GIANT FIBROADENOMA MIMICKING PHYLLOIDES TUMOR: A RARE OCCURRENCE IN A POSTMENOPAUSAL FEMALE
Monika Bansal¹, Anureet Kaur², Jasbir Singh³, Puneet Kaur⁴

CASE REPORT: A 52 years old lady presented with lump in right breast. The lump was noticed around 6 years back in the form of small nodule, which increased progressively in size with a rapid enlargement in last 6 months before presentation to the outpatient department. There was no history of trauma, nipple discharge, fever, anorexia or weight loss. There was no significant family history. On clinical examination, huge enlargement of right breast was found, with presence of a lump measuring about 15x10 cm, while other breast was normal. The overlying skin showed distended veins. It was a firm to hard mass, not fixed to underlying structures and nipple and areola. A clinical diagnosis of Cystosarcoma Phylloides was made. There was no axillary lymph node enlargement. Routine
CASE REPORT

haematological and biochemical examination were within normal limits. Ultrasonography of the mass showed heterogeneous parenchymal pattern, suggestive of fibroadenoma.

The patient was subjected to fine-needle aspiration cytology (FNAC). The cytology smears showed monolayered sheets of benign ductal epithelial cells with few myoepithelial cells in a background of bare nuclei and blood (Figure 1). Only few stromal fragments were seen and hence, a diagnosis of giant fibroadenoma was given. The patient underwent total excision of right breast lump along with nipple and areola. The excised lump was encapsulated, measured 15 cm x 13 cm and weighed 600 gms. Cut surface showed multiple gray white nodules (Figure 2). Histopathological examination showed proliferation of benign glandular and stromal tissue, forming intracanalicular and pericanalicular pattern of growth (Figure 3). Hence a diagnosis of giant fibroadenoma was made. Positive nuclear staining for estrogen and progesterone receptor antibodies was demonstrated by immunohistochemical study. Postoperative recovery was uneventful and the patient is on regular follow up since last 6 months.

DISCUSSION: The nomenclature of fibroadenoma is confusing and a plethora of names exists to designate the lesion such as age related term juvenile fibroadenoma and size related term giant or massive fibroadenoma.[4] According to Stanford School of Medicine, juvenile fibroadenomas of the breast may be multiple and is defined as a circumscribed, often large, breast mass occurring in adolescent females with stromal and epithelial hypercellularity, but lacking leaf like growth pattern of Phylloides tumours. The age distribution ranges from the early teens to over 70 years, with a mean age of about 30 years.[11] Less than 5% of women with a fibroadenoma are post-menopausal.

Giant fibroadenomas comprise approximately 4% of all fibroadenomas and present as rapidly growing unilateral macromastia without definable borders or texture differences. It is more frequently seen in young and black female.[4] In our case the patient was postmenopausal and 52 years old. The tumour measured 15x13 cms in this patient.

These are benign tumors, but their rapid growth and large size together with their rarity may lead to difficulties in the clinical approach. In our case the patient had a history of rapid enlargement of the mass in 6 months.

Increased oestrogen stimulus and receptor sensitivity and a decrease in oestrogen antagonist levels during puberty are thought to be responsible for the etiology.[12] However, in our case the patient was not receiving hormone replacement therapy or exogenous oestrogen in any form.

Other than Giant fibroadenomas, a wide variety of breast conditions can result in solitary or multiple giant masses such as phylloides tumour, virginal hypertrophy, lipoma, hamartoma, cyst, abscess and carcinoma.[13] Clinical examination is essential in evaluating the location, size and number of palpable lesions. It is also important to distinguish these pathological entities preoperatively as the treatment modalities and the prognosis differ quite significantly in these conditions.

One of the most important differential diagnoses in this case was cystosarcoma phylloides, especially because of its age incidence. It forms large, lobulated, homogeneous solid tumour mass with well defined margins. These are mostly benign (95%) tumours, which are seen in the 4th decade.[12] Although these tumours are morphologically similar to fibroadenomas, phylloides tumours are not really encapsulated. Compared to fibroadenoma, phylloides tumours show overgrowth of the stromal compartment which shows increased cellularity, especially in the
CASE REPORT

periductal stromal areas. Mitotic activity is also substantial and epithelial clefts are more elongated in phylloides tumours. It is treated by wide excision with a margin of normal tissue or mastectomy.

An unusual example of fibrous tumour of the breast has been reported in a 62 year old postmenopausal female with history of progressive enlargement in one year.[14] The patient had history of exogenous estrogen intake for 10 years which was associated with accelerated growth of the tumour and showed positive nuclear staining for estrogen receptor antibodies in stromal cells. Fibrous tumour of the breast is a rare, benign stromal proliferation with atrophy of the epithelial component.

Breast carcinomas are typically large masses with irregular borders, associated with features like dimpling or thickening of skin, inverted nipple and discharge from nipple. None of these features was seen in this case.

CONCLUSION: Fibroadenoma 5 cm or more in diameter is considered as giant fibroadenoma and is a common cause of asymmetrical breast enlargement in adolescent and young adult females. However, its incidence in postmenopausal female is not documented. The only known cause is oestrogen replacement therapy which causes breast to enlarge. In our case, no such evidence of exogenous oestrogen was present.
