT and hemodynamic changes: pain accompanied by changes in BP, dyspnea, arrhythmias, decreased level of consciousness or shock.
- Patient with DT without hemodynamic changes: the pain is not accompanied by cardiac changes or in the BP figures, nor by vegetative symptoms.

Assessing the patient’s hemodynamics provides important data that helps detect and differentiate those causes that can cause a risk to the patient’s life. For this reason, DT is classified according to its origin.3

The correct diagnosis and treatment of DT is a great difficulty in healthcare, since 2-10% of patients who go to HEDs for this reason are discharged with a wrong diagnosis, the consequence of this failure increases mortality rate.9

Characteristics of chest pain of ischemic origin

The clinical pattern of DT of ischemic origin includes two clinical situations; angina and AMI, and has the following characteristics (Table 1).

Introduction

Chest pain (CP) is sometimes the reflection of mild pathologies, but in others, it is the expression of extremely serious clinical situations. The general objective is to evaluate the scientific evidence on interventions and treatment in patients with ischemic chest pain in the emergency services. The bibliographic search was carried out in the period of time between November 2019 and May 2020, finally a total of 24 articles were selected. The results show that DT caused by SCA can be treated pharmacologically with the new P2Y12 inhibitors, although it is not recommended that the treatment be exclusively pharmacological. The optimal time to initiate other treatment strategies such as coronaryography and coronary intervention is 12 to 24 hours.

Keywords: chest pain, acute coronary syndrome, nursing care, ischemic heart disease, unstable angina pectoris

Introduction

DT is the main clinical manifestation of Acute Coronary Syndrome (ACS). However, the presence of DT is not as frequent in the older adult. According to the North American National Registry of Myocardial Infarction, chest pain occurs in 77% of patients younger than 65 years, while in the population between 65 and 75 years it occurs in 50% of cases, and it only occurs in 40% of adults over 85 years of age.4

With the aim of improving the quality of healthcare in these patients, in recent years, the creation of chest pain units (UDT) has been launched to centralize healthcare.4

Characteristics of chest pain of ischemic origin

The clinical pattern of DT of ischemic origin includes two clinical situations; angina and AMI, and has the following characteristics (Table 1).

Table 1 Characteristics of ischemic DT

| Location | Chest center, retrosternal. It can be seen in another area from the epigastrium to the neck, interscapular area, jaw, shoulders, arms, wrists and fingers. It is perceived as oppressive, strong, constrictive, or fiery. |
|----------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Associated Symptomatology | Vegetative courtship, fatigue, heartburn, dyspnea, diaphoresis, peripheral vasoconstriction. |
| Dt Pattern | Fixed, without variation on palpation. It is not modified when changing posture. Sudden onset and variable intensity. |
| Precipitating Factors | Stress, physical and mental, cold or any situation that requires an increase in oxygen consumption by the heart. |
| Duration | Typical angina: less than 15 minutes and begins with exercise or stressful situations. Atypical angina: 20 minutes, perceived as a stabbing discomfort. Acute myocardial infarction (AMI/IAM); greater than 30 minutes and more intense. |

Before the arrival of a patient with DT, to the emergency department, two clinical situations can be observed:

- Patient with DT and hemodynamic changes: pain accompanied by changes in BP, dyspnea, arrhythmias, decreased level of consciousness or shock.
- Patient with DT without hemodynamic changes: the pain is not accompanied by cardiac changes or in the BP figures, nor by vegetative symptoms.

Assessing the patient’s hemodynamics provides important data that helps detect and differentiate those causes that can cause a risk to the patient’s life. For this reason, DT is classified according to its origin.5

The correct diagnosis and treatment of DT is a great difficulty in healthcare, since 2-10% of patients who go to HEDs for this reason are discharged with a wrong diagnosis, the consequence of this failure increases mortality rate.9

Chest pain assessment

It is essential to collect information on the following aspects (Table 2):7
Nurse management of ischemic thoracic pain in hospital emergency services

Table 2 Clinical examination of the patient with DT

| Personal history                              | Determine the characteristics of pain |
|------------------------------------------------|--------------------------------------|
| Age, sex.                                      | Start                                |
| Presence of CVRF                               | Duration                             |
| History of cardiovascular pathology.           | Location                             |
| Family history of premature coronary heart disease. | Triggers                           |
| History of infection.                          | Factors that relieve pain.           |
| History of immobilization, if so,              | Symptomatology associated with DT.   |

Cardiovascular risk factors (CVRF)

Cardiovascular diseases (CVD) are the main cause of premature death and disability worldwide, specifically in developed countries, causing high costs in the healthcare system.

In 2016, in Spain, diseases of the circulatory system were the leading cause of death, especially ischemic heart disease was responsible for the majority of deaths.

The etiology of CVD depends on multiple factors, including cardiovascular risk factors (CVRF). CVRFs can be classified into three groups; causal, predisposing and conditioning.

The main most prevalent CVRFs are:

- Diabetes.
- Dyslipidemia.
- HTA.
- Obesity.
- Smoking.
- Alcoholism.

Acute coronary syndrome (ACS)

Acute Coronary Syndrome constitutes a set of ischemic states of the heart. It is classified into 3 groups using the ST segment elevation or not, visible on the ECG.

Cardiomyocyte necrosis is called Acute Myocardial Infarction (AMI) in a clinical setting compatible with acute myocardial ischemia.

During recent years, the incidence of AMI in Castilla-La Mancha is 130 cases per 100,000 inhabitants, and in this autonomous community, AMI is the leading cause of death in women and the second in men.

To make the correct diagnosis of ACS, a first evaluation of the patient with DT must be carried out, which includes the following sections:

- The clinical manifestations of myocardial ischemia include:
  - DT.
  - Dyspnoea.
  - Pain in upper limbs, discomfort in the jaw or in the epigastrium.
  - Diaphoresis, syncope or fatigue.

The clinical history of the patient with suspected ACS is important for the correct diagnosis and treatment. For this reason, the history of coronary heart disease, sex, age, and presence of CVRF associated with ACS should be evaluated.

Elevated levels of cardiac troponin (I or T), or creatinine kinase MB fraction (CKMB), indicate that there is necrosis in myocardial cells. Necrosis of the heart muscle begins to develop 15-30 minutes after complete occlusion of the artery.

Troponin I or T is the cardiac biomarker par excellence due to its sensitivity and specificity indicative of myocardial necrosis. They appear altered in blood between 1-3 hours after the onset of symptoms, and reach their maximum values at 12-48 hours, remaining elevated after 7-10 days.

CKMB is used when other types of biomarkers are not available. It is not recommended to use it for routine diagnosis, since this value rises after 4-8 hours after AMI, and normalizes two or three days later.

The result of the figures for these biomarkers cannot be used as a single result to determine the diagnosis of AMI.

The 12-lead electrocardiogram is the first test that must be performed on every patient who comes to the ED for DT for the first 10 minutes. ECG values and interpretation lead to four possible diagnoses: SCAостей, SCASEST, confusing ECG, normal or nonspecific ECG.

Nitroglycerin is a vasodilator drug, so it is only administered in patients with DT of ischemic origin. Administration is indicated when the patient has a TAS < 90 mmHg or TAD < 100 mmHg, respectively. However, it should not be used if the HR is < 50 bpm or > 100 bpm. Its administration should be discontinued when symptoms have subsided.

Start with an ASA dose of 150-300 mg. If there are any contraindications to administering ASA, Clopidogrel is used as an alternative.

The second antiplatelet drug must be a P2Y12 inhibitor, since they have greater potency and better results, making them the drugs of first choice. If there are any contraindications to the administration of these, Clopidogrel is used instead.

Coronary reperfusion therapy is the basis for the treatment of ACS, specifically for SCAостей, since it is a time-dependent disease whose prognosis largely depends on initial management. Coronary reperfusion includes two strategies: pharmacological thrombolysis and percutaneous coronary intervention.

Risk prediction scales

The Global Registry of Acute Coronary Events (GRACE) scale was developed to predict the prognosis and CVRF associated with patients after ACS, and also assesses the prognosis of death one month and 6 months after discharge from hospital. Another TIMI (Trombolysis in Myocardial Infarction) scoring system developed with the aim of predicting 30-day and one-year mortality after SCAостей. In addition, this scale presents the ability to make a global estimate of the risk presented by this type of patient.

The Heart Score scale was developed to make decisions about those patients who come to the ED with related symptoms or symptoms, with ischemic heart disease. This scale identifies patients with a low risk of major cardiac events. For this reason, it allows evaluating these patients without the need for explorations or tests that do not really require.

Material and methods

The elaboration of this work was carried out through a bibliographic search in scientific databases between the month of November 2019 and May 2020, in order to carry out a narrative review of the literature.

Citation: Álvaro AP. Nurse management of ischemic thoracic pain in hospital emergency services. MOJ Gerontol Ger. 2021;6(2):38-44. DOI: 10.15406/mojgg.2021.06.00265
For the selection of the scientific articles on which this narrative review is based, the following criteria have been carried out:

Inclusion criteria:
- Year of publication: from 2015 (inclusive), until May 2020.
- Free access.
- Text complete.
- Languages: Spanish and English.
- Publications in scientific databases.

Exclusion criteria:
- Articles published prior to 2015.
- Items whose access was by payment.
- Those articles that only the introduction was visible.
- Articles that are not published in scientific databases.
- Articles written in languages other than Spanish and English.

The studies will be identified by means of computerized searches in bibliographic databases and in reference lists of articles. The selected sources of information were in the language of English, French and Spanish. The following databases were used: Pubmed (2014-2019), Scopus (2014-2019), Wos (2014-2019), Google Scholar (2014-2019). The first search was carried out on November 12, 2019 and ended on May 10, 2020. In addition to searching databases, the list of article references was verified, and the information obtained through the analysis of trial registries, protocols and institutional websites.

In November 2019, the electronic bibliographic databases of Pubmed, Scopus, Wos, Google Scholar were consulted to locate articles published from 2015 inclusive to 2020. The language of the studies was limited to English / French / Spanish. Keywords such as “chest pain”, “acute coronary syndrome”, “nursing care”, “ischemic heart disease”, “unstable angina pectoris” were used in the search strategy. Reference lists of included studies were checked to select the most complete ones.

Finally, for this review, a total of 24 articles have been selected. Of all of them, 1 has been published in a journal with level of evidence Q1 and 11 of level of evidence Q2. The rest of the articles have been published in different magazines that do not appear on the Web of Scivencie (WOS), so they do not have a Journal Citation Reports (JCR).

To carry out the selection of these studies, a first bibliographic search was carried out, from which 210 articles were obtained. After applying the inclusion and exclusion criteria, as well as eliminating duplicate and irrelevant articles both by their abstract and by their title, 24 articles were selected for this review.

### Results

Below is a Table 3 that shows the search strategy used to select the articles:

| Table 3 Databases consulted |
|-----------------------------|
| **PubMed/MEDLINE** | **Elsevier/EMBASE** | **Science** | **Dialnet** | **Google Académico** | **Total** |
| Selected | 55 | 54 | 23 | 35 | 43 | 210 |
| Duplicates | 5 | 4 | 2 | 5 | 3 | 19 |
| Payment Access | 10 | 21 | 7 | 5 | 6 | 49 |
| Title Only | 20 | 18 | 4 | 9 | 13 | 64 |
| Summary Only | 11 | 7 | 5 | 8 | 13 | 44 |
| Text Complete | 2 | 1 | 2 | 1 | 4 | 10 |
| Valid | 7 | 3 | 3 | 7 | 4 | 24 |

To carry out the narrative review, 24 articles were used to assess the management of ischemic chest pain in hospital emergency services.

### Discussion

In relation to the risk prediction scales, the most studied are GRACE, TIMI and HEART. Being TIMI and GRACE the most used worldwide for risk assessment, they are also a very useful tool to identify risk situations.30-32

According to the authors Pérez Corral A.M et al, the most widely used scale in HEDs that serve a large number of people is TIMI. It is also used in predicting the risk of death in patients who have undergone STEMI.33,34

The GRACE scale uses the prediction of hospital death after an AMI. The authors Santos Medina M. et al confirm the validity of this scale in their study, which shows that hospital mortality was 51.8% in patients who were at high risk on this scale. However, it is not useful to rule out an SCA.24

GRACE is better able to predict events at one month, while TIMI is better able to predict events at six months. In contrast, these two scales are not useful for diagnosing ACS in patients with an ECG and negative Troponins, despite their high risk.30,32

The HEART scale has greater discriminatory capacity when used in undifferentiated DT, according to the authors Pérez Corral A.M et al. It is more useful for the prognosis of cardiovascular events, compared to the two previous scales.26,27

Patients who come to the HED for DT and who also have a low risk according to the HEART scale, have little probability of developing coronary events in the following 30 days, so they can be discharged from the HUS, this information is supported by the authors Chan AM et al in their study.34,35

With regard to the characteristics of DT, it manifests itself most sharply, and less oppressively. The evolution is over 12 hours and is not usually accompanied by vegetative symptoms. However, in elderly people, ACS manifests itself through atypical DT associated
with the presence of fatigue, dizziness and dyspnea, in addition, the latter increases the probability of suffering an ACS.3,10,37

According to the authors, Domínguez Rodríguez A et al affirm that the physician, sometimes, does not pay attention to 9 important variables that are obtained in the initial evaluation of the patient, since these can lead to the diagnosis of ACS, and are the following: DT of oppressive, retrosternal, epigastric character, irradiated to the shoulders, the precipitating factor of which is a situation of exertion, pain associated with vegetative symptoms and the presence of dyspnea, the duration is between 5-20 minutes of repetition during the last 24 hours.37

In relation to diagnostic tests for DT in HEDs, clinical guidelines recommend performing an ECG, determination of highly sensitive troponins, and cardiovascular risk stratification. ECG and troponins continue to be the two priority tests in patients with DT. Troponin elevation is used as an element in the classification of patients at high risk. There are two other elements that provide important data such as the patient’s medical history and physical examination. There is a clear relationship between the data obtained in the patient’s interview and the objective changes in the ECG with the final and initial diagnosis of ACS.35,38–40

The ECG in the elderly patient usually provides nonspecific data, it is common to observe ST segment elevation and left bundle branch block, for this reason, it is advisable to compare the new ECG with old ones if they are available.36

The presence or not of DT together with the elevation of the troponins has various diagnostic implications; according to the authors González del Hoyo M. et al the absence of DT together with the elevation of troponins is more frequent in elderly patients, this in turn, is related to a decrease in the performance of complementary tests, an increase in mortality, worse prognosis and less diagnosis of ACS. The diagnosis of ACS is more frequent in those patients who do present DT with troponin elevation.40,41

The study carried out by Alfonso F. et al states that the determination of troponins together with the performance of a computed tomography jointly form a more accurate and faster diagnostic strategy for ACS.42

The ACEP recommends using 3 diagnostic elements in those patients who are at risk of suffering major cardiovascular events: determination of the HEART, TIMI scales and troponin seriation, to avoid subjecting patients at low risk to the ischemia provocation test.39

After the evaluation of a heart attack code in the study by Cordero A et al, it was concluded that the hospital stay was shorter after the implantation of said code, with no variation in the mortality rate. The treatment of choice was angioplasty.19

In relation to the treatment of SCASEST, the authors Bueno H et al affirm that mortality is higher in patients with exclusively pharmacological treatment, associated with older patients. With respect to the drugs used in the treatment of ACS, P2Y12 inhibitors have lower scores on the GRACE and CRUSADE scales, but they are less used if the risk of bleeding or ischemia is high on these scales, which is why a increased use of these drugs when there is less risk. Advanced age is the only factor on the GRACE scale that is associated with decreased use of these drugs. These drugs reduce mortality and thrombotic events without increasing bleeding as Clopidogrel does.27,37,43,44

Regarding the optimal time to start coronary revascularization therapy is between 12-24 hours, since greater complications are observed in those patients in whom treatment is started late. The performance of the treatment in this period of time is related to an increase in survival.45,46–54

Conclusion

Chest pain caused by ACS can be treated pharmacologically with the new P2Y12 inhibitors, as they have been shown to reduce mortality and thrombotic events. It is not recommended that the treatment be exclusively pharmacological since mortality is higher. The appropriate time to start other treatment strategies such as coronography and coronary intervention is 12-24 hours. The guidelines recommend the performance of the ECG, together with the determination of troponins and the stratification of the CVR, without forgetting to pay attention to the patient’s medical history and physical examination. In relation to the characteristics of the pain that is caused by ACS, it presents stabbingly, the evolution is longer than 12 hours and is not normally accompanied by vegetative symptoms, however, in elderly patients, DT is atypical and it is associated with fatigue, dizziness, and dyspnea. The TIMI and GRACE scales are the most widely used globally for risk assessment. The best scale that can be used in those HEDs that serve a high volume of patients is TIMI, in addition, this scale better predicts events at 6 months, and GRACE does it at one month. The HEART scale has greater discriminatory power in a patient with undifferentiated type DT.
