Background: Micro RNAs (miRNAs) and piwi interacting RNAs (piRNAs), along with the more ancient eukaryotic endogenous small interfering RNAs (endo-siRNAs) constitute the principal components of the RNA interference (RNAi) repertoire of most animals. RNAi in non-bilaterians – sponges, ctenophores, placozoans and cnidarians - appears to be more diverse than that of bilaterians, and includes structurally variable miRNAs in sponges, an enormous number of piRNAs in cnidarians and the absence of miRNAs in ctenophores and placozoans.

Results: Here we identify thousands of endo-siRNAs and piRNAs from the sponge Amphimedon queenslandica, the ctenophore Mnemiopsis leidyi and the cnidarian Nematostella vectensis using a computational approach that clusters mapped small RNA sequences and annotates each cluster based on the read length and relative abundance of the constituent reads. This approach was validated on 11 small RNA libraries in Drosophila melanogaster, demonstrating the successful annotation of RNAi associated loci with properties consistent with previous reports. In the non-bilaterians we uncover seven new miRNAs from Amphimedon and four from Nematostella as well as sub-populations of candidate cis-natural antisense transcript (cis-NAT) endo-siRNAs. In the ctenophore, the absence of miRNAs is confirmed and an abundance of endo-siRNAs is revealed. Analysis of putative piRNA structure suggests that conserved localised secondary structures in primary transcripts may be important for the production of mature piRNAs in Amphimedon and Nematostella, as is also the case for endo-siRNAs.

Conclusion: Together, these findings suggest that the last common ancestor of animals did not have the entrained RNAi system that typifies bilaterians. Instead it appears that bilaterians, cnidarians, ctenophores and sponges express unique repertoires and combinations of miRNAs, piRNAs and endo-siRNAs.

ABSTRACT

Background: Micro RNAs (miRNAs) and piwi interacting RNAs (piRNAs), along with the more ancient eukaryotic endogenous small interfering RNAs (endo-siRNAs) constitute the principal components of the RNA interference (RNAi) repertoire of most animals. RNAi in non-bilaterians – sponges, ctenophores, placozoans and cnidarians - appears to be more diverse than that of bilaterians, and includes structurally variable miRNAs in sponges, an enormous number of piRNAs in cnidarians and the absence of miRNAs in ctenophores and placozoans.

Results: Here we identify thousands of endo-siRNAs and piRNAs from the sponge Amphimedon queenslandica, the ctenophore Mnemiopsis leidyi and the cnidarian Nematostella vectensis using a computational approach that clusters mapped small RNA sequences and annotates each cluster based on the read length and relative abundance of the constituent reads. This approach was validated on 11 small RNA libraries in Drosophila melanogaster, demonstrating the successful annotation of RNAi associated loci with properties consistent with previous reports. In the non-bilaterians we uncover seven new miRNAs from Amphimedon and four from Nematostella as well as sub-populations of candidate cis-natural antisense transcript (cis-NAT) endo-siRNAs. In the ctenophore, the absence of miRNAs is confirmed and an abundance of endo-siRNAs is revealed. Analysis of putative piRNA structure suggests that conserved localised secondary structures in primary transcripts may be important for the production of mature piRNAs in Amphimedon and Nematostella, as is also the case for endo-siRNAs.

Conclusion: Together, these findings suggest that the last common ancestor of animals did not have the entrained RNAi system that typifies bilaterians. Instead it appears that bilaterians, cnidarians, ctenophores and sponges express unique repertoires and combinations of miRNAs, piRNAs and endo-siRNAs.

RNA interference (RNAi) evolved prior to the divergence of extant eukaryotic lineages, possibly in response to threats from parasitic double-stranded RNA species such as retroviruses and transposons [1]. In contemporary animals, three independent RNAi systems comprise the bulk of the small RNA (sRNA) repertoire: micro RNAs (miRNAs); Piwi interacting RNAs (piRNAs); and endogenous small interfering RNAs (endo-siRNAs). Amongst non-bilaterian animals - sponges, cnidarians and placozoans - miRNAs appear to be lost in latter two lineages, with placozoans and ctenophores also lacking key miRNA biogenic enzymes [2-4]. The absence of miRNAs in the sister lineages to the animal kingdom, choanoflagellates, and fungi [2,5,6], suggests the miRNA system has been lost or evolved independently multiple times [7]. Nonetheless, animal miRNAs play fundamental roles in cell type differentiation and maintenance, and their emergence and proliferation is linked to the evolution of complex multicellularity [8]. The prevalence of miRNAs in plants and algae [9] lends further support to the hypothesis that miRNAs may be important regulators of multicellular development. However, miRNAs do not appear to be essential for animal multicellularity given they are missing from the morphologically complex basal metazoans, the ctenophores [3,4].

There are some marked differences in the miRNA systems of sponges, cnidarians and bilaterians. In contrast to bilaterians, which express a complex repertoire of miRNAs in somatic tissues [10-16], miRNA expression in cnidarians is consistently dwarfed by piRNAs [2,17-19]. The miRNAs of the cnidarian Nematostella vectensis, while capable of bilaterian-like silencing [20], also regularly silence their targets through extensive base pairing followed by cleavage, as observed in plants, rather than by transcript destabilisation or translation- al inhibition [19]. The miRNA repertoire in sponges is substantially lower than in cnidarians and bilaterians with only eight, eleven and nineteen currently reported from the demosponges Amphinomedon queenslandica, Stylissa carteri and Xestospongia testudinaria respectively [2,21]. In Amphinomedon, these differ from other metazoan miRNAs in having a peculiar plant-like pre-miRNA secondary structure, and have no discernable homology with any non-sponge or eumetazoan miRNA [2,22-25].

While questions about miRNA evolution in animals remain unresolved, the roles of the endo-siRNA and piRNA systems during the emergence of the Metazoa have received far less attention. Having evolved deep in eukaryotic evolution, the endo-siRNA pathway was inherited by the crown Metazoa [26,27]. In contrast, piRNAs appear to be a metazoan innovation [2]. A functional PIWI-piRNA pathway is present in Hydra and Nematos-
a miRNA-like hairpin comprised of 16 counts but only three distinct reads results in a uniformity index of (16/3) or 5.3 while an endo-siRNA like hairpin comprised of 16 counts comprising 12 distinct reads results in a uniformity index of (16/12) or 1.3 (Additional file 1). Calculating this index for each sRNA cluster enables segregation of high uniformity (HU) clusters (such as miRNAs) from low uniformity (LU) endo-siRNA and piRNA clusters, as we demonstrate in Drosophila. Amongst the segregated HU clusters are repetitive sequences as well as miRNAs and other biologically significant sRNA clusters which can be secondarily annotated.

Developmental small RNA libraries from Nematostella [19] and Amphimedon and two replicate small RNA libraries from Mnemiopsis [45], were included in our analysis. In addition to the non-bilaterian datasets, we analysed eleven developmental small RNASeq libraries from Drosophila [46]. As the sRNA repertoire of Drosophila is well characterised, we first determined if the classification pipeline produced results consistent with prior published analyses [43,46-48].

**Discrimination and annotation of RNAi classes in Drosophila**

Drosophila is one of the most well-annotated and widely studied model organisms in terms of its small RNA repertoire. Of the three RNAi classes, the best annotated. In total there are 258 miRNAs currently deposited in miRBase (release 21) and 150 of these have been annotated with high confidence [49]. We were able to identify 139 previously reported miRNAs clusters (54% of total) including 121 high confidence miRNAs (81% of total; Additional files 2, 3). The UI of miRNA clusters averaged 122.5 compared to 1.8 for endo-siRNA clusters. No new miRNA candidates were identified in miRBase (release 21) and 150 of these have been certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC 4.0 International license.

Evidence of a ping-pong biogenesis signature (a bias for a uridine at position one and an adenosine at position 10) [40,41,43] was found in the putative piRNAs from both the Drosophila adult female and adult male body libraries as well one of the 2 - 4 day old pupal libraries (Additional file 5). Such a signature was not found in any of the putative endo-siRNAs in which, as expected, only a position one-uridine bias was observed (Additional file 6) [31,37].

To confirm an association between transposons and the putative endo-siRNA and piRNA clusters, the genomic positions of all clusters were intersected with those of annotated coding sequences, including exons, introns, 5’ untranslated regions (5’ UTRs) and 3’ untranslated regions (3’ UTRs), and known and unknown transposons (based on sequence similarity to Repbase entries). Clusters that did not overlap with these genomic elements were deemed to be ‘intergenic’. As anticipated, multi-mapping endo-siRNAs and piRNAs derive primarily from transposons (Fig. 1) [53,54]. In addition, we found that unique endo-siRNA clusters frequently map to exons, 5’ and 3’ UTRs in coding genes (Fig. 1), with unique endo-siRNA clusters underrepresented in introns suggesting that endo-siRNA production occurs after intron splicing.

The program Randfold [55] was used to test the likelihood that the secondary structures predicted to form from the precursor transcripts of endo-siRNA and piRNA clusters could occur by chance. Briefly, Randfold compares the minimum free energy of the predicted secondary structure of a native sequence to the minimum free energies of randomised versions of itself. For each library, Randfold scores were generated for endo-siRNA and piRNA clusters and these were compared to all other clusters (i.e. all clusters other than those under investigation) from the libraries in question (Fig. 2). Both unique and multi-mapping endo-siRNA clusters in Drosophila show evidence of secondary structure while putative piRNA transcripts do not (Fig. 2). This is consistent with most models of endo-siRNA and piRNA biogenesis in bilaterians in which some endo-siRNAs are cleaved from secondarily structured primary transcripts while piRNAs are not [53]. Given that the putative piRNA and endo-siRNA clusters identified
here have proven to be consistent with previously reported properties, we deemed our method to be satisfactory for naive identification and annotation.

**Table 1: Number of annotated miRNA, piRNA and endo-siRNA clusters in *Drosophila, Amphimedon, Nematostella* and *Mnemiopsis***

|                      | miRNA clusters | unique endo-siRNA clusters | multi-mapping endo-siRNA clusters | unique piRNA clusters | multi-mapping piRNA clusters |
|----------------------|----------------|----------------------------|-----------------------------------|-----------------------|-------------------------------|
| *Drosophila*         | 139            | 1,877                      | 3,517                             | 897                   | 8,929                         |
| *Amphimedon*         | 15             | 1,390                      | 7,218                             | 9,547                 | 25,840                        |
| *Nematostella*       | 32             | 232                        | 4,524                             | 7,912                 | 48,465                        |
| *Mnemiopsis*         | 0              | 4,408                      | 23,579                            | 1,235                 | 2,231                         |

**Discrimination and annotation of RNAi classes in non-bilaterians**

Using the same approach undertaken in *Drosophila*, we surveyed the miRNA, piRNA and endo-siRNA repertoire of *Amphimedon, Nematostella* and *Mnemiopsis*. The numbers of clusters corresponding to each RNAi class in each species are summarised in Table 1. Our analysis identified all eight previously reported miRNAs from *Amphimedon*, 62 of the previously reported 141 miRNAs from *Nematostella* and confirmed the absence of miRNAs in *Mnemiopsis*. In addition, we identified seven new miRNA candidates from the sponge
including a second copy of aqu-miR-2016 located just over 1 kilobase (kb) from the originally annotated copy, and four new miRNAs in the cnidarian, all of which are copies of previously reported miRNAs (Additional files 7, 8, 9). None of the newly identified sponge miRNAs share sequence similarity with the miRNAs of Stylissa and Xestospongia [21].

Structurally, three of the new miRNA hairpins (aqu-mir-temp-1,4,6) resemble canonical metazoan pre-miRNAs while the remaining three (aqu-mir-temp-2,3,5) are more similar to the eight previously described long-form miRNAs in Amphimedon (Additional file 7) [2]. All of these candidates possess either low numbers of reads mapping to their passenger strands or variable passenger strand 5' ends [56], however as these characteristics are present in some high confidence miRNAs, such as human hsa-miR-126 [56], we annotate these six loci as candidate novel miRNAs. The remaining HU endo-siRNA-like clusters consist of a mixture of snoRNA, tRNA and rDNA loci, and clusters with highly multi-mapping dominant reads, endogenous hairpin RNAs (hp-RNA; Additional file 10) [57] and secondary structures not consistent with any known sRNA class. Unlike in Drosophila where evidence of a ping-pong biogenesis signature was only found in two of the 11 libraries, a bias for a 5’ uridine and an adenosine at position 10 was detected in all Amphimedon and Nematostella libraries and one of the two Mnemiopsis libraries (Additional file 5). As expected, endo-siRNA clusters only exhibit a bias for a 5’ uridine (Additional file 6) [31,37].

As in Drosophila, unique Amphimedon endo-siRNA clusters frequently map to coding genes (Fig. 1). In contrast, distributions of unique endo-siRNAs do not show a bias towards coding genes in Mnemiopsis or Nematostella. Unique endo-siRNAs in these species map to coding genes with a frequency more similar to that which would be expected if they were randomly distributed throughout the genome (Fig. 1). In all species, multi-mapping endo-siRNA and piRNA clusters tend to map to transposons.

---

**Figure 2. Randfold results for endo-siRNA and piRNA clusters.** Each bar represents the percentage of clusters with Randfold p-values equal to or less than the values stated on the X-axis. The more significant the p-value cutoff, the more confidence there is that the secondary structure of the native sequence is more stable than a randomised version of itself. For each graph, the Randfold scores of either endo-siRNAs or piRNAs are compared to the Randfold scores of all clusters not annotated as endo-siRNAs or piRNAs. For each species, all available datasets were pooled.
Randfold analysis of unique endo-siRNA clusters in *Amphimedon* and *Nematostella* show that they are no more likely to form secondary structures than the putative transcripts of all other unique clusters (i.e. all identified sRNA clusters not including endo-siRNAs). In contrast, unique endo-siRNA clusters in *Mnemiopsis*, as in *Drosophila*, show evidence of secondary structuring, as do multi-mapping endo-siRNA clusters in all four species (Fig. 2).

Unexpectedly, putative piRNA transcripts of *Amphimedon* and *Nematostella* show evidence of secondary structure for both unique and multi-mapping clusters while those in *Mnemiopsis* are more similar to the unstructured piRNAs known from bilaterians (Fig. 2).

**Figure 3.** Library contributions from each RNAi component as a percentage of total library depth. Total contributions of miRNAs, endo-siRNAs, piRNAs and *Mnemiopsis* 25-mer clusters to total library depth. For each, only a single copy of each multi-mapping read was considered.
Figure 4. Co-expression of uniquely-mapping endo-siRNA and piRNA clusters  Each plot is divided into groups of coloured scaffolds/chromosomes, each of which represents a developmental stage; four stages in Amphimedon, nine stages in Nematostella and 11 stages in Drosophila. For each plot, the earliest developmental stage is marked with an arrow indicating the chronological order of developmental stages. Links between scaffolds/chromosomes indicate co-expression from a particular endo-siRNA or piRNA cluster in the two linked developmental stages. For Drosophila, all chromosomes are represented while for Amphimedon and Nematostella, the ten largest genomic scaffolds were used. Beginning with the developmental stage indicated by the arrow, the stages for Amphimedon, Nematostella and Drosophila are as per Fig. 1. For each species, the links shared with a single developmental stage are coloured black for emphasis while the rest are coloured grey. For Amphimedon the emphasised stage is the pre-competent larvae, for Nematostella the female adult and for Drosophila, the female adult head.
Variation in overall RNAi complements in basal metazoans

The relative contributions of sRNAs differ amongst the representative sponge, ctenophore, cnidarian and bilaterian species (Fig. 3). In *Amphimedon* and in all but one *Drosophila* developmental stage, miRNAs comprise the bulk of mapped sRNAs while endo-siRNAs and piRNAs are dominant in *Mnemiopsis* and *Nematostella* respectively. Except for the *Nematostella* libraries, a substantial proportion of each library remains unassigned to one of the three RNAi classes (Fig. 3). This is likely due to the stringent requirements set here for annotating sRNA clusters (see Supplementary Methods, Additional file 4) and the presence of non-RNAi related sRNAs produced by each animal.

Developmental dynamics of endo-siRNA and piRNA expression

Co-expression of endo-siRNA and piRNA clusters across developmental time was investigated for *Drosophila, Amphimedon* and *Nematostella* (Fig. 4; Additional file 11); *Mnemiopsis* was excluded due the absence of developmental data. This analysis highlights differences in the expression dynamics of endo-siRNAs and piRNAs; while many endo-siRNAs are co-expressed in the expression dynamics of endo-siRNAs and piRNAs through the annotation of their small RNA components in the demosponge *Amphimedon*, the ctenophore *Mnemiopsis* and the cnidarian *Nematostella*. We developed a method for the clustering and annotation of mapped sRNA libraries. Application of this method to the bilaterian *Drosophila* recapitulated the results of previous studies [32-35,40,41,51,52], suggesting this approach could be applied to other species.

Specifically, we demonstrate that *Drosophila* miRNAs account for the highest number of mapped reads and piRNAs and endo-siRNAs are dynamically expressed and frequently map to transposons. Endo-siRNAs display a bias for a 5’ uridine and the ping-pong biogenesis signature can be detected in annotated piRNAs. We also showed that 99.8% of annotated *Drosophila* piRNA clusters identified using this method map to previously reported piRNAs and that at least 13% of endo-siRNAs also correspond to previously reported endo-siRNA generating loci. In agreement with the established models of endo-siRNA and piRNA biogenesis, secondary structure appears to be important for *Drosophila* endo-siRNA clusters but not for piRNA clusters.

Using this strategy, we detected all previously reported miRNAs in the *Amphimedon* datasets and 44% of known miRNAs from *Nematostella*. We also confirmed the absence of miRNAs in the ctenophore and showed that endo-siRNAs and piRNAs are the most abundant RNAi classes in *Mnemiopsis* and *Nematostella* respectively. In *Amphimedon*, as in *Drosophila*, unique endo-siRNAs derive primarily from the exons and UTRs of coding genes, consistent with these being derived from mature spliced mRNAs in both species.

Primary transcript secondary structure does not appear to be a requirement for piRNA biogenesis [58], although one study identified a role for the RNA helicase MOV10L1/Armitage in unwinding localised secondary structures of piRNA precursors in mice and *Drosophila* [59]. Orthologues of this helicase can be found in *Amphimedon* (NCBI: XP_019853676.1), *Nematostella* (NCBI: XP_001626596.1, XP_001637169.1) and *Mnemiopsis* (NHGRI: ML005359a). Our analysis did not find any evidence of conserved piRNA cluster secondary structure in *Drosophila* or *Mnemiopsis*, however *Amphimedon* and *Nematostella* piRNA clusters do appear to be structured. This suggests that sites of conserved localised secondary structure within primary piRNA transcripts may be a main source of piRNA production in *Amphimedon* and *Nematostella*.

DISCUSSION

RNA interference systems are important post-tran-
Unique and multi-mapping endo-siRNA clusters in *Drosophila* and *Mnemiopsis* have a propensity to form secondary structures while only multi-mapping endo-siRNA clusters appear to in *Amphimedon* and *Nematostella*. As endo-siRNA directed RNA interference is most efficient for targets with full-length complementarity [60], uniquely mapping endo-siRNAs are expected to silence transcripts arising from the antisense strand from which their host gene was transcribed [61]. Consistent with this, Randfold analysis of the predicted secondary structures formed by *Amphimedon* unique endo-siRNA clusters showed that they are more likely to occur by chance than are the secondary structures formed by multi-mapping endo-siRNA clusters.

Given that (i) *Amphimedon* does not encode an RNA dependent RNA polymerase (RdRP), (ii) secondary structure is probably less important for the biogenesis of most unique endo-siRNAs and (iii) the most efficient targets of unique endo-siRNAs are likely found antisense to themselves, it follows that most unique endo-siRNAs are likely to be the products of cis-Natural Antisense Transcripts (cis-NATs) [35,62] rather than hairpin RNAs. Of the 40,122 coding gene models for *Amphimedon* [63], 8,133 are predicted to be cis-NATs. While this only represents 20.3% of the total coding genes, nearly 50% of all coding gene-mapping unique endo-siRNA clusters align to these genes.

Unique endo-siRNA clusters in *Drosophila* also align to coding genes, although both unique and multi-mapping endo-siRNA clusters show evidence of forming secondary structures. Despite this, the 16% of genes that form cis-NAT pairs in this species account for 22% of all mature coding gene-mapping unique endo-siRNA clusters demonstrating that cis-NATs are the likely source of some uniquely mapping endo-siRNAs in *Drosophila*. Differences in the rate of cis-NAT endo-siRNA production observed between *Drosophila* cell types [52] may account for the lower overall rate detected in comparison to *Amphimedon*. The more compact *Amphimedon* genome may also be responsible for a higher rate of overlapping antisense transcripts [63,64].

**CONCLUSIONS**

The RNAi repertoires of non-bilaterian metazoans - sponges, ctenophores and cnidarians – differ both from each other and from the canonical RNAi repertoire of bilaterians. Although largely comprised of the same three major systems that constitute the bilaterian RNAi repertoire, the degree to which miRNAs, piRNAs and endo-siRNAs are expressed varies substantially between these basal lineages. The unexpected differences in the RNAi repertoire of bilaterians, cnidarians, ctenophores and sponges uncovered here, suggests that while the last common ancestor of extant animals employed miRNA, piRNA and endo-siRNA systems, these were not integrated into the shared ancestral gene regulatory system. This is in contrast to bilaterians, which in general appear to use a common RNAi system [10-16]. Following the emergence of these major metazoan RNAi pathways, lineage-specific evolutionary trajectories appear to have resulted in divergent RNAi strategies evolving in each basal metazoan lineage.

**METHODS**

**Biological sampling and sequencing**

Detailed methods can be found in Supplementary Methods. Briefly, *Amphimedon* material was collected from Heron Island, Australia and RNA extracted using Tri Reagent (Sigma Aldrich). Small RNA libraries were constructed either with the Illumina TruSeq small RNA kit (adult sponge) or the Epicentre ScriptMiner Small RNA-Seq Library Preparation Kit (pre-competent larvae, competent larvae and juvenile). Sequencing was performed on an Illumina HiSeq 2000 at the Institute for Molecular Bioscience, Brisbane, Australia. *Mnemiopsis* (SRS355925, SRS355926) [3], *Nematostella* (SRR039731, SRR039754, SRR039764, SRR039762, SRR039760, SRR039758, SRR039756, SRR039726, SRR039727) [19] and *Drosophila* (SRR013604, SRR018039, SRR016854, SRR013601, SRR013603, GMS360260, SRR013600, SRR013602, GMS360256, GMS360257, SRR014367) [46] datasets were acquired either from NCBI's Sequenced Read Archive (SRA, http://www.ncbi.nlm.nih.gov/sra/) or from NCBI's Gene Expression Omnibus (GEO, http://www.ncbi.nlm.nih.gov/geo).

**Small RNA cluster generation and annotation**

Small RNA reads were mapped to their respective genomes and clustered using bedCluster.pl [66]. A 150 bp window was defined for cluster generation, reflecting the approximate length of the long pre-miRNAs typical of *Amphimedon* [2] and in recognition that miRNA, piRNA and endo-siRNA biogenesis results in products located in overlapping or close genome proximity to one another, all of which derive from an original primary transcript (or two in the case of natural antisense endo-siRNAs) [38]. Only clusters composed of at least three distinct reads (non-perfectly overlapping) and at least 51 bp in length were considered. Clusters corresponding to previously reported miRNAs were annotated as such. tRNAs were predicted with tRNA-scan-SE [67] and snoRNAs with snoSeeker [68], and clusters mapping to these locations were annotated. The minimum free energy of each cluster was defined using RNAfold [69] and Randfold analysis [55] with 100 randomisations.

**endo-siRNA, piRNA and 25-mer cluster annotation**

Both endo-siRNAs and piRNAs clusters were annotated based on the read length composition of their con-
stituent sRNAs. For endo-siRNAs, clusters with peaks of expression at 20, 21 or 22 nt were first selected. If the sum of the reads constituting the peak read length plus or minus one nucleotide was greater than the total number of reads of all other size classes, these were annotated as endo-siRNA clusters. For piRNA annotation an sRNA peak of 26, 27 or 28 nt was required for the non-bilaterians while for *Drosophila*, 24, 25 or 26 nt were selected, reflecting the shorter length of piRNAs in this species [40]. For *Mnemiopsis* 25-mer clusters 24, 25 or 26 nt peak clusters were also selected.

**Circos plots**

Circos plots [70] were constructed that describe the co-expression of clusters in different developmental contexts. Links were formed between corresponding genomic loci from two developmental stages if those loci co-expressed either an endo-siRNA or piRNA cluster in both temporal contexts.

**ADDITIONAL FILE INFORMATION**

**Additional file 1**

**Figure S1. Demonstration of High Uniformity and Low Uniformity sRNA clusters.**

Description of data: Two hypothetical hairpin RNAs demonstrating the difference between a high uniformity and a low uniformity clustering. In (a), a total of 16 reads composed of just three distinct reads map to a hairpin RNA giving a uniformity index of 5.3. In (b), 16 reads also map to a hairpin RNA but these are composed of 12 distinct reads resulting in a uniformity index of just 1.3. The high uniformity cluster (a) is composed of an equal number of reads to the low uniformity cluster (b) however these reads are less evenly distributed along the length of the source hairpin RNA.

**Additional file 2**

**Figure S2. Uniformity of Drosophila endo-siRNA and miRNA clusters.**

Description of data: Endo-siRNA clusters (yellow) display a consistently lower uniformity of small RNA expression (ratio of total read counts:distinct reads) in comparison to miRNA clusters (red) for both unique clusters (above) and multi-mapping clusters (below).

**Additional file 3**

**Locations of annotated RNAi loci from Drosophila, Amphimedon, Nematostella and Mnemiopsis.**

Description of data: Genomic loci of annotated miRNA, piRNA, endo-siRNA and 25-mer clusters in all four species.

**Additional file 4**

**Figure S5. New Amphimedon miRNA candidates.**

Description of data: Wiggle plots and predicted secondary structures of mapped reads across the length of previously described miRNA miR-2016a, the newly identified miR-2016b and six novel miRNA candidates (aqu-mir-temp-1-6). For each cluster, the library with the most mapped reads to each loci was used to construct the graph.

**Additional file 8**

**Figure S6. New Nematostella miRNA candidates.**

Description of data: Wiggle plots and predicted secondary structures of four newly identified miRNAs in the sea anemone. All four miRNAs are new copies of previously identified miRNAs.

**Additional file 9**

**Table S1. New miRNA data.**

Description of data: Sequence and genomic location data for the newly identified *Amphimedon* and *Nematostella* miRNAs.

**Additional file 10**

**Figure S7. Amphimedon endogenous hairpin RNAs.**

Description of data: Wiggle plots and predicted secondary structure of three long highly complementary endo-siRNAs from *Amphimedon* with unevenly distributed mapped sRNA populations.
Additional file 11
Figure S8. Co-expression of multi-mapping endo-siRNA and piRNA clusters across development.
Description of data: Each plot is divided into groups of coloured scaffolds/chromosomes, each of which represents a developmental stage. For each plot, the earliest developmental stage is marked with an arrow indicating the chronological order of the following developmental stages. Links between scaffolds/chromosomes indicate co-expression from a particular endo-siRNA or piRNA cluster in the two linked developmental stages. For Drosophila, all chromosomes are represented while for Amphimedon and Nematostella, the ten largest genomic scaffolds were used. Beginning with the developmental stage indicated by the arrow, the stages for Amphimedon, Nematostella and Drosophila are as per Fig. 1. For each species, the links shared with a single developmental stage are coloured black for emphasis while the rest are coloured grey. For Amphimedon the emphasised stage is the pre-competent larvae, for Nematostella the female adult and for Drosophila, the female adult head.

Additional file 12
Figure S9. Read length distribution of all mapped sRNAs from Mnemiopsis.
Description of data: Numbers of distinct reads (red) and total read counts (blue) of all mapped sRNA size classes from the Woods Hole, MA, USA library (A) and the Miami, FL, USA library (B). Of particular note are the peaks of mapped sRNAs at 21 and 25 nt in both libraries.

Additional file 13
Figure S10. Nucleotide biases of Mnemiopsis 25-mer clusters.
Description of data: Nucleotide biases along the length of all sRNAs mapping to 25-mer clusters. sRNAs were anchored at their 5’ nucleotide and biases are displayed as a percentage of the contribution of each nucleotide at each position. Of note is the tendency for a uracil at position 1.

Additional file 14
Figure S11. Genomic context of 25-mer cluster expression from Mnemiopsis
Description of data: Each colour-coded segment represents the percentage of 25-mer clusters mapping to the specified genomic elements. Percentages slightly exceed 100% due to some regions of the genome encoding multiple types of element. The genome column demonstrates the percentage of the genome covered by the specified genomic elements. Of note is the lack of enrichment of 25-mer clusters from coding genes or transposons.

Additional file 15
Figure S12. Randfold results for Mnemiopsis 25-mer clusters
Description of data: Each bar represents the percentage of clusters with Randfold p-values equal to or less than the values stated on the X-axis. The more significant the p-value cutoff, the more confidence there is that the secondary structure of the native sequence is more stable than a randomised version of itself. For each graph, the Randfold scores of either endo-siRNAs or piRNAs are compared to the Randfold scores of all other clusters. Both datasets were pooled for this analysis.

Ethics approval and consent to participate
No specific ethics approval was required for this project.

Consent for publication
Not applicable.

Competing interests
The authors declare that they have no competing interests.

Funding
This research was supported by an Australian Research Council grant to BMD.

Authors’ contributions
ADC contributed to the design of the project, analysis and interpretation of the data, collected the required material from the field, conducted the laboratory procedures and drafted the manuscript. SLFV, RJT and BMD contributed to the design of the project, analysis and interpretation of the data and drafted the manuscript. All authors have read and approved the final manuscript.

Acknowledgements
We thank Kelin Ru and and Anupma Choudhary for their assistance and advice with the production of the Amphimedon RNASeq libraries and to Paulina Tapia for her assistance with document design. We also thank Carmel McDougall for feedback on the manuscript.
