Risk factors for cardiovascular disease and type 2 diabetes retained from childhood to adulthood predict adult outcomes: the Princeton LRC Follow-up Study

John A Morrison¹, Charles J Glueck²,³*, Jessica G Woo¹ and Ping Wang²

Abstract

Background: Pediatric risk factors predict adult cardiovascular disease (CVD) and type 2 diabetes (T2DM), but whether they predict events independently of adult risk factors is not fully known.

Objective: Assess whether risk factors for CVD and T2DM retained from childhood to adulthood predict CVD and T2DM in young adulthood.

Study design: 770 schoolchildren, ages 5–20 (mean age 12), 26-yr prospective follow-up. We categorized childhood and adult risk factors and 26-year changes (triglycerides [TG], LDL cholesterol, BMI, blood pressure [BP] and glucose ≥, and HDL cholesterol < pediatric and young adult cutoffs). These risk factors and race, cigarette smoking, and family history of CVD and T2DM were assessed as predictors of CVD and T2DM at mean age 38.

Results: Children who had high TG and retained high TG as adults had increased CVD events as adults (p= .0005). Children who had normal BMI and retained normal BMI as adults had reduced CVD events as adults (p=.02). Children who had high BP or high TG and retained these as adults had increased T2DM as adults (p=.0006, p=.003).

Conclusions: Risk factors for CVD and T2DM retained from childhood to adulthood predict CVD and T2DM in young adulthood and support universal childhood screening.

Keywords: Risk factors, Cardiovascular disease, Type 2 diabetes mellitus, Obesity, High blood pressure, Tracking

Background

Recently, an expert panel recommended screening all American children for risk factors for cardiovascular disease (CVD) [1], not just children of parents with known CVD or high risk factors. Pediatric risk factors for atherosclerosis have been shown to associate with young adult atherosclerotic lesions [2], carotid intima-media thickening (CIMT) [3-7], and cardiovascular disease (CVD) events [8]. Moreover, adolescent CVD risk factor status predicts increased adult CIMT, independent of adult risk factors [9,10], and children with metabolic syndrome (MetS) have 2–3 times greater risk of high CIMT and type 2 diabetes mellitus (T2DM) as adults versus children free of MetS [11]. Obese children who remained obese as adults have increased type 2 diabetes (T2DM), hypertension, dyslipidemia, and increased CIMT, but risks for these outcomes are attenuated in obese children who became non-obese adults, with outcomes similar to those non-obese in both childhood and adulthood [12].

It is not well understood whether childhood risk factors cause adult CVD directly, independent of adult risk factors, or only in those individuals whose risk factors tracked into adulthood, thereby increasing the length of exposure to high risk factors [10,13]. The best predictor of high blood pressure (HBP) in adulthood has been reported to be adult obesity or change in obesity; pediatric obesity does not predict adult HBP when adult obesity is
in the model [13]. However, HBP is itself a risk factor, not a CVD event. Positive associations between childhood BMI and adult CIMT are generally attenuated once adjusted for adult BMI [14]. Child-adult relationships may be dependent on tracking of BMI from childhood to adulthood [14], since risk of events increases with the length of exposure [15,16]. There is a stepwise increase in the incidence of T2DM with the duration of obesity [15].

In the current study, our specific aim was to assess whether risk factors for CVD and T2DM retained from childhood to adulthood predict CVD and T2DM in young adulthood or whether childhood risk factors are attenuated [12] by changes in risk factors from childhood to young adulthood.

Methods
We used data from the NHLBI Princeton Follow-up Study (PFS, 1999–2003), a 22–30 year follow-up of black and white former schoolchildren first studied in the NHLBI Lipid Research Clinics (LRC, 1973–1976) [8,17]. PFS collected data following a protocol approved by the Children’s Hospital Institutional Review Board, with signed informed consent [17].

Princeton LRC and PFS studies
The Princeton LRC [18] study was a multistage survey of lipids and other CVD risk factors in students in grades 1–12 and a 50% random sample of their parents by household. The student population in LRC was 72% white and 28% black, with a mean age of 12.3 ± 3.4 years. Participation rates did not differ significantly between races.

The PFS [8] was conducted in adults, 22 to 30 years after their initial pediatric LRC sampling to assess relationships of pediatric risk factors to subsequent adult health events. The subjects’ CVD, T2DM and high blood pressure (HBP) status and use of prescribed medications for lipids, diabetes mellitus, and blood pressure were obtained by questionnaire with an interviewer [8].

After an overnight fast, blood was drawn for measurements of plasma triglyceride (TG), high density lipoprotein cholesterol (HDLc), low density lipoprotein cholesterol (LDLC), systolic blood pressure (SBP), diastolic blood pressure (DBP), BMI, and glucose in children and their parents at the LRC assessment and at the subsequent PFS study 26 years later. There was no contact with the former schoolchildren or their parents during the 26-year interval between the LRC and PFS studies.

Diagnosis of CVD, type 2 diabetes and impaired fasting glucose
At PFS, CVD was defined as myocardial infarction, coronary artery bypass graft, angioplasty, ischemic stroke, and carotid or peripheral artery bypass surgery [8]. Diagnosis of diabetes (T2DM) was based on World Organization of Health criteria, fasting glucose ≥ 7 mmol/l (126 mg/dl) and/or self-report of diabetes with treatment by a physician [19]. We excluded from these analyses 10 subjects who had reported type 1 diabetes mellitus as children at LRC. However, in PFS we did not have a measurement of C-peptides or diabetes autoantibody levels, the gold standard methods of distinguishing type 1 from type 2 diabetes [19]. Diagnosis of impaired fasting glucose (IFG) was made when fasting blood glucose was ≥ 100 but < 126 mg/dl.

Pediatric and young adult risk factor cutoffs
Pediatric risk factor cutoffs included high LDLC (≥ 110 mg/dl [2.82 mmol/l]) [20], high BMI (≥ 85th CDC 2000 age-gender specific percentile), high BP (SBP and/or DBP > 90th age-height specific percentiles in current cohort), and cutoffs published for pediatric metabolic syndrome [21]: high TG (≥ 110 mg/dl [1.24 mmol/l]), low HDLC (≤ 50 mg/dl [1.28 mmol/l] in girls, ≤ 40 [1.03 mmol/l] in boys), and high glucose (≥ 100 mg/dl [5.6 mmol/l]).

Risk factor cutoffs at the PFS were those of the NCEP/ AHA Metabolic syndrome (waist ≥ 102 cm men, ≥ 88 cm women, SBP ≥ 130 mmHg and/or DBP ≥ 85, TG ≥ 150 mg/dl [1.69 mmol/l], HDLC < 40 mg/dl [1.03 mmol/l] men, < 50 mg/dl [1.28 mmol/l] women, glucose ≥ 100 mg/dl [5.6 mmol/l]) [22]. BMI and LDLC cutpoints at the PFS respectively were ≥ 30 kg/m² (CDC, US Obesity Trends, Trends by State 1985–2009), and the current cohort’s gender-race-specific 90th percentile levels.

Statistical methods
CVD risk factor measures in the cohort in childhood (LRC) and adulthood (PFS) were summarized.

To assess for possible selection bias, comparisons were made between the 770 subjects with complete CVD risk factor measures at both the LRC visit and the PFS visit 26 years later, and 695 subjects without complete measures. Comparisons were made by Wilcoxon test or by chi-square test.

Risk factor measures at LRC and PFS were categorized as high vs. not high (for TG, LDLC, BMI, SBP-DBP, and glucose) or low vs. not low (for HDLC) using the above-mentioned cutoffs. The change in status for each risk factor from LRC to PFS was indicated by 4 dummy variables (normal to normal vs. others; abnormal to normal vs. others; normal to abnormal vs. others; abnormal to abnormal vs. others).

Stepwise logistic regression analysis was used to identify significant independent risk factors for young adult CVD, T2DM and IFG at PFS in multivariate analyses. Explanatory variables included age at follow-up and categorical variables: race, pediatric and young adult risk factor status group (high vs. not high) for TG, LDLC,
Table 1 Risk factors for cardiovascular disease and type 2 diabetes mellitus, measured during childhood (LRC) and 26 years later in young adulthood (PFS) in 770 subjects

| Race         | W 561 (73%), B 209 (27%) |

*Spearman correlation between LRC and PFS.*

*After removal of 26 subjects taking cholesterol lowering medications at PFS.*
retained into adulthood characterized the 417 subjects free of T2DM at the PFS visit (65%), Figure 3. The incidence of T2DM was 28.6% in subjects with high BP at LRC and PFS compared to 3.6% in subjects with normal BP at both LRC and PFS, for a relative risk of 8 to 1. The one of 22 subjects with high BP at LRC but normal BP at PFS did have T2DM so the incidence rate was 4.6%. In subjects with normal BP at LRC but high BP at PFS the incidence of T2DM was 8.6%. Thus, there was a linear trend for T2DM across the four BP classification groups ($p < .0001$), Table 2.

High TG retained from childhood to adulthood was much more common in subjects who developed T2DM as adults (31%) than in those free of T2DM (6%), Figure 4. The incidence of T2DM was 27.3% in subjects with high TG at LRC and PFS compared to 3.8% in subjects with normal TG at both LRC and PFS, for a relative risk of 7.1. No person with high TG at LRC but normal TG at PFS had T2DM, incidence rate = 0.0%. In subjects with normal TG at LRC but high TG at PFS the incidence of T2DM was 9.6%. Thus, there was a linear trend for T2DM across the four TG change classification groups ($p < .0001$), Table 2.

By stepwise logistic regression, adult CVD (19 yes, 751 no) was independently and significantly associated with high childhood TG retained adulthood ($p = .0005$) and with age at follow-up ($p = .0009$), and was inversely associated with normal BMI from childhood retained into adulthood, $p = .02$, Table 3.

Adult T2DM (29 yes, 417 no) was associated with BP and TG high in childhood and retained into adulthood ($p = .0006$, .003), with childhood glucose ($p = .006$), with adult age ($p = .002$), and with black race ($p = .04$), Table 3.

**Table 2** Incidence rate (%) of cardiovascular disease (CVD) by triglyceride (TG) and BMI classification in childhood and adulthood and of type 2 diabetes mellitus (T2DM) by blood pressure and triglyceride classification in childhood and adulthood

| Incidence rate | Normal - Normal | High - Normal | Normal - High | High - High | Trend of incidence rate by Mantel-Haenszel $\chi^2$ test |
|---------------|----------------|--------------|--------------|------------|---------------------------------------------------|
| CVD (TG)      | 1.0            | 1.9          | 2.9          | 14.6       | $\chi^2 = 22.4, p < .0001$                        |
| CVD (BMI)     | 0.9            | 2.5          | 4.0          | 6.2        | $\chi^2 = 12.1, p = .0005$                        |
| T2DM (BP)     | 3.6            | 4.6          | 8.6          | 28.6       | $\chi^2 = 17.8, p < .0001$                        |
| T2DM (TG)     | 3.8            | 0            | 9.6          | 27.3       | $\chi^2 = 20.3, p < .0001$                        |
Figure 2 Changes in BMI status groups from childhood to adulthood by adult CVD status.

Figure 3 Changes in BP status groups from childhood to adulthood by adult T2DM status.
Adult IFG (88 yes, 617 no) was positively associated with adult BP and TG (high vs not high), \( p < .0001, p = .0009 \), respectively, and with cigarette smoking, \( p = .018 \), Table 3.

Neither pediatric nor young adult LDLC was associated with young adult CVD, \( p > .05 \).

**Discussion**

In the current study, risk factors for CVD retained from childhood to adulthood predicted CVD in young adulthood. Risk for CVD was attenuated when childhood risk factors were not maintained into adulthood, congruent with the report by Juonala et al. [12]. Children who had high TG and retained high TG as adults had increased CVD events. Children who had normal BMI and retained normal BMI as adults had reduced CVD events. Children who had high childhood BP and TG and retained these into adulthood were more likely to have adult T2DM, children with childhood risk factors not retained were not associated with increased adult T2DM, congruent with the report by Juonala et al. [12].

In contrast to CVD and T2DM, adult IFG was associated with adult high BP, TG, and cigarette smoking, and was not associated with retention of risk factors from childhood to adulthood.

Our finding of a significant association of high TG retained from childhood to adulthood with young adult CVD is consistent with pediatric [8] and adult studies where non-fasting [23-25] and fasting TG [26-29] are independent risk factors for CVD and for ischemic stroke [30]. The association of TG high from childhood through young adulthood with adult CVD may, speculatively, reflect the presence of pediatric metabolic syndrome, a known predictor of adult CVD [18]. Moreover, TG levels in adolescent males have been related to coronary artery calcification 15 to 20 years later in young adults [31]. Coronary artery streaks in 6 to 30 year olds are significantly correlated with antecedent TG and very low density lipoprotein cholesterol [32,33]. In a post-mortem study of 15 to 34 year old men, the percentage of the right coronary arterial intima involved with atherosclerosis correlated with a combination of LDL and VLDL cholesterol levels, and was inversely associated with HDL cholesterol [34].

Normal childhood BMI retained to adulthood was a significant negative risk factor for adult CVD. The association of normal BMI retained from childhood to adulthood with low young adult CVD events is consistent with the report by Chen et al. [35] where clustering of bottom quartile BMI, HOMA IR, SBP, and the ratio of total/HDL cholesterol was associated with decreasing mean values of carotid intima-media thickness in adulthood.

High childhood BP and TG, two components of the metabolic syndrome complex, retained into adulthood were associated with adult T2DM, findings broadly in agreement with pediatric [8] and adult studies where non-fasting [23-25] and fasting TG [26-29] are independent risk factors for CVD and for ischemic stroke [30]. The association of TG high from childhood through young adulthood with adult CVD may, speculatively, reflect the presence of pediatric metabolic syndrome, a known predictor of adult CVD [18]. Moreover, TG levels in adolescent males have been related to coronary artery calcification 15 to 20 years later in young adults [31]. Coronary artery streaks in 6 to 30 year olds are significantly correlated with antecedent TG and very low density lipoprotein cholesterol [32,33]. In a post-mortem study of 15 to 34 year old men, the percentage of the right coronary arterial intima involved with atherosclerosis correlated with a combination of LDL and VLDL cholesterol levels, and was inversely associated with HDL cholesterol [34].

Normal childhood BMI retained to adulthood was a significant negative risk factor for adult CVD. The association of normal BMI retained from childhood to adulthood with low young adult CVD events is consistent with the report by Chen et al. [35] where clustering of bottom quartile BMI, HOMA IR, SBP, and the ratio of total/HDL cholesterol was associated with decreasing mean values of carotid intima-media thickness in adulthood.
with those of Everhart et al. [15] and Lee et al. [16], which suggested that the duration of the risk factor presence from childhood to young adulthood and the cumulative exposure to risk factors predict adult outcomes.

Our finding of an association of glucose levels in childhood with the development of T2DM in adulthood is consistent with a recent report from the Bogalusa Heart Study that fasting plasma glucose in childhood is a predictor of T2DM as observed in the current and previous studies [11,38-40], failure to act on such childhood risk factors high TG, high BP, and obesity [12,16] means the underlying pathology may continue into young adulthood, and also focus diagnostic attention on the potentially high-risk parent.

Identifying CVD risk factors in a child can directly facilitate primary prevention [1] in the child through intervention [1,42,43] in childhood-adolescence might prevent development of CVD or T2DM in young adulthood.

A weakness in the current study is the absence of knowledge concerning when (at what age) participants with normal factors in childhood developed abnormal risk factors and when participants with abnormal factors in childhood developed normal risk factors. Thus, it was not possible to evaluate more precisely the length of time the at-risk state existed.

In the current study, neither pediatric nor young adult LDLc was associated with young adult CVD, perhaps attributable to treatment of high LDLc in 26 of 770 (3.4%) young adults at PFS, or to the fact that with only 19 CVD endpoints by mean age 38, the study may not have had adequate power to declare an LDLc effect significant. Treatment to lower LDLc might, speculatively, also have reduced the power of LDLc to predict CVD.

Conventionally, parental history of CVD serves as an indication for screening for lipid abnormalities in children [44,45]. After detailed review of basing childhood screening on parental history, the recent Expert Panel statement [1] called for universal risk factor screening in children [1]. Identification of CVD risk factors in a child can directly facilitate primary prevention [1] in the child through young adulthood, and also focus diagnostic attention on the potentially high-risk parent.

**Conclusions**

Risk factors for CVD and T2DM retained from childhood to adulthood predict CVD and T2DM in young adulthood and support universal childhood screening.
