ABSTRACT

We present a multi-wavelength analysis of 11 Sunyaev–Zel’dovich effect (SZE)-selected galaxy clusters (10 with new data) from the Atacama Cosmology Telescope (ACT) southern survey. We have obtained new imaging from the Large APEX Bolometer Camera (345 GHz; LABOCA) on the Atacama Pathfinder EXperiment (APEX) telescope, the Australia Telescope Compact Array (2.1 GHz; ATCA), and the Spectral and Photometric Imaging Receiver (250, 350, and 500 μm; SPIRE) on the Herschel Space Observatory. Spatially resolved 345 GHz SZE increments with integrated signal-to-noise ratio (S/N) > 5 are found in six clusters. We compute 2.1 GHz number counts as a function of cluster-centric radius and find significant enhancements in the counts of bright sources at projected radii \( \theta < \theta_{2500k} \). By extrapolating in frequency, we predict that the combined signals from 2.1 GHz-selected radio sources and 345 GHz-selected submillimeter galaxies (SMGs) contaminate the 148 GHz SZE decrement signal by \( \sim 5\% \) and the 345 GHz SZE increment by \( \sim 18\% \). After removing radio source and SMG emission from the SZE signals, we use ACT, LABOCA, and (in some cases) new Herschel SPIRE imaging to place constraints on the clusters’ peculiar velocities. The sample’s average peculiar velocity relative to the cosmic microwave background is \( \langle v_p \rangle = 153 \pm 383 \text{ km s}^{-1} \).

Key words: galaxies: clusters: general – cosmology: observations – submillimeter: galaxies – submillimeter: general

1. INTRODUCTION

Galaxy clusters produce a spectral distortion in the cosmic microwave background (CMB) known as the Sunyaev–Zel’dovich effect (SZE; Zel’dovich & Sunyaev 1969; Sunyaev & Zel’dovich 1970a). The thermal Sunyaev–Zel’dovich effect (tSZ) signal is quantified by \( Y_{\text{SZ}} \equiv \int y \, d\Omega \) in terms of the Compton parameter

\[
y = \int \sigma_T n_e k_B T_e \frac{d\Omega}{m_e c^2} dl,
\]

the Thomson cross section \( \sigma_T \), Boltzmann’s constant \( k_B \), the electron density \( n_e \), the electron temperature \( T_e \), and the line of sight (LOS) path length \( dl \). The Compton parameter is insensitive to cluster redshift, allowing for the unbiased detection of massive clusters out to large distances. This selection is complementary to that of surveys using optical richness or X-ray flux, which generally yield lower-redshift

24 Herschel is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA.
cluster samples (for a review of the SZE in clusters, see, e.g., Carlstrom et al. 2002). The mass function of SZE-selected galaxy clusters has been used to constrain the properties of dark energy, as well as the mean matter density $\Omega_m$ and amplitude of fluctuations $\sigma_8$ (e.g., Sehgal et al. 2011; Benson et al. 2013; Hasselfield et al. 2013b; Planck Collaboration et al. 2014b).

The number of known SZE-selected clusters is rising rapidly. The first surveys produced samples of $\sim 20$ blind SZE-detected clusters (Menanteau et al. 2010; Vanderlinde et al. 2010; Marriage et al. 2011). A sample of 68 SZE-selected clusters from the equatorial footprint of the Atacama Cosmology Telescope (ACT) survey has recently been presented by Menanteau et al. (2013) and Hasselfield et al. (2013b); 158 were detected in the first 720 deg$^2$ of the South Pole Telescope (SPT) SZ survey (Reichardt et al. 2013); 677 were detected in the full 2500 deg$^2$ SPT–SZ survey (Bleem et al. 2014); and $\sim 1200$ more all-sky SZE cluster candidates have been catalogued by the Planck Collaboration et al. (2014c). Yet with samples ranging from 9 (Sehgal et al. 2011) to 18 (Vanderlinde et al. 2010; Benson et al. 2013) clusters, the first analyses found that the statistical errors on $w$ and $\sigma_8$ are already smaller than systematic errors due to uncertainties in the $Y_{SZ}$-to-mass scaling relation. Hasselfield et al. (2013b) confirm this limitation by finding that the improvements in cosmological parameters from their sample of 68 SZE-selected clusters are mainly due to the inclusion of dynamical mass information, not to an increased sample size. Therefore, to further improve constraints from SZE-cluster cosmology using these larger samples, we need a better understanding of the scaling between integrated SZE signal and cluster mass in individual systems. For example, Sifón et al. (2013) have measured the dynamical masses of 16 massive SZE-selected clusters (nine of which are in our sample) and found that disturbed or merging systems could be biasing the derived $Y_{SZ}$-to-mass scaling relations.

A number of physical processes are known to cause deviations from equilibrium scaling relations. Cluster mergers are predicted to cause departures from hydrostatic equilibrium, and can produce transient pressure enhancements that boost the SZE signal (e.g., Poole et al. 2006, 2007; Wik et al. 2008). Such pressure enhancements are invisible in X-ray observations of the massive cluster RXJ1347-1145, for example, but have been revealed through high-resolution SZE-imaging to contribute $\lesssim 10\%$ of the bulk signal (Komatsu et al. 2001; Kitayama et al. 2004; Mason et al. 2010). Kinetic Sunyaev–Zel’dovich (kSZ) signals due to clusters’ peculiar velocities can also introduce additional scatter to $Y_{SZ}$ measurements. Hand et al. (2012) recently achieved a statistical detection of the pairwise kSZ signal from an ACT sample, but the peculiar velocity distribution of clusters remains unconstrained. Mroczkowski et al. (2012) find some evidence for large kSZ distortions in the triple merger system MACS J0717.5+3745, perhaps indicating that high-velocity substructures in merging clusters introduce additional deviations to $Y_{SZ}$. Ruan et al. (2013) predict these deviations could bias $Y_{SZ}$ results by $\lesssim 10\%$. The emission from bright galaxies near the clusters (in projection) can further bias the SZE signal. Synchrotron emission from star-forming galaxies and active galactic nuclei may “fill in” SZE decrements. Reese et al. (2012) estimate contamination from synchrotron sources to be $\lesssim 20\%$ in the 90 GHz SZE decrement based on high-resolution imaging of two ACT clusters, and Sayers et al. (2013) estimate that radio sources contaminate the 140 GHz SZE decrement by $\sim 1$–$20\%$. SZE increments, on the other hand, can be artificially enhanced by the strong infrared emission from dusty, high-redshift star-forming submillimeter galaxies (SMGs; for a review, see Blain et al. 2002). Gravitational lensing by the clusters’ potentials may increase contamination by lensed SMGs (e.g., Knudsen et al. 2008; Jain & Lima 2011; Johansson et al. 2011) or introduce deficits in surface brightness at the location of the cluster (Zencov et al. 2013), and disturbed or merging systems may be more susceptible to lensing effects due to their greater lensing efficiency (e.g., Meneghetti et al. 2007; Zitrin et al. 2013b). Benson et al. (2003) conclude that direct measurements of cluster peculiar velocities in maps with angular resolution $\gtrsim 1$ arcmin will be limited by SMG contamination.

The number counts of the most massive clusters have the potential to constrain cosmological parameters. Unfortunately, these systems also tend to be most affected by the effects described above. Massive systems will produce the greatest gravitational lensing shear, and in our hierarchical universe, they are also commonly disrupted by recent merging activity. In this work, we aim to better understand how these considerations affect the observed SZE signals using high-resolution submillimeter and radio imaging of a representative sample of SZE-selected clusters. We present new observations at 345 GHz (19″ resolution) with the Large APEX Bolometer Camera (LABOCA; Siringo et al. 2009) on the Atacama Pathfinder EXperiment (APEX; Güsten et al. 2006) telescope and at 2.1 GHz (5″ resolution) with the Australia Telescope Compact Array (ATCA) of a sample of massive SZE-selected galaxy clusters. We call the project “LASCAR,” the LABOCA/ACT Survey of Clusters at All Redshifts, in honor of the Lascar volcano near the ACT site in northern Chile. We use these data to measure the properties of the clusters’ spatially resolved SZE increment signals, and quantify the degree of background and foreground radio and infrared galaxy contamination. Section 2 describes our cluster sample. Section 3 presents observations and data reduction techniques. Section 4 assesses the SZE contamination by point sources. Section 5 uses the point-source subtracted multi-wavelength SZE maps to place constraints on cluster peculiar velocities. In Section 6 we discuss our results in the context of previous work, and in Section 7, we conclude. In our calculations, we assume a flat $\Lambda$CDM cosmology with $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_M = 0.27$, and $\Omega_\Lambda = 0.73$ (Komatsu et al. 2011).

2. CLUSTER SAMPLE

Our sample consists of eleven clusters with 148 GHz decrement signal-to-noise ratio ($S/N$) $> 4.7$ from the ACT (Fowler et al. 2007; Swetz et al. 2011) southern survey (Menanteau et al. 2010; Marriage et al. 2011). Our sample is selected from the 15 highest S/N ACT southern clusters, and includes 9 of 10 clusters not known before ACT or SPT; it only excludes one cluster with $z < 0.15$ and three clusters that had been previously mapped with AzTEC (D. Hughes 2015, private communication). The properties are listed in Table 1. The systems span a large redshift range, $z = 0.3$–$1.1$, and have masses $M_{\text{500c}} \gtrsim 3 \times 10^{14} M_\odot$ (Menanteau et al. 2010; Sifón et al. 2010; 2011).

25 This publication is based on data acquired with the Atacama Pathfinder EXperiment (APEX). APEX is a collaboration between the Max-Planck-Institut für Radioastronomie, the European Southern Observatory, and the Onsala Space Observatory.
et al. 2013), where \( M_{500c} = 500(4\pi/3)\rho_{500c}^3 \) and \( r_{500c} \) is the radius enclosing a mass density equal to 500 \( \rho_c \), the critical density of the universe at the redshift of the cluster. We define the angular radius \( \theta_{500c} = r_{500c}/D_A \) and use the typical scaling relation \( M_{500c} \sim 1.6 M_{500c} \) (Duffy et al. 2008) to convert from the dynamical masses of Sifón et al. (2013). Each SZE detection has been confirmed to be a rich optical cluster through follow-up imaging by Menanteau et al. (2010). Included in the sample are the notable cluster mergers ACT J0102-4915, also known as “El Gordo” (Menanteau et al. 2012), and 1E0657-56 (ACT J0658-5557), the original “Bullet” cluster (Markevitch et al. 2002).

### 3. OBSERVATIONS AND DATA REDUCTION

#### 3.1. 345 GHz APEX/LABOCA

We obtained new LABOCA 345 GHz imaging of 10 clusters in 2010–2011 (see Table 1). The LABOCA data for an 11th cluster that is also detected by ACT (ACT-CL J0658-5557) are from the European Southern Observatory (ESO) archive. The following subsections describe the algorithms used to reduce the LABOCA data and extract SZE signals for our full sample of eleven clusters.

#### 3.1.1. LABOCA Observations

Observations were taken using the standard raster spiral mode, in which the telescope traces out one spiral every 35 s at each of four rater points defining a square with 27\('

#### 3.1.2. LABOCA Data Reduction

We reduced the LABOCA data using the Python-based Bolometer Array Analysis Software (BoA\(^27\)) package. The data time-stream \( T(c, t) \), a function of channel \( c \) and time \( t \), is first flux calibrated and corrected for atmospheric absorption. Next, median filtering at each time step is applied to all channels, then to each of twelve subgroups of channels that share readout cabling, then to each of four subgroups that share amplifier boxes. Despiking is performed between stages of median filtering, before a linear baseline is subtracted from each channel; channels with rms noise greater than 4 \( x \) the median value are flagged. Low-frequency “1/f” noise is removed using BoA’s noise-whitening algorithm flatten-Freq, which sets the magnitudes of Fourier modes with

27 http://www.apex-telescope.org/bolometer/laboca/boa/
frequencies less than some cutoff frequency \( f < f_c \) to the average magnitude of those in the range \( f_c < f < 1.2 \times f_c \). Because the celestial scanning velocity increases as a function of time during each scan as \( v(t) \approx (\theta_0 + \dot{\theta} t) \dot{\phi} \), flattenFreq filters out emission on angular scales larger than the cutoff scale \( s_c(t) \) given by 28

\[
s_c(t) = v(t) / f_c = (28 + 3.5 \times t) f_c^{-1} \text{(arcsec)},
\]

with \( t \) in seconds and \( f_c \) in Hz. The data are then gridded onto an equatorial 0.3 × 0.3 image with 3/6 pixels (oversampling the beam by a factor of 5 in each direction). The resulting rms sensitivities within 4' of the centers of the beam-smoothed maps are presented in Table 1.

The above reduction steps, represented by \( R \), operate on time-stream data and return a gridded map, i.e., \( l(\alpha, \delta) = R[T(\cos, t, l)] \), where the parameter \( l \) represents the largest source size to which the entire scan remains responsive. The corresponding \( f_c \) is found from Equation (2) by setting \( s_c \) at \( t = 0 \) (where it achieves its minimum value) equal to \( l \) convolved with the LABOCA beam FWHM \( \theta_{\text{beam}} \):

\[
f_c(l) = \frac{28}{\sqrt{l^2 + \theta_{\text{beam}}^2}} \text{(Hz)},
\]

for \( l \) and \( \theta_{\text{beam}} \) in arcseconds. For \( l = 0' \) and \( l = 120' \), \( f_c(l) = 1.47 \) and 0.23 Hz, respectively.

### 3.1.2. Iterative Multi-scale Algorithm

The filtering steps described above, primarily median filtering on cabling subgroups and noise whitening (Section 3.1.2), can remove the desired astrophysical emission from the data along with atmospheric noise. To recover this lost signal, we have developed an iterative, multi-scale pipeline. Our approach is inspired by techniques used by Enoch et al. (2006) and Nord et al. (2009). One important difference is that we maximize our sensitivity to low-level extended emission by using a series of matched filters to search for signal at multiple cluster-sized spatial scales, similar in nature to adaptive filtering algorithms (e.g., Scoville et al. 2007).

In the technique described below, a single “reduction” refers to one application of the standard pipeline described in Section 3.1.2. Our iterative pipeline is built “on top” of the standard pipeline by chaining together standard reductions using different values of \( f_c \). The first step of the pipeline is reducing the data with aggressive filtering by setting the angular scale of fully preserved emission to \( l = 0' \). This first image, \( M_{l=0'} \), is minimally affected by 1/f noise, although it has complete responsiveness only to point sources. High-significance structures in this first image are located by producing a S/N image \( S(\alpha, \delta) \) using a spatial matched filter (e.g., Serjeant et al. 2003)

\[
S = \frac{I \otimes k}{\sqrt{W \otimes k^2}},
\]

where \( k \) is a 2D Gaussian kernel with FWHM = \( \sqrt{l^2 + \theta_{\text{beam}}^2} \), and \( W(\alpha, \delta) \) is a weight map defined by the inverse variance of

\[28\] In Equation (2), the term \( 3.5 \) in the full equation for the scanning velocity, \( v^2 = \dot{\rho}^2 + (n + \dot{\rho} t)^2 \dot{\phi}^2 \), is ignored because \( \rho^2 < (n + \dot{\rho} t)^2 \dot{\phi}^2 \) during the entire scan.

3.1.3. Iterative Multi-scale Algorithm

Now we begin to search for larger spatial scale emission. \( M_{l=0'} \) (the final, converged model image with \( l = 0' \) filtering) is subtracted from the original time streams, and the residual time-stream is reduced with a relaxed filtering, initially \( l = 30' \). If high-significance 30' scale emission is located using a matched filter, iteration begins again. This process is carried out for \( l = 0', 30', 60', \) and \( 120' \); the final image is the sum of all converged models, plus any residual low-level signals and the remaining noise:

\[
I_{\text{final}} = M_f + R( T - T [M_f] ) - M_l,
\]

where \( M_f \) is the sum of all scales’ converged model images \( M_i \). The array loses sensitivity quickly for angular scales that are larger than the typical size of contiguous subsets of channels that share cabling (i.e., \( \geq 6.7 \)); therefore, the pipeline is limited to \( l \leq 120' \), which allows for recovery of emission on scales up to \( l = 120' \). We detect bright SMGs in all clusters and strong SZE increment signals (S/N > 3.5) in six clusters (see Table 2). The final, converged, iteratively reduced 345 GHz images of all eleven clusters after point-source subtraction and smoothing are shown in Figure 1.

As an instructive check of our approach to data processing, we can compare our map of ACT J0658-5557 to the 345 GHz map made by Johansson et al. (2010) from the same LABOCA data using different reduction software (CRUSH29), and to the 1' resolution 150 GHz map of the cluster made with the APEX-SZ instrument. Johansson et al. (2010) deliberately filter the LABOCA data to suppress extended structure, including SZE increment signal. However, the flux densities they measure for the three most significantly detected SMGs in their Gaussian-matched-filtered map (48.6 ± 1.3, 15.1 ± 1.0, and 6.9 ± 0.9 mJy) agree well with those we have extracted from our own version of the map (48 ± 2, 13 ± 2, and 7 ± 2 mJy: P. Aguirre et al. 2015, in preparation). Halverson et al. (2009) fit an isothermal

\[29\] http://submm.caltech.edu/~sharc/crush/
elliptical $\beta$ model to their SZE decrement observations and determine a projected core radius of 142 ± 18 arcsec that is well-matched to the size of the (rather asymmetric) structure we see in our 345 GHz map. Broadly speaking, our mapping algorithm produces results that are consistent with previous work that focuses on either point sources or extended emission.

### 3.1.4. Systematic Uncertainties of the Iterative Pipeline

In Figure 2, we show the results when a noise-free image of an ideal cluster model is transformed to time-stream data and passed through the full iterative pipeline. We use an isothermal beta profile with $\beta = 0.86$ and core radius $r_c = 1'$, typical parameters for SZE clusters in Marriage et al. (2011). Foreground and background SMGs are modeled by injecting 15 point sources with flux densities ranging between 5 and 20 mJy at random locations in the map. We define the transfer function efficiency (TFE) as the ratio of flux densities of structures in the final map divided by their “true” flux densities in the input model image. Point-source flux densities are measured using a least-squares fit to a circular Gaussian profile with a floating constant offset, and the integrated SZE signal is measured as the integrated flux density within a circular aperture of radius 1.5′ (the typical radius used to extract SZE photometry in Section 5) after subtraction of point sources. For a single-pass reduction, the TFEs of point sources and the extended SZE signal are 0.50 and 0.10, and increase to 0.97 and 0.54 after running the full iterative pipeline. The spatially extended SZE signal is not fully recovered because of the pipeline’s inability to faithfully recover signals on scales larger than 120″. Figure 2 displays the initial model, a single (non-iterative) reduction, and the final iterated image for our simulated cluster, and Figure 3 displays the input and output flux densities of individual point sources before and after iteration.

For extended SZE signals, the TFE will range between 0.10 and 0.54 depending on whether the SZE signal was strong enough to trigger the iterative filter. The TFE for extended emission is ignored in the following sections because identical filtering and aperture photometry is used in all SZE wavebands, and we only require relative photometry to derive peculiar velocities. For SMGs, the flux that remains lost after iteration is much lower than the typical statistical uncertainty of our measurements and can be ignored.

### 3.2. 148 and 218 GHz ACT

We use the ACT 148 and 218 GHz maps, with beam FWHMs of 1.4 and 1.1′ (Hasselfield et al. 2013a), respectively, to constrain the low frequency portions of the clusters’ SZE spectra. Before extracting the integrated flux densities $S_{148}$ and $S_{218}$ for each cluster, we filter the raw ACT maps to mimic the transfer function of our LABOCA observations, which attenuates emission from spatial scales larger than $\gtrsim 120″$. This filtering is done by first taking the 2D Fourier transform of 1 deg$^2$ cutouts around the clusters in the ACT maps. We then apply the same frequency-domain filtering in 2D space for the ACT maps that the BoA algorithm flattenFreq performed on the 1D LABOCA time streams. To transform between temporal and spatial frequencies, we use the angular scanning speed of the LABOCA observations. We approximate the full continuous 35 s APEX raster spiral as a collection of circular

scans at many different radii. One Fourier-filtered map is produced for each discrete scanning speed, and the final filtered maps used to extract 148 and 218 GHz flux densities are taken to be the average of all individual velocity samplings. Beam solid angles at 148 and 218 GHz are taken from Hasselfield et al. (2013a).

We have tested our Fourier-based replication of the LABOCA pipeline spatial filtering by applying this Fourier filtering to the ideal cluster model from Section 3.1.4. We find that the fractional SZE signal recovered within a 1.5 aperture (TFE ≈ 0.53) agrees with the result from the real iterative pipeline (TFE ≈ 0.54).

Figure 1. LABOCA 345 GHz maps after iterative filtering, point-source subtraction, and smoothing. The color scale images represent 345 GHz surface brightness. The black contours represent the LABOCA-filtered ACT 148 GHz decrement intensities with levels indicated in the panels. The gray circle at the lower left represents the effective beam size of the LABOCA maps after smoothing to match the ACT resolution (1.5).
3.3. 2.1 GHz ATCA

3.3.1. ATCA Observations

We acquired 2.1 GHz ATCA observations of the ten clusters in our sample with new LABOCA observations. We used the 16 cm-band receiver with the Compact Array Broadband Backend (CABB) giving 2049 one MHz wide channels spanning 1.1–3.1 GHz. Observations were made in 2011 January (PI: Baker), 2011 December (PI: Baker), and 2012 April (PI: Lindner). All clusters have been observed with the 6A antenna configuration (baseline range $B = 628–5939$ m), and ACT J0102-4915 has additional data in the 1.5B configuration ($B = 31–4301$ m). For flux and bandpass calibration we used PKS 1934-638 (Reynolds 1994). The Australia Telescope National Facility (ATNF) online calibrator database was used.

Figure 1. (Continued.)
to choose one or more suitably bright, nearby, and compact phase calibrators for each cluster; these are listed in Table 3.

The software package MIRIAD (Sault et al. 1995) was used to calibrate, flag, invert, and clean the visibility data. Radio frequency interference (RFI) that affected all channels at a given time or a certain channel at all times was removed manually using pfflag and blflag. Transient RFI was removed using the automated flagging algorithm mirflag (Middelberg 2006). Baseline 1–2 in the 2012 April data contained powerful broad-spectrum RFI and was entirely flagged. First-order multi-frequency synthesis images with robust parameter robust = 0 were made using invert and mfclean. Two rounds of self-calibration were then carried out, one solving for phase only, and one for both phase and amplitude together. The final rms sensitivities at phase center vary over the range 6.9–12 $\mu$Jy beam$^{-1}$ (see Table 4).

3.4. Herschel Observations

To help constrain the high-frequency end of the SZE spectrum when deriving cluster peculiar velocities (see Section 5 below), we use newly obtained 250, 350, and 500 $\mu$m imaging of six targets in our sample using the Spectral and Photometric Imaging Receiver (SPIRE; Griffin et al. 2010) instrument on board the Herschel Space Observatory (Pilbratt et al. 2010). The 6 targets were prioritized within our ATCA sample of 10 on evidence of having high mass (SZE decrement

$^a$ Observations used three phase calibrators.

$^b$ Total un-flagged, on-source integration time.
strength, optical richness, etc. from Menanteau et al. 2010; Sifón et al. 2013), although in the end they did not overlap perfectly with the 5 objects for which we detected strong SZE increments with LABOCA. All SPIRE observations used the Large Map mode with nominal map speed. For five of the six clusters observed (ACT-CL J0102-4915, ACT-CL J0235-5121, ACT-CL J0245-5302, ACT-CL J0330-5227, and ACT-CL J0546-5345), four repetitions apiece of 8′ × 8′ maps centered at four different dither positions yielded a total of 4 × 4 × 139 s = 2224 s of time on-source. For ACT-CL J0330-5227, we were able to fit in four repetitions of a 6′ × 6′ map at a single position, for a total of 1 × 4 × 123 s = 492 s on-source, and, consequently, a much shallower depth. All data were reduced using the Herschel Interactive Processing Environment (HIPE, version 10.3.0; Ott 2010) using standard scripts. The final maps have angular resolutions 17.6, 23.9, and 35.0′ with mean confusion-limited rms map sensitivities of 7.4, 7.2, 7.2 mJy beam⁻¹ in the 250, 350, and 500 μm bands, respectively, for all but ACT-CL J0330-5227.

The typical increment intensities relative to those at 345 GHz are expected to be approximately 0.05%, 2%, and 34% in observations at 250, 350, and 500 μm, respectively. The high sensitivity and comparatively low angular resolution of Herschel/SPIRE, however, mean that our images all suffer badly from confusion: their brightness fluctuations are primarily due to the blending together of bright, unresolved sources (here, SMGs). Section 3.6 describes the approach we have used to disentangle an SZE increment signal from this confused background.

### 3.5. Foreground Galactic Dust Subtraction

The SPIRE maps of ACT-CL J0245-5302 and ACT-CL J0546-5345 contain detectable diffuse emission from Galactic dust on large spatial scales. The mean dust temperatures within 10′ radii (covering the full extent of the SPIRE maps) of the cluster centers as measured by Planck are $T_D^{0245} = 19.9 \pm 0.7$ and $T_D^{0546} = 20.1 \pm 0.3$ K (Planck Collaboration et al. 2014a). To remove the foreground dust emission from the maps, we first generate a model of the smoothly varying foreground dust signal by applying a median filter with kernel size 4′ to the 250 μm maps. This dust model image is then jointly fit to similarly filtered versions of the 350 and 500 μm maps using a modified blackbody thermal spectrum with emissivity fixed at $\beta = 1.57$, the value measured in the directions of both clusters by Planck Collaboration et al. (2014a). The 250 μm dust model is then scaled according to the best-fit dust temperature and subtracted from the 350 to 500 μm maps.

We find best-fitting dust temperatures of $T_D^{0245} = 23^{+2}_{-1}$ and $T_D^{0546} = 19^{+1}_{-1}$ K. The reasonable consistency of our temperatures with the Planck results supports our assumption that Galactic dust is the cause of the observed diffuse signals.

### 3.6. The Sunyaev–Zel’dovich Effect

The deflection in CMB intensity due to the thermal SZE for a single-temperature gas is (Zel’dovich & Sunyaev 1969; Sunyaev & Zel’’dovich 1970b)

$$\Delta I_{\text{SZ}} = y \, I_0 \, g(x, T_e),$$

in terms of the scaled frequency $x = h\nu/k_BT_{\text{CMB}}$, $I_0 = (2k_BT_{\text{CMB}})^2/(hc)^2 = 22.87 \text{ Jy arcmin}^{-2}$, the electron temperature $T_e$, and the Compton parameter $y$ (see Equation (1)). The function $g(x, T_e)$ is the derivative of the Planck function $(dB_e/dT)$ multiplied by the SZE spectrum,

$$g(x, T_e) = \frac{x^4 e^x}{(e^x - 1)^2} \left( \frac{e^x + 1}{e^x - 1} - 4 \right) \left[ 1 + \delta_{\text{SZ}}(x, T_e) \right],$$

where $\delta_{\text{SZ}}$ represents relativistic corrections that become important at high electron temperatures, especially when $x \gg 1$.

The change in CMB intensity due to the kSZ effect is given by (Sunyaev & Zel’dovich 1972)

$$\Delta I_{\text{kSZ}} = -\tau_e \, I_0 \sqrt{\frac{\nu_p}{c}} \frac{dB_e}{dT}$$

$$= -\tau_e I_0 \sqrt{\frac{\nu_p}{c}} \frac{x^4 e^x}{(e^x - 1)^2} \left[ 1 + \delta_{\text{SZ}}(x, T_e) \right],$$

where $\tau_e$ is the electron optical thickness.
where $v_p$ is the cluster LOS peculiar velocity with respect to the CMB in the cluster rest frame, the optical depth to electron scattering $\tau = \int n_e \sigma dl$, and $\delta_{KSZ}$ represents higher-order relativistic corrections.

Equations (6) and (8) are shown to highlight the leading order terms in the thermal and kinetic SZE signal. In our analysis, we do not use the analytic expressions, but instead compute the SZE signal with numerical integration using the C++ package S2PACK (Chluba et al. 2012, 2013). S2Pack allows for fast and accurate computations of the relativistic tSZ and kSZ signals, with $10^{-3}$ precision for temperatures up to $T_e \approx 25$ keV at frequencies up to and including the high-frequency Herschel SPIRE bands ($x \lesssim 20$) and peculiar velocities up to $v_p/c \approx 0.1$ ($v_p \approx 3 \times 10^3$ km s$^{-1}$).

### 3.7. Isolating SZE Signal in SPIRE Maps

We isolate the SZE signal in the 350 and 500 $\mu$m SPIRE maps by using the 250 $\mu$m map (which contains a negligible contribution from SZE signals compared to the 350 and 500 $\mu$m bands) to derive a model for the confused SZE background. This approach was presented by Zemcov et al. (2010), but our implementation of it differs in several important respects. For a given cluster, we begin by producing a model of the background SZE confusion signal at 250 $\mu$m ($B_{250}$) by applying a median filter with kernel size $3 \times$ FWHM$_{250}$ to the 250 $\mu$m image. We then smooth $B_{250}$ to the angular resolution of the 350 $\mu$m image to produce an estimate of the confused background at 350 $\mu$m, $B_{350}$.

We next locate bright sources that stand out from the confused 250 $\mu$m background by first subtracting $B_{250}$ from the original 250 $\mu$m image, and then searching for point sources in the resulting background-subtracted image using a spatial matched filter (e.g., Serjeant et al. 2003). The matched filter identifies high S/N peaks, which are then individually fit to an ideal 250 $\mu$m PSF with positions and flux densities allowed to vary. Sources are extracted to an S/N level of 4.5$\sigma$; we find 100–200 sources per cluster. The properties of the 250 $\mu$m point sources represent a starting point for modeling bright SMGs at 350 $\mu$m.

The 350 $\mu$m point source map is then fit to a $3N + 2$ parameter model consisting of the confused background plus bright SMGs. The offset $a$ and scaling $b$ of the confused background template and the remaining $3N$ parameters representing the coordinates $x'$ and flux densities $S$ of bright SMGs are combined into a parameter vector $\theta = \{(x'_i, S_i) \}_{i=1}^N, a, b$. The resulting model

$$M(x'; \theta) = a + b B_{350} + \sum_n S_n e^{-|x' - x'_i|^2/2\sigma^2},$$

is then fit to the 350 $\mu$m image using least-squares minimization. The optimization is carried out using Powell’s method (Powell 1964), where in each iteration the parameters are minimized individually. Powell’s method works well for this problem because each source affects only a small fraction of the data. This joint optimization naturally accommodates the increased blending that occurs in the longer wavelength images. A 350 $\mu$m source is considered an SMG and subtracted from the map if its final converged position is less than a distance 0.25 FWHM$_{350}$ from the location initially guessed for that source from the 250 $\mu$m data. To avoid fitting the confusion model to the cluster signal itself, the above optimization is carried out once while masking in the central cluster region and allowing all parameters in $\theta$ to vary, then once more without the mask and holding $a$ and $b$ fixed at their previously fit values.

The process described above is repeated (independently, but in the same way) for the SPIRE 500 $\mu$m map. Emission that remains in the 350 and 500 $\mu$m maps after subtraction of the 250 $\mu$m-inspired SMG background model is due either to (a) SZE increment or (b) SMGs that were not detected in the 250 $\mu$m map at all, possibly because they lie at very high redshifts. After removing the SMG confusion noise, the 350 and 500 $\mu$m maps have mean rms sensitivities of 2.9 and 2.7 mJy beam$^{-1}$, respectively.

Figure 4 shows an example of the 500 $\mu$m SZE extraction process in ACT-CL J0102-4915. The upper panel shows the original SPIRE 500 $\mu$m image. The lower panel shows the image after removal of the confused SZE background using the technique described above (and after Fourier-filtering the image to simulate the LABOCA transfer function). Radial profiles of the resulting SZE signals for clusters with Herschel SPIRE coverage are shown in Figure 5.

To test the reliability of our data reduction pipeline and source extraction algorithm, we compared our 250 $\mu$m integral number counts to those from the Herschel Multi-tiered Extragalactic Survey (HerMES; Oliver et al. 2010). Because our point-source removal technique breaks up 350 and 500 $\mu$m sources and divides their flux among multiple 250 $\mu$m counterparts, our number counts for 350 and 500 $\mu$m cannot be meaningfully compared to those of Oliver et al. (2010). We can, however, compute the number density of sources with $S_{250} > 100$ mJy around all clusters with Herschel SPIRE data (except ACT-CL J0330-5227, which has significantly reduced sensitivity), also masking within 5' radii of the cluster centers to avoid the effects of gravitational lensing. At these bright flux densities where completeness corrections will be minimal, we find $N_{c, 100 \text{ mJy}} = 8.0 \pm 4.0$ deg$^{-2}$, in agreement with the results from Oliver et al. (2010) who find $N_{c, 100 \text{ mJy}} = 12.8 \pm 3.5$ deg$^{-2}$.

### 4. Point Source Contamination

#### 4.1. SMGs

In the iteratively reduced LABOCA images, we find bright SMGs superposed on the clusters’ extended SZE emission. A complete analysis of the statistical properties of the detected SMGs and their multi-wavelength counterparts will be presented in a forthcoming paper (P. Aguirre et al. 2015, in preparation). Here we only consider the SMGs nearest to the clusters and study how their presence affects the measured SZE signals.

SMGs are extracted from the iterative multi-scale LABOCA map (Section 3.1.3) of a given cluster using the following process. First, SMG locations are found by using a spatial matched filter (Serjeant et al. 2003) to search for sources shaped like the ideal telescope PSF within an unsharp-masked version of the map. The unsharp mask uses a median filter with a kernel size of $3 \times$ FWHM, and allows for point sources to be disentangled from the diffuse large spatial-scale SZE signals near the cluster centers. Next, we measure the flux density of each detected SMG by fitting the original (non-unsharp-masked) data at the source’s location with an ideal PSF while
holding the position fixed and varying the flux density and a non-negative background offset.

We detect a total of 36 S/N > 4 point sources within θ_{500c} of our 11 cluster centers, giving an estimated total flux density per cluster of 46\pm32 mJy in high-significance SMGs. Using the combined area of 0.10 deg^2, this sample has cumulative number counts of \textit{N} (> 10 mJy) = 223 \pm 49 deg^{-2}, 6–10 times greater than those of sources with comparable brightness in blank fields (Weiß et al. 2009). Due to the negative k-corrections and high redshifts of SMGs, the number density enhancement is likely due to gravitational lensing by the clusters’ potentials. Gravitational lensing does not alter the average integrated flux density of the projected SMG population, but it does increase the Poisson “shot noise” variance (e.g., Refregier & Loeb 1997), and could introduce a bias in flux-constrained (i.e., either a S/N threshold or upper limit) aperture photometry near versus away from clusters.

The 345 GHz flux density in bright SMGs inside the smaller apertures used in our analysis of the SZE (Section 5) is 26\pm3 mJy, corresponding to 6 \pm 5 mJy at 218 GHz and 2 \pm 2 mJy at 148 GHz. The scaling to lower frequencies is done using a modified Planck function with parameters \(\beta = 1.5\) and \(T_0 = 37.4\,\text{K}\), values for typical blank-field 345 GHz-selected SMGs (Wardlow et al. 2011). The contaminating SZE signal represents 18\% of the SZE signal per cluster at 345 GHz, and 2\% at 148 GHz, respectively. The contaminating SMGs are subtracted from the maps before further analysis of the SZE signals.

4.1.1. El Gordo and “La Flaca”

El Gordo (ACT-CL J0102-4915) has two bright point sources projected at small clustercentric radii; the brighter of the two (\(S_\nu = 36 \pm 2\) mJy) we refer to as “La Flaca.” We briefly describe La Flaca’s properties here because it is exceptionally bright (the next brightest SMG within our sample has a flux density of \(\sim 27\) mJy and is located in ACT-CL J0438-5419), second in brightness only to the lensed SMG (e.g., Wilson et al. 2008; Johansson et al. 2010) behind the Bullet cluster (ACT-CL J0658-5557). La Flaca is located at \(\alpha = 15^\circ \ 732207\ \delta = -49:252415\) and has an extremely faint radio counterpart with \(S_{21} = 24 \pm 7\) \(\mu\)Jy. To test the possibility that La Flaca is a local SZE enhancement, we compare the spectral fits of the source’s LABOCA+SPIRE photometry using a modified blackbody spectrum and thermal SZE spectrum. Figure 6 shows the best-fit curves for each model. We find that the SZE spectral shape is incompatible with the data; thus, La Flaca is more likely to be a high-redshift dusty star-forming galaxy than a compact SZE enhancement.

The best-fit modified Planck function parameters are \(z = 4.1\) and \(L_{B} = 3.2 \times 10^{12} L_{\odot}\), assuming the median observed \(T_0 = 37.4\,\text{K}\) and \(\beta = 1.5\) from the LABOCA Extended-CDFS SMG survey (LESS; Wardlow et al. 2011). Using the 610 MHz Giant Metre-wave Radio Telescope (GMRT) data (Lindner et al. 2014), we derive a radio spectral index of \(\alpha \sim -1.3\), giving a redshift estimate of \(z = 4.0\) based on the radio-to-far-
IR spectral index (Carilli & Yun 1999), in agreement with that of the spectral fit and further supporting the conclusion that La Flaca is a high-redshift SMG.

There are two faint Hubble Space Telescope sources within 1″ of La Flaca’s 345 GHz centroid. The brighter source has a magnitude of $m_{775} = 23.8$ and resembles a spiral galaxy, and the fainter source has a magnitude of $m_{775} = 26.8$ and is unresolved. La Flaca is also only a few arcseconds away from the positions of gravitational lensing critical curves for background galaxies between $z = 4–9$ (Zitrin et al. 2013a).

4.2. Radio Sources

Radio and IR-bright sources can potentially “fill in” SZE decrement signals and artificially enhance SZE increment signals in the 15 resolution SZE maps typically used to detect clusters. With our high-resolution 2.1 and 345 GHz imaging, we can disentangle the signals of point sources from those of the true SZE signal, allowing us to derive more robust measurements of the thermal and kinetic SZE signals. In this section, we quantify the degrees of radio and submillimeter contamination of the SZE signal.

4.2.1. 2.1 GHz Number Counts

We use the Common Astronomy Software Applications (CASA; McMullin et al. 2007) task findsources to fit elliptical Gaussian profiles to all bright sources in the ATCA maps down to a significance of 4σ and out to the 10% primary beam power radius (22″). We adopt a primary beam profile based on the effective mean frequency of each observation (see Table 4). To minimize radial selection bias, we only consider sources that have primary beam-corrected flux densities above the detection threshold at all radii, i.e., $>4\sigma/0.1 = 400 \mu Jy$. Additionally, only compact sources that have major and minor FWHMs, $a$ and $b$, satisfying $a < 3 \times \text{FWHM}_\text{maj}^\text{beam}$, $b > 0.5 \times \text{FWHM}_\text{min}^\text{beam}$ and $a/b < 1.5 \times \text{FWHM}_\text{maj}^\text{beam}/\text{FWHM}_\text{min}^\text{beam}$ are kept. We consider only compact sources because extended radio sources like jets and lobes from active galactic nuclei have steep radio spectral indices and will therefore contribute negligibly in the frequency range $\nu \geq 148$ GHz. These criteria result in a total for all clusters of 1934 radio sources with flux densities between 28 $\mu Jy$ and 1.65 Jy.

Fainter sources have an increased chance of having their flux densities scattered below the detection threshold by noise, thus lowering their completeness. Because the noise in the 2.1 GHz maps is nearly Gaussian, we correct for completeness using an analytic correction in the following way. The completeness probability, $C$, that a source with true flux density $S_e$ will be detected above a threshold of $N_\theta$ is given by

$$C = 1 - \Phi\left(\frac{N_\theta - S_e}{\sigma}\right). \quad (10)$$

where $\Phi(x)$ is the cumulative normal distribution function. The completeness correction is then implemented by computing number counts using a weighted histogram with weights $w_i = C_i^{-1}$.

Figure 7 (upper panel) shows combined and individual 2.1 GHz number counts in nine log-spaced flux density bins. The power-law index of the counts $\delta$, where $dN/dS \propto S^{-\delta}$, is $\delta \approx 1.7$. We next compute the number counts in three disjoint regions defined relative to the clusters’ physical radii, and find that the counts in the $\theta < 2$ regions are elevated (especially at high flux densities) compared to the more distant regions (Figure 7, lower panel), in agreement with a previous radio survey of southern X-ray-selected clusters (Slee et al. 2008). This enhanced source density in cluster interiors is likely due to the presence of both radio-loud cluster member galaxies and (possibly at a lower level) gravitationally lensed background AGNs and star-forming galaxies. We have also checked for variation in the counts for the top, bottom, left, and right halves of the radio images and find no significant differences.

4.2.2. Radio Contamination Extrapolated to 148 GHz

We use our 610 MHz GMRT image of ACT-CL J0102-4915 (Lindner et al. 2014) to compute the radio spectral index $\alpha_{2.1}^{610}$ distribution of 2.1 GHz sources, which allows us to extrapolate their flux densities to the higher frequencies of the SZE decrement. We find 28 2.1 GHz/610 MHz pairs of sources with $<1″$ (7.8 kpc) separation and $>4\sigma$ significance out to a 6′ radius relative to the SZE decrement centroid, and compute their spectral indices as

$$\alpha_{2.1}^{610} = -\log \left(\frac{S_{2.1}}{S_{610}}\right)/\log (2.1/610). \quad (11)$$

The distribution $\alpha_{2.1}^{610}$ is shown in Figure 8. We find a median spectral index $\alpha_{2.1}^{610}_{\text{median}} = 0.56$ with interquartile range 0.37–0.69. Only 4.9% of ATCA radio sources have optically selected cluster member counterparts (for the clusters that overlap between the two samples) from Sifón et al. (2013). The disjoint source catalogs, along with the fact that our spectral index distribution is similar to that of Owen et al. (2009), indicates that radio source contamination in our clusters is due mostly to foreground and background galaxies.
allowing us to use the spectral index distribution measured in the field of ACT-CL J0102-4915 to predict the 148 GHz contamination in our full cluster sample. The recent study by Gralla et al. (2014) of the average submillimeter emission associated with 1.4 GHz-selected AGN finds that a low-frequency estimate of average AGN spectral index remains valid when extrapolating all the way to 218 GHz, validating our extrapolation of 2.1 GHz emission up to the ACT bands at 148 and 218 GHz.

Because we only measure the spectral indices of sources that are detected at both 610 MHz and 2.1 GHz, we check for sources with flat/inverted spectral indices that may not be detected at 610 MHz but could be bright at 2.1 GHz and higher frequencies by searching for 20 GHz counterparts to our ATCA and GMRT detections using the Australia Telescope 20 GHz survey (AT20G; Murphy et al. 2010). There is one match between the AT20G catalog (Murphy et al. 2010) and our ATCA and GMRT sources. The source lies 15′ away from the center of cluster ACT-CL J0215-5212 and has $\alpha_{20} = 0.11 \pm 0.01 \text{ Jy}$ and $S_{21} = 0.011867 \pm 0.001726 \text{ Jy}$, giving an inverted spectral index of $\alpha = 1.0$. This source is only $10^8$ away from a much brighter ATCA source with $S_{21} = 0.897 \pm 0.001 \text{ Jy}$.

We detect 346 2.1 GHz sources with $S_{21} > 4\sigma$ within $\theta_{500}$ of our ten clusters with ATCA imaging, corresponding to a mean 2.1 GHz flux density within $\theta_{500}$ per cluster of $39^{+6}_{-5} \text{ mJy}$. After scaling the flux density to the 148 GHz SZE decrement using $\alpha_{610, \text{median}} = 0.56$ and including an additional uncertainty based on the variation in the spectral index between the extremes of the interquartile range, the typical contaminating radio signal from 2.1 GHz-detected synchrotron radio sources is estimated to lie between 2.1 and 8.1 mJy in the 148 GHz SZE decrement.

Inside the photometric apertures used to constrain the clusters’ peculiar velocities (Section 5), radio sources contribute $28 \pm 8 \text{ mJy}$, corresponding to $3 \pm 1 \text{ mJy}$ at 148 GHz, which is $3\%$ of the typical decrement signal in our sample.

5. PECULIAR VELOCITIES

In addition to its Hubble-flow velocity, a galaxy cluster can have a velocity offset with respect to its local CMB rest-frame, known as its peculiar velocity $v_p$. As well as being interesting in its own right as a statistical cosmological probe of large-scale structure (e.g., Doré et al. 2003), $v_p$ introduces a frequency-independent temperature fluctuation known as the kinetic SZ (kSZ; Equation (8)), in contrast to the frequency-dependent SZ signal due to thermal motion of the electrons in the cluster (SZ; Equation (6)). This kSZ contribution can therefore affect the scaling between thermal $Y_{\text{SZ}}$ and cluster mass.

Mroczkowski et al. (2012) report that their 268 GHz data for the triple-merger cluster MACS J0717.5+3745 adequately fit their SZ model only if they allow for a strong kSZ distortion from a high-velocity subcomponent. It is unclear whether strong kSZ distortions like those seen by Mroczkowski et al. (2012) are common in merging clusters. Recent results from Planck Collaboration et al. (2014d) only constrain the rms fluctuations in $v_p$ to be $\leq 800 \text{ km s}^{-1}$ (95% confidence) for a sample from the Meta Catalogue X-ray Detected Clusters (Piffaretti et al. 2011). If transient kSZ distortions are common in merging cluster systems, then the $Y_{\text{SZ}}$—mass relation in SZ clusters may be significantly affected. As a cautionary indicator here, Sifón et al. (2013) find at least one indication of dynamical activity in $81^{+19}_{-12} \%$ (13/16) of a representative sample of ACT clusters (nine of which overlap with this paper’s sample).

We use our point source-subtracted multi-band data to constrain the peculiar velocities of our targets by parametrizing the observed SZ signal with $v_p$ and the integrated SZ signal $Y_{\text{SZ}}$. The iterative pipeline (Section 3.1.2) faithfully recovers extended emission only up to angular scales of $\sim 2'$, while $\theta_{500}$-values can be much larger. Therefore, to strengthen constraints while fitting for $v_p$, we choose circular apertures for each cluster (typically 1.5–2' radii) that contain the observed scale of emission in the 345 GHz images. $Y_{\text{SZ}}$ is therefore the effective integrated SZ signal within each of these apertures, and a lower limit on $Y_{\text{SZ}}(\theta \leq \theta_{500})$. We have recently obtained Chandra imaging (PI: Hughes) for many clusters in our sample and use these data to independently measure $T_e$ in these systems (J. P. Hughes et al. 2015 in preparation). The systematic errors due to the different weighting between the X-ray-derived electron temperatures ($\propto n_e^2$) and the optical
depth-weighted electron temperatures used in the calculations of the SZ effect are expected to be only 10–20 km s\(^{-1}\) (Sehgal et al. 2005). For the current analysis, we set \(k_B T_e = 5\) keV (see Table 2) for clusters with unknown gas temperatures.

For each integrated flux density measurement \(S_{SZ,i}\) at \(x_i = h \nu_i/k_B T_e\), we compute the expected SZE signal \(S_{SZ,model}(Y_{SZ}, \nu_i, v_p, T_e)\). We fit the data to the multi-band model using a grid-based search. The noise in all images is nearly Gaussian, and therefore the conditional probability density of obtaining measurements \(S_{SZ,i}\), given the model parameters \(\theta = (Y_{SZ}, v_{pec})\) is

\[
p_i(x_i; \theta) \propto e^{-(S_{SZ,i} - S_{SZ,model})^2/2\sigma_i^2}.
\]

The joint probability density of obtaining all measurements is then given by \(P(x; \theta) \propto \prod_i p_i\). We take as the best-fit parameters those that maximize the likelihood function, and the final quoted 1σ uncertainties in \(v_p\) and \(Y_{SZ}\) are found by marginalizing over the 2D likelihood parameter space and integrating the resulting 1D probability functions within isocontours to contain ±68% probability. The best-fit peculiar velocities and corresponding 68.2% confidence intervals are presented in Table 2.

At 148 and 345 GHz, the SZE signal is much brighter than the background confusion noise. The situation is reversed for 350 and 500 \(\mu\)m, where great efforts must be made to extract the SZE signal from the strong SMG background (i.e., see Section 3.7). Recent work by Zemcov et al. (2013) has shown that by subtracting bright submillimeter point sources near massive clusters, one will produce a deficit in the surface brightness of the local cosmic infrared background compared to an off-cluster sky region. By subtracting point sources at a level comparable to that used in Section 3.7, Zemcov et al. (2013) find a typical intensity deficit of \(\sim 0.5\) MJy sr\(^{-1}\) in the cores of four massive clusters. This may be related to why our SPIRE 500 \(\mu\)m photometry is systematically low compared to the other bands (see Figure 9).

Because of this extra uncertainty in the SPIRE photometry, we present peculiar velocity fits for individual clusters both including and excluding the SPIRE data points (Table 2); other sample-wide properties are computed with only ACT+LABOCA photometry. Figure 9 shows the best-fit SZE spectra for all clusters, with the \(\chi^2\) per degree of freedom (\(\chi^2/d\nu\)) and \(p\) values indicated in the panels.

The mean peculiar velocity of the sample is \(\langle v_p \rangle = 153 \pm 383\) km s\(^{-1}\), consistent with the limit of 72 ± 60 km s\(^{-1}\) found by Planck Collaboration et al. (2014d) using the variance of the CMB toward X-ray detected clusters. The measured peculiar velocity dispersion of the clusters in our sample is 1449 km s\(^{-1}\), and represents an upper limit to the intrinsic peculiar velocity dispersion. Halverson et al. (2009) find that the mass-weighted SZE-derived temperature measured for the Bullet cluster (10.8 ± 0.9 keV; Halverson et al. 2009) is significantly lower than that derived from the X-ray observations (13.9 keV; Govoni et al. 2004). This difference is caused by the different sampling functions for X-ray-derived temperatures (\(\propto f_n^2\)) and SZE-derived temperatures (\(\propto fn\)). We adopt the SZE-based temperature for the Bullet cluster from Halverson et al. (2009) and derive a large peculiar velocity of 3100–1500 km s\(^{-1}\). This signal is unlikely to be caused by contamination of sources fainter than \(S_{45} < 10\) mJy, because positive signal contamination acts to push \(v_{pec}\) to more negative values. In the Bullet cluster, Markevitch (2006) finds a central “bullet” collision velocity of 4700 km s\(^{-1}\). Our signal may be due to a kSZ distortion related to this high-velocity subcomponent, similar to the findings of Mroczkowski et al. (2012) for MACS J0177.5+3745.

5.1. Impact of \(v_{pec}\) on \(Y_{SZ}-M\) Scaling Relations

We next compute \(Y_{SZ}^{0}\), the best-fit integrated SZ signal when the peculiar velocity is fixed at \(v_{pec} = 0\) km s\(^{-1}\), and define the systematic uncertainty due to non-zero \(v_{pec}\) as \(\Delta Y_{SZ}^{pec} = \left| Y_{SZ} - Y_{SZ}^{0} \right| \). We use the \(Y_{SZ}-M\) scaling relation \(M \propto Y_{SZ}^{0.48±0.11}\) from Sifón et al. (2013) to derive a relative systematic uncertainty in cluster mass due to the clusters’ peculiar velocities of \(\langle \Delta M/M \rangle = 3.5 \pm 0.8\%\). Because the fractional change in \(\Delta M_{SZ}\) due to a non-zero peculiar velocity is independent of the mean Compton parameter, our aperture-based estimate of the relative uncertainty in \(Y_{SZ}\) can be directly applied to cluster-integrated \(Y_{SZ}\) measurements.

5.2. Comparison to Simulations

To understand the intrinsic scatter and systematic uncertainties in our derived values for \(v_{pec}\), we applied our technique of extracting \(v_{pec}\) (Section 5) to the realistic simulated cluster images from the all-sky maps of Sehgal et al. (2010). We use the “Full SZ” images at 148, 219, and 350 GHz, which contain thermal and kinetic SZ signals from clusters, groups, and the intracluster medium. The large scale mass distribution is created using a dark matter N-body simulation with a comoving box size of \(L = 1000\) h\(^{-1}\) Mpc (for details, see

\[\text{http://lambda.gsfc.nasa.gov/toolbox/thsim_ov.cfm}\]

Figure 8. Spectral index \(\alpha_{148}^{21}\) of 28 pairs of >4\(\sigma\) significance in 2.1 GHz and 610 MHz sources within of the center of ACT-CL J0102-4915. The median and interquartile range are \(\alpha_{148}^{21}_{\text{median}} = 0.56\) and 0.37–0.69, respectively. For comparison, the gray dashed line shows the 1.4 GHz/330 MHz spectral index distribution of radio sources detected from deep observations of the Lockman Hole North (Owen et al. 2009).
Sehgal et al. 2007, 2010. We cut out $0.3 \times 0.3$ images around 100 simulated clusters that were randomly chosen among those with $z > 0.3$ and $M_{\text{vir}} > 3 \times 10^{14} M_{\odot}$. For each cluster image, we applied the Fourier-based LABOCA filtering, extracted the total flux densities at 148, 219, and 350 GHz within a 1.5′ aperture centered on the central halo position, and performed the maximum likelihood fit from Section 5.

We find an intrinsic scatter in output $v_{\text{pec}}$ of $\sigma_{v_{\text{pec}}} = 213$ km s$^{-1}$, and a bias of $\langle (v_{\text{pec, out}}/v_{\text{pec, in}}) - 1 \rangle$ of 0.36. For 0′25 apertures, the scatter is 137 km s$^{-1}$ and the median bias is 0.15. Given that the smaller apertures reduce the bias and scatter, we attribute both effects to the aperture-dependent irreducible error from assuming a single temperature and velocity throughout the volume of a cluster.

To investigate the source of the scatter and bias in more detail, we next performed an experiment exactly the same as above, except that we computed the photometry for each system while varying the relation between the gas temperature assumed in the maximum likelihood fit $T_{\text{fit}}$, and the true gas temperature of the cluster $T_{\text{true}}$. When $T_{\text{fit}} = T_{\text{true}}$, we find negligible scatter and bias, but for $T_{\text{true}} = 0.8 \times T_{\text{fit}}$, we find a median bias in the recovered peculiar velocity of 0.2. This induced temperature-related bias can explain the bias we see in the extracted $v_{\text{pec}}$ of the simulated clusters above: in the simulations, $T_{\text{true}}$ is measured in the 3D centers of the clusters, and larger apertures will include more cool gas at larger cluster-centric radii. This effect is also likely operating in the real observations since the X-ray-derived gas temperatures are weighted by $n_{e}^{2}$ and preferentially sample the dense interiors of clusters. This might explain, for example, the 22% difference found by Halverson et al. (2009) in SZE- and X-ray-derived temperatures quoted above. Figure 10 shows the input and output peculiar velocities for each of the three numerical experiments above.

Figure 9. Best-fit SZE spectra for all 11 clusters in our sample. The solid black curve and purple region show the best-fit model and 68% confidence region for 148, 218, and 345 GHz photometry, and the dashed red line shows the best-fit model when including the Herschel SPIRE bands at 250, 350, and 500 μm. The fit quality ($\chi^2/\nu$) when using only ACT+LABOCA bands is indicated in the panels, with the corresponding value when including SPIRE photometry shown in parentheses. From left to right, the data points are ACT 148 GHz, ACT 218 GHz, LABOCA 345 GHz, SPIRE 500 μm, and SPIRE 350 μm (the latter two only for the six clusters with Herschel observations).
mean individual contamination ($\langle \Delta S/S \rangle$) by radio sources in our sample is 6%.

Benson et al. (2003) constrained the peculiar velocities of six clusters using the Sunyaev–Zel’dovich Infrared Experiment in three frequency bands between 150 and 350 GHz, and placed a constraint on the intermediate universe bulk flow velocity of $<1420$ km s$^{-1}$ (95% confidence), consistent with ours.

7. CONCLUSIONS

We present high-resolution 345 GHz LABOCA, 2.1 GHz ATCA (10 of 11) and Herschel SPIRE (6 of 11) imaging of 11 massive SZE-selected clusters from the ACT southern survey (Menanteau et al. 2010; Marriage et al. 2011). We use these data to constrain the levels of radio source and SMG contamination of the SZE signals of the clusters, and also to constrain the cluster peculiar velocities using the kSZ effect.

We find that the contamination by 2.1 GHz radio sources of the 148 GHz SZE decrement is $3 \pm 1$ mJy per cluster, or $\sim3\%$ of the SZE decrement signal in our analysis. We measure the 2.1 GHz number counts in three disjoint regions around the clusters, $\theta < \theta_{500c}$, $\theta_{2500} < \theta < \theta_{500c}$, and $\theta_{500} < \theta < 5 \theta_{500c}$, and find an enhancement in the counts for $\theta < \theta_{2500}$.

The typical contamination from bright, unresolved SMGs is $26 \pm 3$ mJy (18%) per cluster at 345 GHz, scaling to a 2% effect on the 148 GHz decrement. The number counts of bright SMGs are $\sim 10$ times greater than blank field measurements, likely due to gravitational lensing by the clusters’ potentials (as seen in, e.g., Knudsen et al. 2008; Johansson et al. 2011). The combined contamination by SMGs and radio sources ($\sim 5\%$ of the 148 GHz decrement signal on average) may contribute to, but still remains less than, the scatter found in the kSZ-to-mass scaling relation of SZE clusters.

After subtraction of the bright SMGs, we use our multi-band data to constrain the peculiar velocities of the clusters. For clusters with high-significance SZE detections, the typical uncertainty in $\upsilon_{\text{pec}}$ is $\pm 1000$ km s$^{-1}$, and for the full sample we find a mean peculiar velocity of $\langle \upsilon_{\text{pec}} \rangle = 153 \pm 383$ km s$^{-1}$. By comparing the best-fit $Y_{\text{SZ}}'$ values with and without fitting for $\upsilon_{\text{pec}}$, we estimate that peculiar velocities introduce a scatter to the SZ-estimated mass of clusters at the level of $\langle \Delta M/M \rangle = 3.5 \pm 0.8\%$.

Future observations with higher angular resolution and support for multiple instantaneous millimeter/submillimeter bandpasses can help reduce the uncertainties on $\upsilon_{\text{pec}}$. Higher angular resolution can resolve a larger fraction of the CIB into point sources, and therefore reduce the magnitude of the remaining confused SMG background. The capability to observe multiple wavebands spanning the SZE decrement to the increment would allow the wavebands to be analyzed homogeneously, reducing the complexity of data reduction and related systematic uncertainties. These capabilities can be provided by wide-format multi-band bolometer cameras on telescopes like the Large Millimeter Telescope and the upcoming Cerro Chajnantor Atacama Telescope.

6. COMPARISON TO PREVIOUS WORK

Figure 11 shows the combined absolute and relative contamination levels from radio sources and SMGs in our sample. Our results are in general agreement with previous predictions and measurements of radio and infrared source contamination at 148 GHz. For example, based on simulations of the microwave sky, Sehgal et al. (2010) predicted that $<20\%$ of clusters with $M_{2500} > 10^{14} M_\odot$ and $z < 0.8$ should have their decrements filled in by $>50\%$. In our sample of clusters, we find a mean individual contamination fraction of $\langle \Delta S/S \rangle = 8\%$, and none with contamination $>50\%$.

Lima et al. (2010) presented analytic predictions of the Poisson variance in SZ flux density due to lensed background SMG populations. At 148 GHz, Lima et al. (2010) predict $\sigma_{\text{lensed SMG}} \sim 2-3$ mJy within $r_{2500c}$. Within our 1–2” radius apertures (similar to $r_{2500c}$ for our cluster sample), we estimate the rms intensity of 148 GHz fluctuations due only to the significantly detected LABOCA point sources to be 2 mJy.

Using 14, 30, and 140 GHz observations of 45 massive clusters, Sayers et al. (2013) estimate the fractional contamination due to radio sources to be $\sim20\%$ on average, with only 1/4 of clusters showing contamination greater than 1%.
