Joint IRS Location and Size Optimization in Multi-IRS Aided Two-Way Full-Duplex Communication Systems

Christos N. Efrem and Ioannis Krikidis, Fellow, IEEE

Abstract—Intelligent reflecting surfaces (IRSs) have emerged as a promising wireless technology for the dynamic configuration and control of electromagnetic waves, thus creating a smart (programmable) radio environment. In this context, we study a multi-IRS assisted two-way communication system consisting of two users that employ full-duplex (FD) technology. More specifically, we deal with the joint IRS location and size (i.e., the number of reflecting elements) optimization in order to minimize an upper bound of system outage probability under various constraints: minimum and maximum number of reflecting elements per IRS, maximum number of installed IRSs, maximum total number of reflecting elements (implicit bound on the signaling overhead) as well as maximum total IRS installation cost. First, the problem is formulated as a discrete optimization problem and, then, a theoretical proof of its NP-hardness is given. Moreover, we provide a lower bound on the optimum value by solving a linear-programming relaxation (LPR) problem. Subsequently, we design two polynomial-time algorithms, a deterministic greedy algorithm and a randomized approximation algorithm, based on the LPR solution. The former is a heuristic method that always computes a feasible solution for which (a posteriori) performance guarantee can be provided. The latter achieves an approximate solution, using randomized rounding, with provable (a priori) probabilistic guarantees on the performance. Furthermore, extensive numerical simulations demonstrate the superiority of the proposed algorithms compared to the baseline schemes. Finally, useful conclusions regarding the comparison between FD and conventional half-duplex (HD) systems are also drawn.

Index Terms—Intelligent reflecting surface, IRS deployment, full-duplex communication, discrete optimization, NP-hardness, linear-programming relaxation, randomized rounding, approximation algorithm.

I. INTRODUCTION

INTelligent reflecting surface (IRS), also known as reconfigurable intelligent surface, has been considered as one of the most effective techniques to cope with the signal blockage in communication networks operating in millimeter-wave (mmWave) frequency bands. IRS is a planar surface which is installed on the walls or ceilings of buildings so as to create virtual line-of-sight (LoS) links between the transmitters and receivers, thus overcoming the physical obstacles between them. In particular, IRS consists of (mostly) passive reflecting elements that can independently induce a controllable phase shift on the incident electromagnetic wave [2], [3], [4].

Moreover, IRSs are not expected to perform any sophisticated signal processing operations that require radio-frequency (RF) chains, but only the necessary amplitude attenuation and phase rotation of signals via low-power electronic circuits. In other words, high-cost active components (e.g., power amplifiers) are not required, thus leading to low energy consumption and implementation cost. For this reason, IRSs are usually referred to as “nearly-passive” devices. In addition, they have much lower implementation cost than conventional technologies of active transceivers, such as amplify-and-forward, decode-and-forward relays and multiple-input-multiple-output systems [5], [6].

On the other hand, full-duplex (FD) wireless technology has the potential to double the spectral efficiency, compared to its half-duplex (HD) counterpart, by allowing simultaneous transmission and reception within the same frequency band. This can be achieved at the expense of higher implementation complexity due to the required loop-interference cancellation techniques [7], [8], [9]. Recently, there is a growing interest of the research community in combining IRSs with FD systems in order to exploit their benefits and advantages [10], [11], [12], [13], [14], [15], [16].

A. Related Work

To begin with, [17] presents an aerial-IRS (AIRS) system architecture in order to enhance the system performance, compared to the conventional terrestrial IRS, by exploiting the high altitude of AIRS. In particular, the authors study the joint optimization of the transmit beamforming of the ground source-node as well as the placement and passive beamforming of the AIRS. In addition, the single-IRS deployment problem (inside a 3-dimensional box), where an access point communicates with multiple users via the IRS, has been investigated in [18]. Specifically, the weighted sum rate maximization problem has been formulated for three multiple access schemes: non-orthogonal multiple access (NOMA), frequency division...
multiple access (FDMA), and time division multiple access (TDMA). In order to deal with these problems, the authors have used several methods, namely, monotonic optimization, semidefinite relaxation, alternating optimization and successive convex approximation. The capacity region of an IRS-aided communication system with two users has been studied in [19], for centralized and distributed (in two locations) IRS deployments. In millimeter-wave networks assisted by a single IRS, the optimal system performance is achieved when the IRS is placed closer to the receiver than the transmitter [20].

Furthermore, the problem of joint IRS deployment, phase-shift design as well as power allocation for maximizing the energy efficiency of a NOMA network has been recently formulated and solved using machine learning methods [21]. As concerns the coverage of an IRS-assisted network with one base station and one user equipment, [22] has examined the IRS placement problem to maximize the cell coverage by optimizing the IRS orientation and horizontal distance from the base station. Also, the optimal number of reflecting elements for an IRS, assisting the communication between a transmitter and a receiver, has been proposed in [23]. In particular, the system rate, energy efficiency, and their tradeoff are maximized by taking into consideration the signaling overhead required for the channel estimation and IRS phase-shift configuration.

Moreover, the (single) FD relay location and power optimization problem in a point-to-point (P2P) communication system has already been addressed in [24], [25], and [26]. Finally, [27], [28], [29], [30] have developed efficient optimization algorithms for the deployment of ground stations in RF and optical satellite networks with site diversity.

B. Main Contributions

In the majority of existing works, the IRS positions are assumed to be known in advance. However, IRS locations have a great impact on the overall system performance. As a result, their optimization is extremely important and deserves its own study. In this paper, we design efficient (polynomial-time) algorithms to jointly optimize the location and size (i.e., the number of reflecting elements) of multiple distributed IRSs in a two-way FD communication network. Specifically, the major contributions of this work are the following:

- **Extension of the IRS system model introduced in [11] to multi-IRS systems, including not only small-scale fading but also large-scale path loss. In this way, we exploit the geometric characteristics (i.e., the distances between users and IRSs) of the wireless network. Specifically, the deployment of multiple IRSs has two attractive features: i) small-scale diversity between the reflecting elements of the same IRS, and ii) large-scale diversity between the reflecting elements of distinct IRSs. In addition, the channel coefficients of a given user-to-IRS or IRS-to-user link can follow an arbitrary probability distribution (not necessarily Rayleigh fading as in [11]), while distinct IRSs may have different channel distributions.**

- **Recent works dealing with the IRS deployment often assume a continuous (bounded/unbounded) area for installing an IRS (for example, [18], [20], and [22]). Unlike previous research, in this article we consider a predetermined and finite set of available IRS locations, thus taking into account physical constraints for the IRS positions. This is of great practical interest, since IRSs are usually installed on the facades, walls or ceilings of existing buildings. Nevertheless, if we are interested in installing IRSs within a bounded continuous area, then this region can be divided into a sufficiently large finite number of distinct points (this method is known as discretization). Therefore, the proposed methodology is still applicable.**

- **Mathematical formulation of a discrete optimization problem in order to minimize an upper bound of system outage probability, which is subject to several constraints: minimum and maximum number of reflecting elements for each IRS, maximum number of installed IRSs, maximum total number of reflecting elements and maximum total IRS installation cost. In addition, a theoretical proof of its computational complexity (NP-hardness) is given.**

- **Furthermore, we construct a linear-programming relaxation (LPR) so as to lower bound the optimum value. Then, we develop two polynomial-time algorithms, namely, a deterministic greedy algorithm and a randomized approximation algorithm, whose key ingredient is the LPR solution. The first is a heuristic method which always finds a feasible solution to the problem, while the second achieves an approximate solution via randomized rounding. For the randomized algorithm, we also provide probabilistic performance guarantees using concentration inequalities (in particular, Hoeffding’s bound).**

- **Finally, numerical results show the superiority of the proposed algorithms compared to the benchmarks, while useful comparisons between FD and HD schemes are provided as well.**

C. Outline and Notation

The remainder of this paper is organized as follows. Section II describes the system model, while Section III formulates the optimization problem and studies its computational complexity. Afterwards, Section IV develops and analyzes the proposed optimization algorithms. In addition, numerical results are provided in Section V. Finally, useful conclusions and future research directions are given in Section VI, while Appendices A, B and C contain the proofs of theorems.

**Mathematical notation:** Italic letters denote (real/complex) scalars, boldface letters represent vectors and matrices, while calligraphic letters stand for sets and events. $|z|$ denotes the absolute value (or magnitude) of a complex number $z$ and $j = \sqrt{-1}$ is the imaginary unit. In addition, $|A|$ and $B^\mathsf{T}$ represent the cardinality of a set $A$ and the complement of an event $B$, respectively. The Cartesian product of the sets $(A_n)_{n \in N} = \{A_1, \ldots, A_N\}$ is denoted by $\times_{n \in N} A_n = A_1 \times \cdots \times A_N$. Moreover, $0_N$ is the $N$-dimensional zero vector and $[\cdot]_\mathsf{T}$ stands for the matrix transpose. The symbols $\leq \text{ and } \sim$ mean “equal by definition” and “distributed as”, respectively.
In this paper, we deal with a multi-IRS system assisting a two-way P2P communication link, as shown in Fig. 1, where the locations of users are fixed (i.e., the two users do not move). In particular, each user equipment (UE) operates in FD mode and therefore is equipped with either a single shared-antenna or a pair of separate antennas for signal transmission and reception, depending on the FD implementation [7]. In addition, $N = \{1, \ldots, N\}$ represents the set of available locations for installing an IRS (with $N \geq 1$), while $I = \{i_1, \ldots, i_T\}$ (where $I = |I|$) stands for the set of finally installed IRSSs. In each time-slot, we assume that exactly one IRS from the set $I$ is active and the remaining IRSs are idle (i.e., non-reflective). UE-1 transmits its data to UE-2, through the active IRS, and UE-2 transmits its data to UE-1, through the same IRS, simultaneously (i.e., within the same time-slot) by using the same frequency band. Note that FD technology is actually applied at both UEs, whereas IRSs are treated as passive devices that inherently operate in FD [11]. The transmit power of each UE is considered fixed for all time-slots; power control is outside the scope of this paper. Since both UEs suffer from strong loop-interference (LI) due to the FD operation, they employ the same LI-cancellation techniques (e.g., passive and active suppression in the analog/digital domain) [7], [8], [9], resulting in residual LI.

Moreover, the total UE-to-IRS and IRS-to-UE transmission time is within a coherence interval of the wireless channel. As a result, the forward and backward channels between a UE and an IRS can be regarded almost identical (reciprocal channels) [11]. Also, the direct link between UEs is considered strongly attenuated (high path-loss) due to the long distance, high carrier-frequency, or severe blockage by physical obstacles (no direct link). All IRSs are assumed to be passive (i.e., performing only phase shifts without amplification) and have negligible delay regarding the reflection of incident electromagnetic waves. We assume perfect channel state information (CSI), i.e., without estimation errors, and global CSI knowledge, i.e., available to both UEs [11]. Furthermore, there is a central controller that performs the IRS activation, adjusts the IRS phase-shifts and communicates the necessary CSI knowledge between UEs via separate low-latency wireless/wired backhaul links (illustrated by dash-dotted lines in Fig. 1).

Let $L_n$ be the number of reflecting elements of the $n^{th}$ IRS. The channel coefficient from UE-1 (UE-2) to the $n^{th}$ reflecting element of the $n^{th}$ IRS is denoted by $h_{n,\ell} = |h_{n,\ell}|e^{j\phi_{n,\ell}}$ (respectively, $g_{n,\ell} = |g_{n,\ell}|e^{j\phi_{n,\ell}}$), for every $n \in N$ and $\ell \in L_n = \{1, \ldots, L_n\}$. Also, the channel coefficients remain constant during one time-slot, but they change independently between distinct time-slots. For notational convenience, the channel coefficients corresponding to the $n^{th}$ IRS can be grouped in vector form, i.e., $\mathbf{h}_n = [h_{n,1}, \ldots, h_{n,L_n}]^\top$ and $\mathbf{g}_n = [g_{n,1}, \ldots, g_{n,L_n}]^\top$. All channel coefficients are assumed to be mutually independent [11], while, for a given $n \in N$, $\mathbf{h}_n$ and $\mathbf{g}_n$ are individually independent and identically distributed (i.i.d.) with possibly different probability distributions (e.g., Rice and Rayleigh distributions, respectively). The diagonal ($L_n \times L_n$) phase-shift matrix of the $n^{th}$ IRS is given by $\mathbf{\Phi}_n = \text{diag}(\delta_{1,1}^{n}, \ldots, \delta_{L_n,L_n}^{n})$, i.e., we consider only phase-shifts and not amplitude attenuation.

Under the above assumptions and following a similar approach with [11], the received signals at UE-1 and UE-2 in time-slot $t$ (after the LI mitigation), when only the $n^{th}$ IRS is active, are expressed as follows

$$y_1(t) = \sqrt{P_2} \sqrt{\delta_{n,2}} \delta_{n,1} \mathbf{\Phi}_n \mathbf{h}_n s_2(t) + \sqrt{P_1} \delta_{n,1} \mathbf{h}_n \mathbf{\Phi}_n h_n s_1(t) + \xi_1(t) + w_1(t),$$

$$y_2(t) = \sqrt{P_2} \delta_{n,2} \mathbf{g}_n \mathbf{\Phi}_n g_n s_2(t) + \sqrt{P_1} \delta_{n,1} \mathbf{g}_n \mathbf{\Phi}_n g_n s_1(t) + \xi_2(t) + w_2(t),$$

where $P_k$, $s_k(t)$, $\xi_k(t)$ and $w_k(t)$ are the transmit power, information symbol, residual LI and additive white Gaussian

1 IRS-assisted systems with imperfect CSI have been studied in [31]. The extension of our methodology to such a case deserves further investigation.

2 There are practical models where the amplitude and phase-shift of IRS elements are dependent on each other, e.g., [32]. However, these models are beyond the scope of this paper.
between the IRS and UE-k, respectively, for \( k \in \{1, 2\} \). In addition, \( \delta_{n,k} = A_0 d_{n,k}^{-\alpha} \) accounts for the large-scale path loss between the \( n \)th IRS and UE-k, where \( A_0 \) is a positive constant that depends on the carrier frequency, \( d_{n,k} \), their Euclidean distance, and \( \alpha \) is the path-loss exponent which depends on the wireless propagation environment. Note that, in the above equations, the first term represents the desired signal, while the second term is the self-interference (SI) induced by the IRS reflection of users’ own transmitted symbols. Given that UE-k has knowledge of \( P_k, s_k(t), \delta_{n,k}, h_k \) (required for \( k = 1 \)), \( g_n \) (needed for \( k = 2 \)), and \( \Phi_n \), it can completely remove the SI. Moreover, the residual LI \( \xi_k(t) \) and AWGN \( w_k(t) \) are modeled as independent zero-mean complex Gaussian random variables with variances \( \sigma_{\xi_k}^2 \) and \( \sigma_{w_k}^2 \), respectively. The variance of \( \xi_k(t) \) can be further expressed as \( \sigma_{\xi_k}^2 = \omega P_k^g \), where the constants \( \omega > 0 \) and \( \nu \in [0, 1] \) depend on the LI cancellation technique applied at the UEs [11].

For the sake of simplicity, we assume the following: \( P_1 = P_2 = P \) (the same transmit power), \( \mathbb{E}(|s_1(t)|^2) = \mathbb{E}(|s_2(t)|^2) = 1 \) (unit-power information symbols), \( \sigma_{w_1}^2 = \sigma_{w_2}^2 = \sigma_w^2 \) and \( \sigma_{\xi_1}^2 = \sigma_{\xi_2}^2 = \sigma_{\xi_k}^2 = \omega P_k^g \) (equal noise and residual-LI power). Consequently, the instantaneous signal-to-interference-plus-noise ratio (SINR) at both UEs, after the SI elimination, when communicating via the \( n \)th IRS is given by

\[
\gamma_n = \rho_n \left( \sum_{\ell \in L_n} |h_{n,\ell}||g_{n,\ell}| e^{j(\phi_{n,\ell} + \delta_{n,\ell} + \psi_{n,\ell})} \right)^2, \tag{3}
\]

where

\[
\rho_n = \frac{P \delta_{\ell}}{\sigma_{\xi_k}^2 + \sigma_w^2}, \tag{4}
\]

with \( \delta_{\ell} = \delta_{n,1} \delta_{n,2} \) being the overall path-loss between the two UEs through the \( n \)th IRS. This SINR formula is quite similar to that in [11], except for the total path-loss term \( \delta_{\ell} \) that is explicitly included in \( \rho_n \) instead of being incorporated in the channel coefficients \( h_{n,\ell} \) and \( g_{n,\ell} \).

Furthermore, the IRS phase-shifts are optimally designed in order to maximize the instantaneous SINR, that is,

\[
\phi_{n,\ell}^* = -\delta_{n,\ell} - \psi_{n,\ell}, \quad \forall \ell \in L_n = \{1, \ldots, L_n\}. \tag{5}
\]

Note that the IRS phase-shifts are adjusted by the central controller after obtaining the necessary CSI knowledge (channel coefficients’ phases) from the UE that performs the channel estimation. Also, we assume IRS phase-shifts without quantization errors, i.e., the IRS phase-shift resolution is infinite; in practice, if the number of bits, \( B \), used for controlling the phase of a reflecting element is very large (resulting in \( 2^B \) possible discrete values), then the quantization error can be considered insignificant.

Therefore, the maximum SINR at both UEs (when communicating via the \( n \)th IRS) is written as

\[
\gamma_n^* = \rho_n \left( \sum_{\ell \in L_n} |h_{n,\ell}||g_{n,\ell}| e^{j(\phi_{n,\ell} + \delta_{n,\ell} + \psi_{n,\ell})} \right)^2, \tag{6}
\]

where \( \zeta_n = \sum_{\ell \in L_n} \zeta_{n,\ell} \), with \( \zeta_{n,\ell} = |h_{n,\ell}||g_{n,\ell}| \geq 0 \), \( \forall \ell \in L_n \). Observe that the random variables \( \zeta_{n,\ell} \in L_n \) are i.i.d., because \( h_n \) and \( g_n \) are mutually independent and individually i.i.d.. Next, we denote the cumulative distribution function (CDF) of each \( \zeta_{n,\ell} \) by \( F_n : [0, +\infty) \to [0, 1] \), i.e.,

\[
F_n(u) = \Pr(\zeta_{n,\ell} \leq u), \quad \forall \ell \in L_n. \tag{7}
\]

Remark 1 (Rayleigh Fading): If \( h_n \) and \( g_n \) are i.i.d. complex normal/Gaussian random variables with zero mean and variance \( \sigma^2 \), then \( |h_{n,\ell}||g_{n,\ell}| \sim \text{Rayleigh}(\sigma/\sqrt{2}) \). In addition, according to [11], the CDF of each Rayleigh-product random variable \( \zeta_{n,\ell} \) is given by

\[
F^R_n(u) = 1 - \frac{2u}{\sigma^2} K_1 \left( \frac{2u}{\sigma^2} \right), \tag{8}
\]

where \( K_1(\cdot) \) is the modified Bessel function of the second kind of the first order.

Given an SINR threshold \( \gamma_{th} \), the outage probability of each UE is defined as \( P_{out,n}(L_n) = \Pr(\gamma_{n,\ell} \leq \gamma_{th}/\rho_n) \). Unfortunately, an exact closed-form expression of \( P_{out,n}(L_n) \) is usually not available in general (or hard to compute even if it exists). Nevertheless, to circumvent this difficulty, we resort to an upper bound of outage probability, i.e.,

\[
P_{out,n}(L_n) = \Pr \left( \sum_{\ell \in L_n} \zeta_{n,\ell} \leq \sqrt{\gamma_{th}/\rho_n} \right) \overset{a)}{\leq} \Pr \left( \max_{\ell \in L_n} \{\zeta_{n,\ell}\} \leq \sqrt{\gamma_{th}/\rho_n} \right) = \Pr \left( \bigcap_{\ell \in L_n} \{\zeta_{n,\ell} \leq \sqrt{\gamma_{th}/\rho_n} \} \right) \overset{b)}{=} \prod_{\ell \in L_n} \Pr(\zeta_{n,\ell} \leq \sqrt{\gamma_{th}/\rho_n}) \overset{c)}{=} \left[ F_n \left( \sqrt{\gamma_{th}/\rho_n} \right) \right]^{L_n} \overset{d)}{=} P_{out,n}(L_n), \tag{9}
\]

where inequality (a) is due to the fact that \( \sum_{\ell \in L_n} \zeta_{n,\ell} \geq \max_{\ell \in L_n} \{\zeta_{n,\ell}\} \), while equalities (b) and (c) follows from the independence of random variables \( \zeta_{n,\ell} \in L_n \) and equation (7), respectively. It is interesting to observe that the upper bound holds for any (arbitrary) CDF \( F_n(\cdot) \), while \( P_{out,n}(L_n) \) and \( P_{out,n}(L_n) \) are both nonincreasing functions of \( L_n \). In addition, \( \lim_{L_n \to \infty} P_{out,n}(L_n) = \lim_{L_n \to \infty} P_{out,n}(L_n) = 0 \), provided that \( F_n(\sqrt{\gamma_{th}/\rho_n}) < 1 \).

In order to derive the SINR formula, observe that \( g_n^T \Phi_n h_k = (\xi_k, \Phi_n h_k)^T = h_k, \Phi_n g_k = \sum_{\ell \in L_n} |h_{n,\ell}||g_{n,\ell}| e^{j(\phi_{n,\ell} + \delta_{n,\ell} + \psi_{n,\ell})} \).

In order to derive an approximation by equating the mean and variance of the two distributions. For instance, the Gamma distribution can approximate several complicated distributions by tuning its shape and scale parameters [11].
A. IRS Activation Policy

As we mentioned earlier, exactly one IRS is activated in each time-slot by the central controller, while the remaining IRSs are inactive (i.e., non-reflective). In particular, the central controller activates the IRS that achieves the highest (instantaneous) SINR among the installed IRSs [33], i.e.,

\[ i^* \in \arg\max_{i \in I} \{ \gamma_i^* \} \iff \gamma_i^* = \max_{i \in I} \{ \gamma_i^* \}, \]  

(10)

where \( \gamma_i^* \) is given by (6).

B. Upper Bound of System Outage Probability

Based on the aforementioned IRS activation strategy, the system outage probability can be computed as follows

\[
P_{\text{out}}(I, L) \triangleq \Pr(\gamma_{\text{out}}^* \leq \gamma_{\text{th}}) = \Pr\left( \max_{i \in I} \{ \gamma_i^* \} \leq \gamma_{\text{th}} \right) = \Pr\left( \bigcap_{i \in I} \{ \gamma_i^* \leq \gamma_{\text{th}} \} \right) \approx \prod_{i \in I} P_{\text{out},i}(L_i),
\]

(11)

where \( L = [L_1, \ldots, L_N]^\top \) and \( \gamma_{\text{th}} \) is the SINR threshold. Equalities (d) and (e) follow from (10), the independence of \( \{ \gamma_i^* \}_{i \in I} \) (due to the independence of \( \{ \gamma_i \}_{i \in I} \)) and the definition of \( P_{\text{out},i}(L_i) \approx \Pr(\gamma_i^* \leq \gamma_{\text{th}}) \), respectively.

Afterwards, by combining (11) with (9), we obtain the following upper bound of system outage probability

\[
P_{\text{out}}(I, L) \leq \prod_{i \in I} \left[ F_i(\sqrt{\gamma_{\text{th}}/\rho_i}) \right] L_i \triangleq \mathcal{T}_{\text{out}}(I, L).
\]

(12)

C. IRS Installation Cost Model

In this paper, we model the installation cost of IRS \( n \in \mathcal{N} \) as an affine function of the number of reflecting elements, i.e.,

\[
C_n(L_n) = c_n + \lambda_n L_n,
\]

(13)

where \( c_n \geq 0 \) is the fixed deployment cost and \( \lambda_n \geq 0 \) is the cost rate (measured in cost-units per element) of the corresponding IRS. In addition, the total installation cost is defined as the sum of the costs of all IRSs in the set \( I \), i.e.,

\[
C_{\text{tot}}(I, L) = \sum_{i \in I} C_i(L_i) = \sum_{i \in I} (c_i + \lambda_i L_i).
\]

(14)

Remark 2: In general, the IRS installation cost can be any nondecreasing function of the number of reflecting elements. In this case, we can approximate the installation cost by an affine function given by (13). In particular, the coefficients \( \{c_n, \lambda_n\} \) can be adjusted so as to minimize the error between the two functions (a procedure known as curve fitting) within a given interval of interest, e.g., for \( L_n \in \{ L_{n_{\min}}, \ldots, L_{n_{\max}} \} \).

D. Implementation Issues

First of all, the central controller is responsible for the synchronization of the following operations: 1) channel estimation for all the installed IRSs, 2) transfer of the total CSI knowledge from UE-2, that performs the channel estimation, to the central controller, 3) IRS activation and phase-shift adjustments (performed by the central controller, according to equations (5), (6) and (10)) plus notification of these decisions to both UEs, and 4) transfer of CSI corresponding to the activated IRS from the central controller to UE-1. It is very important for UEs to know which IRS is active, in each time-slot, together with the corresponding channel coefficients and phase-shift matrix in order to achieve complete cancellation of the SI. Consequently, the overall required overhead is \( \Theta(L_{\text{tot}}) \), where \( L_{\text{tot}} \) is the total number of reflecting elements.

Regarding the channel estimation of the (installed) IRSs, we can utilize \( I = [I] \) distinct orthogonal resource-blocks (e.g., frequency bands or time-slots), one for each IRS. Suppose that we want to estimate the channels between the IRS \( i \in I \) and UEs. In the corresponding resource-block, all the remaining IRSs are kept inactive (i.e., non-reflective), UE-1 acts only as a transmitter and UE-2 acts only as a receiver. In particular, UE-2 estimates the pair of channel coefficients \( \{ \delta_{i,1}, h_i \}, \{ \delta_{i,2}, g_j \} \) based on the received signal (observation), assuming that the transmitted symbols of UE-1 and IRS phase-shifts (pilot signals) are known to the receiver (UE-2); more details about the channel estimation procedure can be found in [34].

E. Half-Duplex (HD) Scheme

If the system operates in half-duplex (HD) mode, then the UEs transmit their data in two distinct time-slots:

\[ c_n \]

Note that \( c_n \) includes the rent of IRS location for a specific period of time, while \( \lambda_n \) can be obtained from IRS manufacturers and is expected to be the same for all IRSs (in general, it may be different for distinct IRSs).
time-slot 1 is allocated for UE-1 transmission and time-slot 2 for UE-2 transmission. As a result, each UE is equipped with a single antenna, utilizing the same frequency band, and there is no interference at all (neither self nor loop interference).

In this case, we can study the performance of HD scheme by appropriately modifying the previous equations of FD scheme. In particular, we should replace $\rho_n$ in (4) with $\rho_n^{HD} = P_B n / \sigma_w^2$ (since $\sigma_w^2 = 0$) and also $\gamma_n$ with $\gamma_n^{HD} = (1 + \gamma_n) / 2 - 1$, which is obtained by equating the spectral efficiencies of the two schemes, i.e., $\log(1 + \gamma_n^{HD}) = H^0_n$. The latter replacement is made for fair comparison between FD and HD scenarios in terms of outage probability.

III. OPTIMIZATION PROBLEM FORMULATION AND COMPUTATIONAL COMPLEXITY

In this section, we study the minimization of the upper bound of system outage probability $P_{out}(\mathcal{I}, L)$, given by (12), under various constraints. In particular, the IRS deployment problem consists of two components, namely, the selection of locations for installing IRSs and the determination of IRS sizes (that is, the number of reflecting elements).

Herein, we consider a predetermined and finite set of available IRS locations, thus taking into account physical constraints for the IRS positions. This is of great practical interest, since IRSs are usually installed on the facades, walls or ceilings of existing buildings. However, if we are interested in installing IRSs within a bounded continuous area, then this region can be divided into a sufficiently large finite number of distinct points (this technique is known as discretization). As a result, the proposed approach is still applicable.

As reported in Section II, the IRSs in the set $\mathcal{I}$ are installed only once, during the initial design of the system. After the installation phase, the central controller performs, in each time-slot, the IRS activation between the installed IRSs.

In this context, the joint IRS location and size optimization problem is formulated as follows

$$\min_{\mathcal{I}, L} P_{out}(\mathcal{I}, L) \equiv \prod_{i \in \mathcal{I}} \left[ F_i(\sqrt{\gamma_n^{HD}/\rho_n}) \right]^{L_i} \tag{15a}$$

s.t. $\mathcal{I} \subseteq \mathcal{N}$

$$L_n \in \{L_{n\min}, \ldots, L_{n\max}\}, \forall n \in \mathcal{N} \tag{15b}$$

$$|\mathcal{I}| \leq M \tag{15c}$$

$$L_{tot}(\mathcal{I}, L) \equiv \sum_{i \in \mathcal{I}} L_i \leq L_{n\max} \tag{15d}$$

$$C_{tot}(\mathcal{I}, L) \equiv \sum_{i \in \mathcal{I}} (c_i + \lambda_i L_i) \leq C_{\max} \tag{15e}$$

where $L_{n\min}, L_{n\max} \geq 0$ are the minimum and maximum number of reflecting elements of the $n$th IRS, respectively (with $L_{n\min} \leq L_{n\max}$). For example, IRS manufacturers may have some restrictions on the production process, while there are space limitations on the area (dimensions) that an IRS can occupy in a specific location/building.\(^9\) Also, $M \in \{0, 1, \ldots, N\}$ is the maximum number of installed IRSs, resulting in an IRS-cardinality constraint. Finally, $L_{n\max}, c_{\max} \geq 0$ denote the maximum total number of reflecting elements and the maximum total IRS installation cost, respectively. Note that constraint (15e) implicitly imposes an upper bound on the overall signaling overhead (channel estimation and feedback), which is required for IRS activation and phase adjustments (see Section II-D). In addition, for a given $\mathcal{I} \subseteq \mathcal{N}$, the values of $\{L_n\}_{n \in \mathcal{N}\setminus\mathcal{I}}$ are ultimately meaningless, since no IRS is installed at these locations. For convenience, Table I summarizes the mathematical symbols used in optimization throughout the paper.

A. Transformation Into Discrete Optimization Problem

Now, let us introduce a vector of binary (0/1) variables $\mathbf{x} = [x_1, \ldots, x_N]^{\top}$ such that, for all $n \in \mathcal{N}$, $x_n = 1$ if and only if (iff) $n \in \mathcal{I}$. Subsequently, the set $\mathcal{I}$ is replaced by the vector $\mathbf{x}$ in all functions that contained it with a slight abuse of notation. In particular, $\mathcal{I}$ and $\mathbf{x}$ are interchangeable because the one can be derived from the other by exploiting their iff-relation. With these in mind, we can make the following observations:\(^10\) 1) $P_{out}(\mathcal{I}, L) = \prod_{n \in \mathcal{N}} \left[ F_n(\sqrt{\gamma_n^{HD}/\rho_n}) \right]^{x_n L_n}$, 2) $|\mathcal{I}| = \sum_{n \in \mathcal{N}} x_n$, 3) $L_{tot}(\mathcal{I}, L) = \sum_{n \in \mathcal{N}} x_n L_n$ and 4) $C_{tot}(\mathcal{I}, L) = \sum_{n \in \mathcal{N}} (c_n + \lambda_n L_n) x_n$. Therefore, problem (15) can be written as follows

$$\min_{\mathbf{x}, L} P_{out}(\mathbf{x}, L) \equiv \prod_{n \in \mathcal{N}} \left[ F_n(\sqrt{\gamma_n^{HD}/\rho_n}) \right]^{x_n L_n} \tag{16a}$$

s.t. $x_n \in \{0, 1\}, \forall n \in \mathcal{N}$

$$L_n \in \{L_{n\min}, \ldots, L_{n\max}\}, \forall n \in \mathcal{N} \tag{16b}$$

$$\sum_{n \in \mathcal{N}} x_n \leq M \tag{16c}$$

$$L_{tot}(\mathbf{x}, L) \equiv \sum_{n \in \mathcal{N}} x_n L_n \leq L_{n\max} \tag{16d}$$

$$C_{tot}(\mathbf{x}, L) \equiv \sum_{n \in \mathcal{N}} (c_n + \lambda_n L_n) x_n \leq C_{\max} \tag{16e}$$

where $\mathbf{x}$, $L$ are the decision/optimization variables.

Since $\log(\cdot)$ is a monotonically increasing function, we can replace $P_{out}(\mathbf{x}, L)$ with its logarithm, without altering the set of optimal solutions. Hence, we obtain the equivalent discrete optimization problem

$$\min_{\mathbf{x}, L} G(\mathbf{x}, L) \equiv \log \left( P_{out}(\mathbf{x}, L) \right) = \sum_{n \in \mathcal{N}} \beta_n (x_n L_n) \tag{17a}$$

s.t. $x_n \in \{0, 1\}, \forall n \in \mathcal{N}$

$$L_n \in \{L_{n\min}, \ldots, L_{n\max}\}, \forall n \in \mathcal{N} \tag{17b}$$

$$L_{tot}(\mathbf{x}, L) \equiv \sum_{n \in \mathcal{N}} x_n L_n \leq L_{n\max} \tag{17c}$$

\(^9\)In addition, $L_{n\max}$ can be appropriately chosen to ensure that the spatial correlation among the IRS elements is negligible, i.e., $d \geq \lambda / 2$, where $d$ is their separation distance and $\lambda$ is the wavelength. For example, let $S_n$ be the maximum rectangular area of the $n$th IRS. Assuming uniform rectangular deployment of IRS elements (with $L_n = L_{n\max}^L$ and $d^2 = \theta^2 = \lambda/2$), we should guarantee that $(L_n^2 - 1)(L_n^2 - \lambda/2)^2 \leq S_n$. This inequality is satisfied if $L_{n\max} = 4S_n^{1/2}$, because $(L_n^2 - 1)/2 \leq L_n^2 \leq L_{n\max}$.

\(^10\)In order to avoid the undefined quantity $0^0$, we assume that $F_n(\sqrt{\gamma_n^{HD}/\rho_n}) > 0$, for all $n \in \mathcal{N}$.
Throughout the paper, we confront the problem of finding a (globally) optimal solution to problem (17). As we will see later, this problem is rather unlikely to be globally solved in polynomial time due to its discrete (and, thus, nonconvex) structure.

**Remark 3 (Feasibility):** Optimization problem (17) is always feasible, since the solution \((x, L) = (0, N, L^{\min})\), where \(L^{\min} = [L_1^{\min}, \ldots, L_N^{\min}]^\top\), satisfies all constraints.

### B. NP-Hardness

Afterwards, we examine the computational complexity of finding a (globally) optimal solution to problem (17).

**Theorem 1 (NP-Hardness):** Assume that the functions \(\{F_n(\cdot)\}_{n \in N}\), defined in (7), are continuous and (strictly) increasing. Then, the discrete optimization problem (17) is NP-hard.

**Proof:** See Appendix A. \(\square\)

### IV. OPTIMIZATION ALGORITHMS

Subsequently, we present the exhaustive-search (or brute-force) technique, a linear-programming relaxation (LPR), a greedy method as well as a randomized algorithm with complexity analysis for each one. The solution of LPR plays a central role in the design of greedy and randomized algorithms.

#### A. Exhaustive-Enumeration Algorithm

The exhaustive-enumeration method checks all possible solutions and selects that with the minimum objective value satisfying all constraints. In particular, for all subsets \(\mathcal{I}\) of \(N\) with cardinality at most \(M\), the algorithm examines all arrangements of reflecting elements. More specifically, for a given subset \(\mathcal{I}\), the number of arrangements of reflecting elements is \(\prod_{i \in \mathcal{I}}(L_i^{\max} - L_i^{\min} + 1)\), because the decision variable \(L_i\) can take \((L_i^{\max} - L_i^{\min} + 1)\) distinct values. In addition, for each arrangement, the algorithm requires \(\Theta(|\mathcal{I}|)\) time to compute the objective value, \(G(\mathcal{I}, L) = \sum_{i \in \mathcal{I}} \beta_i L_i\), and check the feasibility of constraints \(L_{\text{tot}}(\mathcal{I}, L) \leq L_{\text{tot}}^{\max}, c_{\text{tot}}(\mathcal{I}, L) \leq C_{\text{tot}}^{\max}\). Therefore, its overall runtime is \(\Theta(\sum_{\mathcal{I} \subseteq N} |\mathcal{I}| \prod_{i \in \mathcal{I}} R_i)\), where \(R_n = L_n^{\max} - L_n^{\min} + 1\) for all \(n \in N\).

It is not difficult to conclude that the algorithm has exponential complexity in terms of the size of the problem. Let us suppose that \(R_n = R \geq 1\) for all \(n \in N\). In this case, the algorithm requires \(\Theta \left( \sum_{\mathcal{I} \subseteq N} |\mathcal{I}| R^{|\mathcal{I}|} \right) = \Omega \left( \sum_{\mathcal{I} \subseteq N} |\mathcal{I}| R^{|\mathcal{I}|} \right) = \Omega \left( \binom{N}{M} M R^M \right)\) arithmetic operations to find the global minimum. Furthermore, if \(M = \lceil N/2 \rceil\), its complexity becomes \(\Omega \left( 2^N \sqrt{N} \right)\), since \(\left( \binom{N}{\lceil N/2 \rceil} \right) = \Theta \left( \frac{2^N}{\sqrt{N}} \right)\) and \([N/2] \geq N/2\).

Ultimately, albeit achieving a globally optimal solution, the exhaustive-enumeration algorithm has extremely high complexity and is therefore impractical.

#### B. Lower Bound Using Linear-Programming Relaxation

Despite the difficulty of computing the global minimum, we will show how to efficiently compute (in polynomial-time) a lower bound of the optimum value \(G^*\). Firstly, by using auxiliary decision variables \(z = [z_1, \ldots, z_N]^\top\), problem (17) can be equivalently written in the following form:

\[
\min_{x, L, z} \sum_{n \in N} \beta_n z_n
\]
Secondly, by relaxing the integer/discrete constraints, 

\[ x_n \in \{0, 1\}, \quad \forall n \in \mathcal{N} \]  

\[ L_n \in \{L_n^{\min}, \ldots, L_n^{\max}\}, \quad \forall n \in \mathcal{N} \]  

\[ z_n = x_n L_n, \quad \forall n \in \mathcal{N} \]  

\[ \sum_{n \in \mathcal{N}} x_n \leq M \]  

\[ \sum_{n \in \mathcal{N}} z_n \leq L_{\text{tot}}^{\max} \]  

\[ \sum_{n \in \mathcal{N}} c_n x_n + \sum_{n \in \mathcal{N}} \lambda_n z_n \leq C_{\text{tot}}^{\max} \]  

\[ (18b) \quad (18c) \quad (18d) \quad (18e) \quad (18f) \quad (18g) \]

Notice that this problem is nonlinear due to the equality constraints \( z_n = x_n L_n \). In order to obtain a linear problem, we apply further relaxation by replacing the set of constraints \( L_n^{\min} \leq L_n \leq L_n^{\max} \) and \( z_n = x_n L_n \) with the linear constraints \( L_n^{\min} x_n \leq z_n \leq L_n^{\max} x_n \). In this way, we can remove the decision variable \( L \) and formulate the following linear-programming relaxation (LPR) problem

\[ \min_{x, L, z} \sum_{n \in \mathcal{N}} \beta_n z_n \]  

s.t. \( 0 \leq x_n \leq 1, \quad \forall n \in \mathcal{N} \)  

\[ L_n^{\min} \leq L_n \leq L_n^{\max}, \quad \forall n \in \mathcal{N} \]  

\[ \sum_{n \in \mathcal{N}} x_n \leq M \]  

\[ \sum_{n \in \mathcal{N}} z_n \leq L_{\text{tot}}^{\max} \]  

\[ \sum_{n \in \mathcal{N}} c_n x_n + \sum_{n \in \mathcal{N}} \lambda_n z_n \leq C_{\text{tot}}^{\max} \]  

\[ (19a) \quad (19b) \quad (19c) \quad (19d) \quad (19e) \quad (19f) \quad (19g) \]

Notice that this guaranteed feasibility of problem (17) (see Remark 3) implies the feasibility of problems (18), (19) and (20). In what follows, \((x^\dagger, z^\dagger)\) and \(G^\dagger = \sum_{n \in \mathcal{N}} \beta_n z_n^\dagger\) denote an optimal solution and the global minimum of the LPR problem (20), respectively. Obviously, \(G^\dagger \leq G^*\), that is, \(G^\dagger\) is a lower bound of \(G^*\).

Finally, given that the linear problem (20) has \( V = 2N \) = \( \Theta(N) \) decision variables and \( U = 4N + 3 \) = \( \Theta(N) \) constraints, a globally optimal solution can be computed in \( O((U + V)^{1.5} \sqrt{V}) = O(N^{3.5}) \) time using an interior-point method [35].

### C. Deterministic Greedy Algorithm

Now, we are ready to develop a heuristic algorithm of polynomial complexity to obtain a feasible solution for the discrete problem (17). This procedure is given in Algorithm 1 and is called LPR-based greedy algorithm (LPR-GA).

First, the proposed algorithm applies deterministic rounding, using the solution of LPR (step 1), in order to compute the decision variable \( L' \) (steps 3–9):

\[ L'_n = \begin{cases} \text{round} \left( \frac{z_n^\dagger}{x_n^\dagger} \right), & \text{if } x_n^\dagger \neq 0 \\ \text{round} \left( \frac{1}{2} (L_n^{\min} + L_n^{\max}) \right), & \text{otherwise} \end{cases} \]

\[ (20a) \quad (20b) \quad (20c) \quad (20d) \quad (20e) \quad (20f) \]

Observe that, if \( x_n^\dagger \neq 0 \), then \( L_n^{\min} \leq z_n^\dagger / x_n^\dagger \leq L_n^{\max} \) (due to the feasibility of LPR problem) and therefore \( \{z_n^\dagger / x_n^\dagger\} \in \{L_n^{\min}, \ldots, L_n^{\max}\} \). Also, the same holds for \( \text{round} \left( \frac{1}{2} (L_n^{\min} + L_n^{\max}) \right) \) in case of \( x_n^\dagger = 0 \). In other words, the above deterministic rounding guarantees that \( L'_n \in \{L_n^{\min}, \ldots, L_n^{\max}\} \) for all \( n \in \mathcal{N} \).

Concerning the computation of \( x' \), the proposed algorithm sorts the entries of \( x^\dagger \) \( = \left[ x_1^\dagger, \ldots, x_N^\dagger \right] ^\top \) \( \in [0, 1]^N \) in descending order (step 11). Then, by starting from the zero vector, it successively selects IRS locations (based on their
sorting) until the violation of at least one of the constraints: \( \sum_{n \in \mathcal{N}} x_n \leq M, L_{tot}(x, L) \leq L_{tot}^{max} \) and \( C_{tot}(x, L) \leq C_{tot}^{max} \) (steps 12–17). Finally, it removes the last selected IRS location if \( L_{tot} > L_{tot}^{max} \) or \( C_{tot} > C_{tot}^{max} \) (steps 18–20); note that the IRS-cardinality constraint is automatically satisfied due to the construction of the while-loop, so there is no need to check it in step 18.

Obviously, the solution \((\bar{x}', \bar{L}')\) returned by Algorithm 1 is guaranteed to be feasible for problem (17), thus \( G^* \leq G' \triangleq G(\bar{x}', \bar{L}'), \) i.e., \( G' \) is an upper bound of \( G^* \).

**Remark 4 (A Posteriori Performance Guarantee):** It is possible to provide an approximation guarantee after the termination of Algorithm 1 using the already obtained solution of LPR, that is, \( 0 \leq G' - G^* \leq G' - G^* \).

Regarding the complexity of Algorithm 1, the LPR problem can be solved in \( O(N^{3.5}) \) time, the computation of \( L' \) requires \( \Theta(N) \) time, while the computation of \( x' \) requires \( O(N \log N + N) = O(N \log N) \) arithmetic operations in total. Hence, the overall complexity of LPR-GA is \( O(N^{3.5} + N \log N) = O(N^{3.5}) \). In other words, it has the same asymptotic complexity (up to a constant) as the LPR problem.

### D. Randomized Approximation Algorithm

Since problem (17) is NP-hard, a polynomial-time algorithm for computing its global optimum cannot exist, unless P=NP. However, we can use randomized rounding, a powerful technique, in order to achieve an approximate solution with high probability.

Afterwards, we present an efficient (i.e., polynomial-time) approximation algorithm that finds provably near-optimal solutions. This method is shown in Algorithm 2 and is referred to as LPR-based randomized algorithm (LPR-RA).

First of all, Algorithm 2 finds an optimal solution \((\bar{x}^1, \bar{z}^1)\) to the LPR problem in step 1, and then employs randomization (steps 2–21) to compute an approximate solution \((\tilde{x}, \tilde{L})\) according to the following probabilistic rules, for all \( n \in \mathcal{N} \),

\[
\tilde{x}_n = \begin{cases} 
1, & \text{with probability } x_n^1 \\
0, & \text{with probability } 1 - x_n^1
\end{cases}
\tag{22}
\]

and

\[
\tilde{L}_n = \begin{cases} 
\lfloor L_n^1 \rfloor + 1, & \text{with probability } \frac{\text{frac}(L_n^1)}{\text{frac}(L_n^1)}, \\
L_n^1, & \text{with probability } 1 - \frac{\text{frac}(L_n^1)}{\text{frac}(L_n^1)},
\end{cases}
\tag{23}
\]

where \( L_n^1 = z_n^1/x_n^1 \) is defined whenever \( x_n^1 \neq 0 \). For a given LPR solution \((\bar{x}, L')\), the random variables \((\tilde{x}_n, \tilde{L}_n)\) are independent. Also, we define the random variable \( \tilde{\bar{x}}_n = \tilde{x}_n \tilde{L}_n \) for all \( n \in \mathcal{N} \).

In case \( x_n^1 \neq 0 \), observe that \( L_{n, \min} \leq L_n^1 \leq L_{n, \max} \) (because \( L_{n, \min} x_n^1 \leq z_n^1 \leq L_{n, \max} x_n^1 \)), therefore rule (23) implies

\[
\tilde{L}_n \sim \text{Uniform}\left(\{L_{n, \min}^1, \ldots, L_{n, \max}^1\}\right), \quad \text{if } x_n^1 = 0,
\tag{24}
\]

where \( L_n^1 = z_n^1/x_n^1 \) is defined whenever \( x_n^1 \neq 0 \). For a given LPR solution \((\bar{x}, L')\), the random variables \((\tilde{x}_n, \tilde{L}_n)\) are independent. Also, we define the random variable \( \tilde{\bar{x}}_n = \tilde{x}_n \tilde{L}_n \) for all \( n \in \mathcal{N} \).

Note that the function \( \text{rand}(0, 1) \) in steps 4 and 12 returns a random number uniformly distributed in the interval [0, 1]. Also, the function \( \text{rand}(L_{n, \min}^1, L_{n, \max}^1) \) in step 19 returns a random number uniformly distributed in the set \( \{L_{n, \min}^1, \ldots, L_{n, \max}^1\} \). The outputs of different function calls are independent.

**Algorithm 2 LPR-Based Randomized Algorithm (LPR-RA)**

**Input:** \( N, \beta = [\beta_1, \ldots, \beta_N]^\top, L_{\min} = [L_{\min}^1, \ldots, L_{\min}^N]^\top, L_{\max} = [L_{\max}^1, \ldots, L_{\max}^N]^\top, M, L_{\max}^\top, c = [c_1, \ldots, c_N]^\top, \lambda = [\lambda_1, \ldots, \lambda_N]^\top, C_{\max}^{\top} \)

**Output:** An approximate solution \((\tilde{x}, \tilde{L})\) of discrete problem (17)

1: Solve the LPR problem (20) to obtain an optimal solution \((x^1, z^1)\).
2: for all \( n \in \mathcal{N} \) do
3: \( \triangleright \) Computation of \( \tilde{x}_n \)
4: \( r := \text{rand}(0, 1) \)
5: if \( r \leq x_n^1 \) then \( \triangleright \) with probability \( x_n^1 \)
6: \( \tilde{x}_n := 1 \)
7: else \( \triangleright \) with probability \( 1 - x_n^1 \)
8: \( \tilde{x}_n := 0 \)
9: end if
10: \( \triangleright \) Computation of \( \tilde{L}_n \)
11: if \( x_n^1 \neq 0 \) then
12: \( s := \text{rand}(0, 1) \)
13: \( L_n^1 := z_n^1/x_n^1 \)
14: if \( s \leq \text{frac}(L_n^1) \) then \( \triangleright \) with probability \( \text{frac}(L_n^1) \)
15: \( \tilde{L}_n := \lfloor L_n^1 \rfloor + 1 \)
16: else \( \triangleright \) with probability \( 1 - \text{frac}(L_n^1) \)
17: \( \tilde{L}_n := \lfloor L_n^1 \rfloor \)
18: end if
19: end if
20: \( \tilde{\bar{x}}_n := \text{rand}(I_{n, \min}^1, I_{n, \max}^1) \)
21: end for
22: return \((\tilde{x}, \tilde{L})\)

that \( \tilde{L}_n \in \{L_{n, \min}^1, \ldots, L_{n, \max}^1\} \). Also, the same holds when \( x_n^1 = 0 \) due to (24). Hence, the probabilistic rules (22)–(24) ensure that the approximate solution returned by LPR-RA, \((\tilde{x}, \tilde{L})\), satisfies the integer/discrete constraints automatically, i.e., \( \tilde{x}_n \in \{0, 1\} \) and \( \tilde{L}_n \in \{L_{n, \min}^1, \ldots, L_{n, \max}^1\} \) for every \( n \in \mathcal{N} \).

Now, it remains to answer how close is the achieved objective value \( G' \triangleq G(\tilde{x}, \tilde{L}) \) to the global minimum \( G^* \), and whether or not the last three constraints, (17d), (17e) and (17f), are satisfied. Of course, there is no absolute/deterministic answer to these type of questions since \( \tilde{x} \) and \( \tilde{L} \) are random variables. Nevertheless, we can provide some (a priori) probabilistic guarantees on the algorithm’s performance.

**Theorem 2 (Expectation Guarantees):** The solution \((\tilde{x}, \tilde{L})\) of LPR-RA has the following properties:

\[
E\left(G(\tilde{x}, \tilde{L})\right) = G^1, \tag{25}
\]

\[
E\left(\sum_{n \in \mathcal{N}} \tilde{x}_n\right) = \sum_{n \in \mathcal{N}} x_n^1 \leq M, \tag{26}
\]

\[
E\left(L_{tot}(\tilde{x}, \tilde{L})\right) = \sum_{n \in \mathcal{N}} z_n^1 \leq L_{tot}^{max}, \tag{27}
\]
\[ E \left( C_{\text{tot}}(\mathbf{x}, \mathbf{L}) \right) = \sum_{n \in N} c_n x_n^2 + \sum_{n \in N} \lambda_n z_n^2 \leq C_{\text{tot}}^{\text{max}}. \tag{28} \]

**Proof:** See Appendix B. \( \square \)

In other words, the solution \((\mathbf{x}, \mathbf{L})\) satisfies in expectation the three constraints (17d)–(17f) and its objective value is in expectation equal to that of LPR.

Afterwards, we give some deviation guarantees using concentration inequalities, that is, probability bounds on how close a random variable is from some value (typically, its expectation).

**Theorem 3 (Deviations Guarantees):** Let \[ \sum_{n \in N} (\beta_n L_{n}^{\text{max}})^2, \quad \Delta_1 = N \left( \geq 1 \right), \quad \Delta_2 = \sum_{n \in N} (L_{n}^{\text{max}})^2 \]
and
\[ \Delta_3 = \sum_{n \in N} (c_n + \lambda_n L_{n}^{\text{max}})^2 \text{ with } \Delta_0, \Delta_2, \Delta_3 > 0. \]
Then, the solution \((\mathbf{x}, \mathbf{L})\) achieved by Algorithm 2 satisfies the following probabilistic conditions:
\[ \Pr(\xi_k) \geq 1 - \xi, \quad \forall k \in \{0, 1, 2, 3\}, \tag{29} \]
where \(\xi = (N + 1)^{-2} \in (0, 1/4]\) and the events \(\{\xi_k\}_{k=0}^{3}\) are defined by
\[ \xi_0 = \left\{ G(\mathbf{x}, \mathbf{L}) \leq G^* + \epsilon_0 \right\}, \tag{30} \]
\[ \xi_1 = \left\{ \sum_{n \in N} x_n \leq M + \epsilon_1 \right\}, \tag{31} \]
\[ \xi_2 = \left\{ L_{\text{tot}}(\mathbf{x}, \mathbf{L}) \leq L_{\text{tot}}^{\text{max}} + \epsilon_2 \right\}, \tag{32} \]
\[ \xi_3 = \left\{ C_{\text{tot}}(\mathbf{x}, \mathbf{L}) \leq C_{\text{tot}}^{\text{max}} + \epsilon_3 \right\}. \tag{33} \]

with \(\epsilon_k = \sqrt{\Delta_k \log(N + 1)} > 0\) for all \(k \in \{0, 1, 2, 3\}\).

Furthermore, the approximate solution \((\mathbf{x}, \mathbf{L})\) satisfies the following inequalities (which are called overall deviation guarantees):
\[ \Pr \left( \bigcap_{k=1}^{3} \xi_k \right) \geq 1 - \xi', \tag{34} \]
\[ \Pr \left( \bigcap_{k=0}^{3} \xi_k \right) \geq 1 - \xi'', \tag{35} \]
where \(\xi' = 3\xi \in (0, 3/4]\) and \(\xi'' = 4\xi = 4(N + 1)^{-2} \in (0, 1]\).

**Proof:** See Appendix C. \( \square \)

In essence, \(\epsilon_0\) quantifies the deviation from the global optimum, while \(\{\xi_k\}_{k=1}^{3}\) express the violation tolerance for each constraint. Moreover, (34) has to do with the satisfiability of the three constraints (17d)–(17f), while (35) includes additionally the objective value.

Notice that \(\xi = \xi(N) = o(1), \quad \xi' = \xi'(N) = o(1)\) and \(\xi'' = \xi''(N) = o(1)\). Therefore, an approximate solution satisfying any nonempty subset of \(\{\xi_k\}_{k=0}^{3}\) can be found with high probability, i.e., with probability \(1 - o(1)\). However, observe that there is an inherent tradeoff between the probability bound \(1 - \xi\) and a deviation tolerance \(\xi_k\) that is, both of them increase with \(N\) but with different growth rates.

**Remark 5 (Performance Improvement):** In order to enhance the algorithm’s performance (i.e., achieve better probability bounds), we can use multiple i.i.d. rounding trials at the cost of increased computational complexity.

For example, let \(T\) be the number of rounding trials and \((\mathbf{x}^{(t)}, \mathbf{L}^{(t)})\) be the approximate solution obtained in rounding trial \(t \in \{1, \ldots, T\}\). Also, for every \(k \in \{1, 2, 3\}\), let \(\xi_k^{(t)}\) be the event \(\xi_k\) (see (31)–(33)) with \((\mathbf{x}, \mathbf{L})\) replaced by \((\mathbf{x}^{(t)}, \mathbf{L}^{(t)})\). Then, the probability of finding at least one approximate solution \((\mathbf{x}^{(t)}, \mathbf{L}^{(t)})\) satisfying all the events \(\{\xi_k^{(t)}\}_{k=1}^{3}\), within \(T\) rounding trials, is lower bounded by
\[ \Pr \left( \bigcup_{t=1}^{T} \left( \bigcap_{k=1}^{3} \xi_k^{(t)} \right) \right) = 1 - \Pr \left( \bigcap_{t=1}^{T} \left( \bigcup_{k=1}^{3} \xi_k^{(t)} \right) \right) \]
\[ = 1 - \prod_{t=1}^{T} \Pr \left( \bigcup_{k=1}^{3} \xi_k^{(t)} \right) \]
\[ = 1 - \left[ \Pr \left( \bigcup_{k=1}^{3} \xi_k \right) \right]^{T} \]
\[ \geq 1 - \xi'^{T}, \tag{36} \]
where the first and fourth equalities are because of De Morgan’s law, the second and third equalities follows from the i.i.d. assumption of rounding trials, while the last inequality is due to (34). It is not hard to see that, given \(\xi' \in (0, 3/4]\), this probability tends to 1 as \(T \rightarrow \infty\).

Concerning the complexity of Algorithm 2, the LPR problem requires \(O(N^{3.5})\) time, while the computation of \((\mathbf{x}, \mathbf{L})\) takes \(\Theta(N)\) time. As a result, the total complexity of LPR-GA is \(O(N^{3.5} + N) = O(N^{3.5})\), that, is asymptotically the same (up to a constant) as that of LPR and LPR-GA. In case of \(T\) i.i.d. rounding trials (see Remark 5), the computational complexity increases to \(O(N^{3.5} + NT)\). Finally, the complexity and performance of all optimization algorithms are summarized in Table II.

V. NUMERICAL RESULTS AND DISCUSSION

The main objective of this section is twofold: the first is to compare the performance of optimization algorithms (in terms of the upper bound of system outage probability) and the second is the comparison between FD and HD schemes.

A. Simulation Setup

We generate random system configurations, where UE-1 and UE-2 are constantly located at \((0, 0)\) and \((100, 0)\), respectively, while each IRS location is uniformly distributed either inside the rectangle \([30, 70] \times [20, 40]\) or \([30, 70] \times [-40, -20]\), with probability \(1/2\) of being in each rectangle.\(^{13}\)

\(^{13}\)In practice, if Algorithm 2 fails to find a feasible solution despite performing a relatively large number of rounding trials, then we can use Algorithm 1 that is guaranteed to find a feasible solution.

\(^{14}\)The convergence of Algorithms 1 and 2 is theoretically guaranteed, since the number of for/while-loop iterations is finite for any given \(N\) (recall that \(M \leq N\)).

\(^{15}\)Here, the IRSs are distributed in the 2D-space for the sake of simplicity. Nevertheless, the proposed methodology is straightforwardly applicable to 3D-space scenarios, where the IRSs may be located at different heights.
All channel coefficients are generated according to Remark 1 (i.e., Rayleigh fading). Unless otherwise stated, the system parameters are presented in Table III; the positions of UEs and IRSs are on the x-y plane and all coordinates are expressed in meters. Note that, for a given problem, the IRS locations \( \{ (x_n, y_n), \beta_n \}_{n \in N} \) are all fixed (the randomization is only used for problem generation). Since there are no established values of IRS cost parameters yet, the simulations are just indicative to evaluate algorithms’ performance. In addition, all figures present average values obtained from \( 10^3 \) independent simulation scenarios. Also, the LPR problem (20) is solved using CVX software [36] with SDPT3 solver [37].

Moreover, for every problem instance, LPR-RA performs a maximum number of i.i.d. rounding trials, \( T_{\text{max}} \), in order to increase the probability of achieving a feasible solution. In particular, Algorithm 2 generates independent approximate solutions successively and terminates either when a feasible solution is found or when the maximum number of trials is reached. In all figure captions, we have included the percentage of problems for which LPR-RA returned a feasible solution, within the maximum number of rounding trials.

Despite the fact that a comparison with the optimum value would have been useful, this does not appear in the numerical results (except Fig. 6) because the complexity of the exhaustive-enumeration algorithm is extremely high.

For example, consider a problem with \( N = 25, M = 7, L_{\text{min}} = 5 \) and \( L_{\text{max}} = 40 \) (as shown in Table III). In this case, the exhaustive-enumeration algorithm would require at least \( \binom{N}{M} MR^M \approx 2.637 \times 10^{17} \) arithmetic operations, where \( R = L_{\text{max}} - L_{\text{min}} + 1 \) (cf. Section IV-A). If each operation takes approximately 1 \( \mu \)s, then the algorithm’s runtime (for a single problem) is roughly \( 7.325 \times 10^6 \) hr \( \approx 3.052 \times 10^8 \) d \( \approx 8.362 \times 10^9 \) yr, which is obviously prohibitive.

Nevertheless, we definitely know that the minimum value always lies between LPR (lower bound) and LPR-GA (upper bound, since its solution is guaranteed to be feasible), that is, \( G^\dagger \leq G^* \leq G' \). Similar inequalities also hold for the upper bound of system outage probability, \( \overline{P}_\text{out}(\cdot) \), due to the monotonicity of exponential function; recall that \( G(\cdot) = \log(\overline{P}_\text{out}(\cdot)) \).

**B. Baseline Schemes (Benchmarks)**

In order to evaluate the performance of the proposed algorithms, we consider (besides the lower bound obtained from LPR) two baseline schemes:

- **Average-element greedy algorithm (AEGA):** First, the number of reflecting elements \( L_n \) is set equal to \( L_n^{\text{avg}} = \frac{1}{2} \left[ L_{\text{min}} + L_{\text{max}} \right] \) for all \( n \in N \). Then, we sort the IRS locations in ascending order among the IRS locations not selected yet, while satisfying all constraints.
- **Maximum-element greedy algorithm (MEGA):** This algorithm follows the same procedure as AEGA by replacing \( L_n^{\text{avg}} \) with \( L_n^{\text{max}} \), for all \( n \in N \).

Both methods are heuristic algorithms (i.e., without a priori performance guarantees) with computational complexity...
Fig. 2. Upper bound of system outage probability versus the maximum total IRS installation cost. The percentage of problems for which LPR-RA has achieved a feasible solution is [98.5, 98.4, 99.3, 98.6, 99.1, 99.2, 99.5]% for each value of \( C_{\text{tot}}^{\text{max}} \), respectively.

Fig. 3. Upper bound of system outage probability versus the maximum number of reflecting elements. The percentage of problems for which LPR-RA has found a feasible solution is [98.7, 98.4, 98.1, 98.3, 99.6, 98.3] for each value of \( L_{\text{max}} \), respectively.

Fig. 4. Upper bound of system outage probability versus the number of available IRS locations. The percentage of problems for which LPR-RA has returned a feasible solution is [97.7, 98.2, 98.5, 98.9, 99.1, 98.7, 99.6]% for each value of \( N \), respectively.

Fig. 5. Upper bound of system outage probability versus the SINR threshold. The percentage of problems for which LPR-RA has returned a feasible solution is [97.7, 98.2, 98.5, 98.9, 99.1, 98.7, 99.6]% for each value of \( \gamma_{\text{th}} \), respectively.

Outage probability is \( O(N \log N) \) because of the sorting procedure. In addition, they always find a feasible solution due to their design.

C. Performance Comparison of Optimization Algorithms

Subsequently, the performance of optimization algorithms is examined by varying the maximum total IRS installation cost, the maximum number of reflecting elements, the number of available IRS locations, the SINR threshold as well as the noise power.

1) Impact of the Maximum Total IRS Installation Cost: Fig. 2 shows the upper bound of system outage probability, against the maximum total IRS installation cost, achieved by AEGA, MEGA, LPR, LPR-GA (Algorithm 1) and LPR-RA (Algorithm 2). As expected, the outage probability is a nonincreasing function of \( C_{\text{tot}}^{\text{max}} \) for all algorithms, since larger \( C_{\text{tot}}^{\text{max}} \) translates to a less restricted feasible set. Furthermore, the proposed algorithms, LPR-GA and LPR-RA, achieve higher performance than the two benchmarks, AEGA and MEGA (with AEGA having the worst performance). It is interesting to observe that LPR-GA and LPR-RA exhibit very similar (almost identical) performance, which is close to the lower bound of LPR. Intuitively, we anticipate such behavior because both algorithms rely on LPR. Finally, LPR-RA demonstrates extremely high percentage (above 98%) of achieving a feasible solution within \( T_{\text{max}} = 50 \) rounding trials.

2) Impact of the Maximum Number of Reflecting Elements: The effect of the maximum number of reflecting elements (for each IRS) on the system outage probability is presented in Fig. 3. Similar conclusions with Fig. 2 can be drawn here as well. In addition, MEGA performs slightly worse than LPR-GA and LPR-RA for small values of \( L_{\text{max}} \) (e.g., 25 and 30), whereas their difference in performance becomes more apparent as \( L_{\text{max}} \) increases.

3) Impact of the Number of Available IRS Locations: Fig. 4 illustrates the system outage probability as a function of the number of candidate locations for installing an IRS. More specifically, we can observe that, as \( N \) increases, all algorithms achieve lower outage probability because there are more options available for the IRS deployment. Once again, the proposed algorithms (LPR-GA and LPR-RA) significantly outperform the baseline schemes, especially when \( N \) is relatively large, and remain close to the lower bound (and, thus, to the global minimum) for all values of \( N \). The latter demonstrates the robustness of the developed algorithms in terms of the size of the search space (cf. Figs. 2 and 3).

4) Impact of the SINR Threshold: The upper bound of the system outage probability versus the SINR threshold is shown in Fig. 5. In particular, the outage probability increases with \( \gamma_{\text{th}} \) for all optimization algorithms, which is intuitively expected. Furthermore, it is interesting to note that the distance of the objective value achieved by AEGA, MEGA, LPR-GA, LPR-RA from the lower bound decreases as the SINR threshold increases. Roughly speaking, this means that the achieved solution tends to be globally optimal, especially for LPR-GA and LPR-RA.

5) Impact of the Noise Power and Comparison With Exhaustive Search: Here, we also consider the exhaustive enumeration algorithm under small-scale setups with the following parameters: \( \gamma_{\text{th}} = 3 \) dB, \( N = 7, M = 4, L_{\text{min}} = 35, L_{\text{max}}^{\text{max}} = 50, L_{\text{max}}^{\text{max}}\text{tot} = 115, C_{\text{tot}}^{\text{max}} = 30 \). In Fig. 6, it is clear that the upper bound of outage probability increases with the noise power, for all algorithms. In spite of the fact that the proposed algorithms do not achieve the global minimum (recall that...
problem (17) is NP-hard, according to Theorem 1), their performance is again much higher than AEGA and MEGA. Moreover, the average number of selected IRS locations, the average total number of reflecting elements, and the average total IRS installation cost are respectively: [1.4, 60.6, 21.2] for AEGA, [1.2, 61.5, 20.8] for MEGA, [1.7, 86, 21.9] for LPR-GA, [22, 1.7, 85.9] for LPR-RA, and [2.1, 92.7, 24.5] for exhaustive enumeration. We can observe that LPR-GA/RA selects more IRS locations and reflecting elements at the expense of higher cost compared to AEGA/MEGA; this is also true if we compare exhaustive enumeration with LPR-GA/RA.

D. Comparison Between FD and HD Systems

Afterwards, the optimization algorithms are used in order to make meaningful comparisons between FD and HD wireless technologies.\textsuperscript{16}

1) Impact of the Transmit Power of UEs: Firstly, let us examine the effect of the transmit power of UEs on the system outage probability. According to Fig. 7, the proposed optimization algorithms perform much better than the two benchmarks, especially for high transmit power, in both HD and FD schemes. In addition, we can observe that FD is superior to HD system (in terms of outage probability) when $P < 26$ dBm, irrespective of the algorithm used for comparison. On the other hand, FD is inferior to HD scheme when $P > 26$ dBm.

2) Impact of the Residual-LI Power: Secondly, we study how the residual-LI power affects the system outage probability, assuming constant transmit power. Based on Fig. 8, it is obvious that LPR-GA and LPR-RA again show better performance compared to the baseline schemes, not only in FD but also in HD scenario. Moreover, for the FD scheme, the upper bound of system outage probability increases rapidly with the residual-LI power. Finally, FD outperforms HD system when $\sigma^2_{LI}$ is approximately less than $-70.4$ dBm, whereas HD is preferable when $\sigma^2_{LI}$ is greater than $-70.4$ dBm (regardless of the comparison algorithm). In other words, FD is more beneficial than HD technology, provided that the LI at each UE is sufficiently suppressed.

\textsuperscript{16}For details on the HD scheme, see Section II-E.
VI. CONCLUSION AND FUTURE WORK

In this paper, we have dealt with the minimization of outage probability in a two-way FD communication system assisted by multiple IRSs. In particular, we have transformed the joint IRS location and size optimization problem into a discrete problem, which turned out to be NP-hard. In order to overcome this difficulty, two efficient (polynomial-time) algorithms have been proposed, which are based on the solution of LPR. The first is a deterministic greedy method, while the second is a randomized approximation algorithm. According to the numerical results, the developed algorithms have shown much higher performance than the benchmarks. Their achieved objective values have also been close to the lower bound and, therefore, to the global minimum. Moreover, we have observed that FD outperforms HD scheme, provided that the LI at both UEs is adequately mitigated; this is in line with our intuition.

Finally, we mention several challenging research directions: i) extension to multiple-antenna systems with multiple users, ii) analysis of IRS-activation schemes with lower signaling overhead using, for example, partial CSI knowledge and iii) investigation of IRS phase-adjustment errors due to imperfect CSI or phase-quantization errors (finite phase-shift resolution).

APPENDIX A

PROOF OF THEOREM 1

It is sufficient to show that there is a special case of problem (17) which is NP-hard. Let us consider the following case: \( L_n^\min = L_n^\max = L_n > 0 \) (hence, \( L_n = L_n^\min \)) for all \( n \in \mathcal{N} \), \( M = N \) (so, the IRS-cardinality constraint can be omitted, because \( \sum_{n \in \mathcal{N}} x_n \leq N \) for all \( x \in \{0,1\}^N \)) and \( L_n^\max = \sum_{n \in \mathcal{N}} L_n^\max \) (therefore, the constraint of maximum total number of reflecting elements can be omitted, since \( \sum_{n \in \mathcal{N}} x_n^\phi \leq \sum_{n \in \mathcal{N}} L_n^\max \) for all \( x \in \{0,1\}^N \) and \( L_n \in \{L_n^\min, \ldots, L_n^\max\} \)). As a consequence, problem (17) reduces to

\[
\begin{align*}
\min_x \quad & \sum_{n \in \mathcal{N}} (\beta_n L_n^\phi) x_n \\
\text{s.t.} \quad & x_n \in \{0,1\}, \quad \forall n \in \mathcal{N} \\
& \sum_{n \in \mathcal{N}} (c_n + \lambda_n L_n^\phi) x_n \leq C^\max_{\text{tot}}.
\end{align*}
\]

By converting it into a maximization problem, we obtain

\[
\begin{align*}
\max_x \quad & \sum_{n \in \mathcal{N}} \varphi_n x_n \\
\text{s.t.} \quad & x_n \in \{0,1\}, \quad \forall n \in \mathcal{N} \\
& \sum_{n \in \mathcal{N}} \theta_n x_n \leq C^\max_{\text{tot}},
\end{align*}
\]

where \( \varphi_n = -\beta_n L_n^\phi \geq 0 \) and \( \theta_n = c_n + \lambda_n L_n^\phi \) for every \( n \in \mathcal{N} \). A crucial observation here is that each coefficient in \( \{\varphi_n, \theta_n\}_{n \in \mathcal{N}} \) can be any positive integer. To prove this, let \( \kappa_n, \mu_n > 0 \) be arbitrary integers. Then, we can find a problem instance such that \( \rho_n = \gamma_n / \left( F_n^{-1}(e^{-\kappa_n/L_n^\phi})^2 \right) \), \( 0 \leq c_n \leq \mu_n \) and \( \lambda_n = (\mu_n - c_n) / L_n^\phi \geq 0 \) for all \( n \in \mathcal{N} \), where \( F_n^{-1}(\cdot) \) is the inverse function of \( F_n(\cdot) \) given by (7); the existence of \( F_n^{-1}(\cdot) \) is guaranteed, because \( F_n(\cdot) \) is continuous and (strictly) increasing. As a result, \( \beta_n = \log \left( F_n(\sqrt{\gamma_n/\rho_n}) \right) = -\kappa_n/L_n^\phi < 0 \), thus \( \varphi_n = \kappa_n \) and \( \theta_n = \mu_n \) as well.

Furthermore, if \( \{\varphi_n, \theta_n\}_{n \in \mathcal{N}} \) and \( C^\max_{\text{tot}} \) are all restricted to be positive integers, then problem (38) becomes identical to the knapsack problem which is known to be NP-hard [38]; this completes the proof.

APPENDIX B

PROOF OF THEOREM 2

First of all, due to (22)–(24), we have that

\[
\begin{align*}
\mathbb{E}(\tilde{x}_n) &= 1 \cdot x_n^1 + 0 \cdot (1 - x_n^1) = x_n^1, \\
\mathbb{E}(\tilde{L}_n | x_n^1 \neq 0) &= (\lceil L_n^1 \rceil + 1) \frac{\lceil L_n^1 \rceil}{\lceil L_n^1 \rceil} + [L_n^1 - \lceil L_n^1 \rceil] \\
&= \lceil L_n^1 \rceil + L_n^1 = L_n^1, \\
\mathbb{E}(\tilde{L}_n | x_n^1 = 0) &= \frac{1}{2} (L_n^\min + L_n^\max).
\end{align*}
\]

Furthermore, by defining the random variable \( \tilde{z}_n = \tilde{x}_n \tilde{L}_n \) for all \( n \in \mathcal{N} \) and exploiting the independency of \( \tilde{x}_n \) and \( \tilde{L}_n \), we get the following conditional expectations:

\[
\begin{align*}
\mathbb{E}(\tilde{z}_n | x_n^1 \neq 0) &= \mathbb{E}(\tilde{z}_n | x_n^1 \neq 0) \mathbb{E}(\tilde{L}_n | x_n^1 \neq 0) \\
&= x_n^1 \mathbb{E}(\tilde{L}_n) = z_n^1, \\
\mathbb{E}(\tilde{z}_n | x_n^1 = 0) &= \mathbb{E}(\tilde{z}_n | x_n^1 = 0) \mathbb{E}(\tilde{L}_n | x_n^1 = 0) \\
&= 0 \cdot \frac{1}{2} (L_n^\min + L_n^\max) = 0 \leq z_n^1,
\end{align*}
\]

where the latter is based on the fact that: if \( x_n^1 = 0 \), then \( z_n^1 = 0 \) and \( \tilde{x}_n = 0 \). As a result, combining the above equations, we obtain

\[
\mathbb{E}(\tilde{z}_n) = z_n^1 \quad \text{for all } n \in \mathcal{N}.
\]

Because of the linearity of expectation and the feasibility of \((\tilde{x}_n, \tilde{z}_n)\), we obtain

\[
\begin{align*}
\mathbb{E}(G(\tilde{x}, \tilde{L})) &= \mathbb{E} \left( \sum_{n \in \mathcal{N}} \beta_n \tilde{z}_n \right) = \sum_{n \in \mathcal{N}} \beta_n \mathbb{E}(\tilde{z}_n) \\
&= \sum_{n \in \mathcal{N}} \beta_n z_n^1 = G^1, \\
\mathbb{E} \left( \sum_{n \in \mathcal{N}} \tilde{x}_n \right) &= \sum_{n \in \mathcal{N}} \mathbb{E}(\tilde{x}_n) = \sum_{n \in \mathcal{N}} x_n^1 \leq M, \\
\mathbb{E}(\tilde{L}_n | \tilde{x}_n) &= \mathbb{E} \left( \sum_{n \in \mathcal{N}} \tilde{z}_n \right) = \sum_{n \in \mathcal{N}} \mathbb{E}(\tilde{z}_n) \\
&= \sum_{n \in \mathcal{N}} z_n^1 \leq L_n^\max, \\
\mathbb{E}(\tilde{C}_n | \tilde{x}_n) &= \mathbb{E} \left( \sum_{n \in \mathcal{N}} c_n \tilde{x}_n + \sum_{n \in \mathcal{N}} \lambda_n \tilde{z}_n \right) \\
&= \sum_{n \in \mathcal{N}} c_n \mathbb{E}(\tilde{x}_n) + \sum_{n \in \mathcal{N}} \lambda_n \mathbb{E}(\tilde{z}_n) \\
&= \sum_{n \in \mathcal{N}} c_n x_n^1 + \sum_{n \in \mathcal{N}} \lambda_n z_n^1 \leq C^\max_{\text{tot}}.
\end{align*}
\]

Therefore, Theorem 2 has been proven.
In order to prove Theorem 3, we make use of a concentration inequality for sums of independent and bounded random variables, namely, Hoeffding’s inequality. This is a generalization of the well-known Chernoff bound, which applies to Bernoulli random variables.

Lemma 1 (Hoeffding’s Inequality [39]): Let \( \{X_n\}_{n \in \mathbb{N}} \) be a finite set of independent random variables, with \( X_n \in [a_n, b_n] \) for all \( n \in \mathbb{N} \) (where \( a_n \leq b_n \)), and \( X \triangleq \sum_{n \in \mathbb{N}} X_n \). Then, for any \( u > 0 \),
\[
\Pr\left( X - \mathbb{E}(X) > u \right) \leq e^{-2u^2/\Delta},
\]
where \( \Delta = \sum_{n \in \mathbb{N}} (b_n - a_n)^2 \).

The probability of approximating the optimum value within a given tolerance \( \epsilon_0 > 0 \) is lower bounded by
\[
\Pr\left( G(\bar{x}, \bar{L}) \leq G^* + \epsilon_0 \right) = 1 - \Pr\left( G(\bar{x}, \bar{L}) > G^* + \epsilon_0 \right) \geq 1 - \Pr\left( G(\bar{x}, \bar{L}) > G^* + \epsilon_0 \right) \geq 1 - e^{-2\epsilon_0^2/\Delta_0},
\]
where \( \Delta_0 = \sum_{n \in \mathbb{N}} (\beta_n L_n^{\max})^2 \). Here, the first inequality is because \( G^* \leq G^* \), while the second inequality follows from Lemma 1 by taking advantage of (25) and noticing that \( G(\bar{x}, \bar{L}) = \sum_{n \in \mathbb{N}} \beta_n (\bar{x}_n L_n) = \sum_{n \in \mathbb{N}} \beta_n \bar{z}_n \) is the sum of independent random variables \( \{\beta_n \bar{z}_n\}_{n \in \mathbb{N}} \) with \( \beta_n \bar{z}_n \in [\beta_n L_n^{\max}, 0] \); recall that \( \beta_n \leq 0 \). By assuming \( \Delta_0 > 0 \) and setting \( \epsilon_0 = \sqrt{\Delta_0 \log(N + 1)} > 0 \), we get (29) for \( k = 0 \).

Regarding the probabilistic guarantee for the IRS-cardinality constraint, we have for any \( \epsilon_1 > 0 \)
\[
\Pr\left( \sum_{n \in \mathbb{N}} \bar{x}_n \leq M + \epsilon_1 \right) = 1 - \Pr\left( \sum_{n \in \mathbb{N}} \bar{x}_n > M + \epsilon_1 \right) \geq 1 - \Pr\left( \sum_{n \in \mathbb{N}} \bar{x}_n > \sum_{n \in \mathbb{N}} x_n^1 + \epsilon_1 \right) \geq 1 - e^{-2\epsilon_1^2/\Delta_1},
\]
where \( \Delta_1 = N \). The two inequalities follows from (26) and Lemma 1. Finally, by choosing \( \epsilon_1 = \sqrt{\Delta_1 \log(N + 1)} > 0 \) we obtain (29) for \( k = 1 \).

Moreover, based on (27) and Lemma 1, we obtain for any \( \epsilon_2 > 0 \)
\[
\Pr\left( L_{\text{tot}}(\bar{x}, \bar{L}) \leq L_{\text{tot}}^{\max} + \epsilon_2 \right) = 1 - \Pr\left( L_{\text{tot}}(\bar{x}, \bar{L}) > L_{\text{tot}}^{\max} + \epsilon_2 \right) \geq 1 - \Pr\left( L_{\text{tot}}(\bar{x}, \bar{L}) > \sum_{n \in \mathbb{N}} \epsilon_n^1 + \epsilon_2 \right) \geq 1 - e^{-2\epsilon_2^2/\Delta_2},
\]
where \( \Delta_2 = \sum_{n \in \mathbb{N}} (L_n^{\max})^2 \). Note that \( L_{\text{tot}}(\bar{x}, \bar{L}) = \sum_{n \in \mathbb{N}} \bar{x}_n L_n = \sum_{n \in \mathbb{N}} \bar{z}_n \) is the sum of independent random variables \( \{\bar{z}_n\}_{n \in \mathbb{N}} \) with \( \bar{z}_n \in [0, L_n^{\max}] \). Inequality (29) for \( k = 2 \) can be easily derived, assuming \( \Delta_2 > 0 \) and setting \( \epsilon_2 = \sqrt{\Delta_2 \log(N + 1)} > 0 \).

Although \( \bar{x}_n \) and \( \bar{z}_n \) are not independent random variables, \( C_{\text{tot}}(\bar{x}, \bar{L}) = \sum_{n \in \mathbb{N}} c_n \bar{x}_n + \sum_{n \in \mathbb{N}} \lambda_n (\bar{x}_n L_n) \) can be written as the sum of independent random variables \( \{(c_n + \lambda_n L_n)\bar{x}_n\}_{n \in \mathbb{N}} \), i.e., \( C_{\text{tot}}(\bar{x}, \bar{L}) = \sum_{n \in \mathbb{N}} (c_n + \lambda_n L_n) \bar{x}_n \), with \( (c_n + \lambda_n L_n) \bar{x}_n \in [0, c_n + \lambda_n L_n^{\max}] \). As a consequence, the probability of the event \( \mathcal{E}_3 \) can be lower bounded by
\[
\Pr\left( C_{\text{tot}}(\bar{x}, \bar{L}) \leq C_{\text{tot}}^{\max} + \epsilon_3 \right) = 1 - \Pr\left( C_{\text{tot}}(\bar{x}, \bar{L}) > C_{\text{tot}}^{\max} + \epsilon_3 \right) \geq 1 - \Pr\left( \sum_{n \in \mathbb{N}} c_n \bar{x}_n^1 \right) + \sum_{n \in \mathbb{N}} \lambda_n \bar{x}_n^1 + \epsilon_3 \) \geq 1 - e^{-2\epsilon_3^2/\Delta_3},
\]
where \( \Delta_3 = \sum_{n \in \mathbb{N}} (c_n + \lambda_n L_n^{\max})^2 \), while the two inequalities result from the combination of (28) with Lemma 1. Assuming \( \Delta_3 > 0 \) and choosing \( \epsilon_3 = \sqrt{\Delta_3 \log(N + 1)} > 0 \), we have (29) for \( k = 3 \). Hence, (29) has been proven for all \( k \in \{0, 1, 2, 3\} \).

Now, let us consider inequality (34). By applying De Morgan’s law and the union bound theorem, we obtain
\[
\Pr\left( \bigcap_{k=1}^{3} \mathcal{E}_k \right) = 1 - \Pr\left( \bigcup_{k=1}^{3} \mathcal{E}_k^c \right) = 1 - \Pr\left( \bigcup_{k=1}^{3} \mathcal{E}_k^c \right),
\]
(53)
\[
\Pr\left( \bigcup_{k=1}^{3} \mathcal{E}_k^c \right) \leq \sum_{k=1}^{3} \Pr(\mathcal{E}_k^c) = \sum_{k=1}^{3} \left( 1 - \Pr(\mathcal{E}_k) \right).
\]
(54)

Subsequently, by combining the above equations and leveraging (29), we deduce
\[
\Pr\left( \bigcap_{k=1}^{3} \mathcal{E}_k \right) \geq 1 - \sum_{k=1}^{3} \left( 1 - \Pr(\mathcal{E}_k) \right) \geq 1 - 3\xi = 1 - \xi'.
\]
(55)

Finally, inequality (35) can be derived by following similar steps as above, so Theorem 3 follows immediately.

**Christos N. Efrem** received the Diploma and Ph.D. degrees in electrical and computer engineering from the National Technical University of Athens (NTUA), Athens, Greece, in 2015 and 2021, respectively. He is currently working as a Post-Doctoral Researcher with the Department of Electrical and Computer Engineering, University of Cyprus, Nicosia, Cyprus. His research interests include the design and analysis of optimization algorithms with applications in wireless communication networks.

**Ioannis Krikidis** (Fellow, IEEE) received the Diploma degree in computer engineering from the Computer Engineering and Informatics Department (CEID), University of Patras, Greece, in 2000, and the M.Sc. and Ph.D. degrees in electrical engineering from the Ecole Nationale Supérieure des Télécommunications (ENST), Paris, France, in 2001 and 2005, respectively. From 2006 to 2007, he worked as a Post-Doctoral Researcher with ENST. From 2007 to 2010, he was a Research Fellow with the School of Engineering and Electronics, The University of Edinburgh, Edinburgh, U.K. He currently is an Associate Professor with the Department of Electrical and Computer Engineering, University of Cyprus, Nicosia, Cyprus. His current research interests include wireless communications, cooperative networks, 6G communication systems, wireless powered communications, and secrecy communications.
