Abstract. The exceptionally high luminosities of gamma-ray bursts (GRBs), gradually emerging as extremely useful probes of star formation, make them promising tools for exploration of the high-redshift Universe. Here we present a carefully selected sample of \textit{Swift} GRBs, intended to estimate in an unbiased way the GRB mean redshift ($z_{\text{mean}}$), constraints on the fraction of high-redshift bursts and an upper limit on the fraction of heavily obscured afterglows. We find that $z_{\text{mean}} = 2.8$ and that at least 7\% of GRBs originate at $z > 5$. In addition, consistent with pre-\textit{Swift} observations, at most 20\% of afterglows can be heavily obscured. The redshift distribution of the sample is qualitatively consistent with models where the GRB rate is proportional to the star formation rate in the Universe. We also report optical, near-infrared and X-ray observations of the afterglow of GRB 050814, which was seen to exhibit very red optical colours. By modelling its spectral energy distribution we find that $z = 5.3 \pm 0.3$. The high mean redshift of GRBs and their wide redshift range clearly demonstrates their suitability as efficient probes of galaxies and the intergalactic medium over a significant fraction of the history of the Universe.

Key words. cosmology: observations – dust, extinction – early Universe – galaxies: high redshift – gamma rays: bursts

1. Introduction

The potential of long-duration (>2s) gamma-ray bursts (GRBs) as probes of the high-redshift Universe has long been recognised. The immense luminosities of the bursts, coupled with their origin in the core collapse of massive stars (Hjorth et al. 2003\textsuperscript{a}, Stanek et al. 2003\textsuperscript{a} and γ-ray penetration through dust, suggests a variety of intriguing applications. Much effort has been directed into the use of bursts for studying star formation (e.g. Fruchter et al. 1999, Christensen et al. 2003, Tanvir et al. 2004, Jakobsson et al. 2005\textsuperscript{a}), as backlights for exploring high-redshift galaxies and the intergalactic medium (e.g. Vreeswijk et al. 2004, Jakobsson et al. 2004\textsuperscript{a}) and even as probes of cosmological parameters (e.g. Ghirlanda et al. 2004, Mörtsell & Sollerman 2005\textsuperscript{a}). Although the GRB population observed until the end of 2004 had enabled much progress in the field, it was widely expected that the launch of \textit{Swift}, and the subsequent order of magnitude increase in the number of GRBs open to detailed study, would allow further insight into the high-redshift Universe (Gehrels et al. 2004\textsuperscript{a}). Indeed, the ability of \textit{Swift} to locate and follow-up a fainter burst population than was previously possible (Berger et al. 2005\textsuperscript{b}) has allowed more distant bursts to be studied. The mean redshift of pre-\textit{Swift} bursts was $z_{\text{mean}} = 1.4$, while bursts discovered by \textit{Swift} now have $z_{\text{mean}} = 2.8$, including the first burst to have been discovered with $z > 6$, GRB 050904 at $z = 6.29$ (Haislip et al. 2005\textsuperscript{a}, Kawai et al. 2005\textsuperscript{a}, Price et al. 2005\textsuperscript{b}, Tagliaferri et al. 2005\textsuperscript{a}, Watson et al. 2005\textsuperscript{a}).

High-redshift bursts, whose afterglows may already be faint due to the large luminosity distance\textsuperscript{1} (e.g. GRB 020124: Berger et al. 2002, Hjorth et al. 2003\textsuperscript{b}) are rendered essentially invis-

\textsuperscript{1} However, due to time dilation, little decrease is expected in the spectral energy flux in a given frequency band and at a fixed time of observation after the GRB with increasing redshift (Lamb & Reichart 2000).
2 P. Jakobsson et al.: A mean redshift of 2.8 for Swift gamma-ray bursts

able at optical wavelengths for $z > 6$ due to hydrogen opacity when the redshifted Ly$\alpha$ break sweeps through the optical regime; an effect that is clearly seen in galaxies in the Hubble Deep Field (e.g. Spinrad et al. 1998, Weymann et al. 1998). Therefore, a simple diagnostic of a high-redshift burst is its absence in deep optical observations and detection in a redder filter. Such a detection does not unambiguously fix the redshift, since high local extinction ($A_V$) will also markedly reduce the short wavelength flux. However, with multi-wavelength observations it is possible to distinguish the curved red spectrum expected for an extinguished burst, from the sharp cut-off due to the Ly$\alpha$ break. This method is similar to that which has been used successfully (and accurately) in the selection and study of Lyman-break galaxies (Steidel & Hamilton 1992, 1993), but in fact is likely to be even more robust thanks to the simple power-law spectra exhibited by GRB afterglows.

In this paper we introduce an objective Swift sample, appropriate for determining the $z_{\text{mean}}$ of GRBs, estimate the fraction of high-redshift bursts and an upper limit on the fraction of heavily obscured afterglows. We also compare the redshift distribution of the sample to models, predicted before the availability of these results, where the GRB rate is proportional to the star formation rate. In addition, we present optical, near-infrared (NIR) and X-ray observations of the GRB 050814 afterglow and a fit to the resulting spectral energy distribution (SED), allowing us to determine a well constrained redshift of $z = 5.3 \pm 0.3$.

2. Observations

GRB 050814 was discovered by the Burst Alert Telescope (BAT) aboard the Swift satellite on 14.485 August 2005 UT (Rettter et al. 2005). The burst exhibited a slow rise and decline above the background level, with a poorly constrained $t_{90}$ of 65$^{+20}_{-50}$ s (Tueller et al. 2005). The X-ray Telescope (XRT) slewed promptly to the location and began taking data at $\Delta t = 138$ s, where $\Delta t$ is the time from the onset of the burst, revealing a fading X-ray source (Morris et al. 2005). Observations with the UV/Optical Telescope began at $\Delta t = 167$ s but failed to reveal an optical afterglow (OA) candidate to a limiting magnitude of $V = 20.5$ mag (Blustin et al. 2005a). A marginally ($2\sigma$) detected OA candidate was reported by Cenko (2005) based on observations at the Palomar 60-inch telescope.

We observed the GRB 050814 XRT error circle in $V/R$ with the Andalucía Faint Object Spectrograph and Camera (ALFOSC) on the Nordic Optical Telescope (NOT) at $\Delta t \approx 13.5$ hr. A point-like object was detected displaying a red $R - I$ colour, its absence in the $V$-band suggesting a high-redshift origin (Jensen et al. 2005). Additional $I$-band imaging was secured at the NOT using both ALFOSC and the MOSaic Camera (MOSCA), confirming the fading behaviour of the OA candidate. Supplementary $R$-band imaging was obtained at the Isaac Newton Telescope (INT) using the Wide Field Camera (WFC). All the data were de-biased, flatfield corrected and combined using standard methods. The instrumental optical magnitudes were transformed to the Johnson photometric system using observations of Landolt (1992) standards. The journal of the observations including the results of our photometry is presented in Table 1.

NIR observations were pursued at the United Kingdom Infrared Telescope (UKIRT) using the UKIRT Fast Track Imager (UFTI) at $\Delta t \approx 22$ hr ($K$) and $\Delta t \approx 66$ hr ($J$). The data were pipeline processed through the ORACDR system (Cavanagh et al. 2004) to produce flattened, dark- and sky-subtracted mosaic images. Flux calibration was performed against the standard star FS141.

We have also analysed the Swift/XRT observations of GRB 050814 and used these to complement our optical/NIR dataset. Processed event files from the archive were used and background subtracted spectra and light curves from Windowed Timing (WT) and Photon Counting (PC) modes were produced in a standard way.

3. Spectral energy distribution of the afterglow

Our multiband observations of the GRB 050814 afterglow allowed the construction of its SED. We extrapolated the magnitudes to a common epoch, namely the nearly simultaneous epoch of our initial $VRI$ NOT observations ($\Delta t = 14$ hr). This was carried out by taking into account the decay indices (as calculated from our photometry in Table 2) $a_V = 1.34 \pm 0.12$ and $a_K = 2.08 \pm 0.12$ ($F_\nu \propto t^{-a} \nu^{-\beta}$). This discrepancy in the decay indices implies a late time ($\Delta t \geq 24$ hr) rapid decay with $a > 2.08$, although the sparse sampling of the light curve means that the timing of this break is poorly constrained. It might be the jet break, a suggestion supported by the fact that

| $\Delta t$ [days] | Telescope/Instrument | Magnitude | Seeing [arcsec] | Exp. time [s] |

$^a$ Days after 14.485 August 2005 UT.
Fig. 1. The spectral energy distribution of the GRB 050814 afterglow at $\Delta t = 14 \text{ hr}$. The strong break blueward of the I-band is too strong to be readily explained by reddening alone and is best fit by the presence of the Ly$\alpha$ break at $z = 5.3$. The solid curve is a fit to the data at that redshift. The dashed line shows the spectral slope expected from a synchrotron emission in the fireball model with $\beta = 1$. The filter response functions are also shown. The horizontal error bars represent the FWHM of each filter. The V-band upper limit is $2\sigma$. The inset shows the VRJK observations (filled squares) along with the X-ray spectrum (filled triangles) at $\Delta t = 14 \text{ hr}$. The dashed line is the same $\beta = 1$ slope as in the main panel.

Fig. 2. The calculated $\chi^2$ as a function of the GRB 050814 redshift. Low redshifts are ruled out by the data and cannot be fit by extinction. Very high $z > 7$ redshifts are ruled out by the presence of the afterglow in the I-band. The best fit redshift, indicated by the vertical dashed line, is $z = 5.3$ although a range of redshifts from $5.0 < z < 5.6$ have similar $\chi^2$ values.

The XRT light curve displays a break at approximately $28 \text{ hr}$ with a pre-break slope of $\alpha_X = 0.58 \pm 0.05$. We have used $\alpha_X$ to obtain lower limits on the extrapolated JK fluxes.

The SED is shown in Fig. 1 where we have corrected the observed data points for foreground (Galactic) extinction using thereddening maps of Schlegel et al. (1998), giving $E(B-V) = 0.028 \text{ mag}$ at that position on the sky. We note that the flux from the host galaxy has not been subtracted. However, the host is faint enough ($I > 24.7 \text{ mag}$) that it should contribute less than 2% of the flux at the epoch we are exploring. The SED has a strong break blueward of the I-band, exhibiting colours of $I-K = 3.44 \pm 0.29 \text{ mag}$ and $R-I = 2.87 \pm 0.10 \text{ mag}$, corresponding to spectral slopes of $\beta_{IK} = 1.78 \pm 0.12$ and $\beta_{RI} = 11.70 \pm 0.04$, respectively. The latter value is unreasonable for GRB afterglows, implying an electron energy power-law index more than ten times higher than normally observed. Even in the case of high $A_V$, such steep slopes cannot be obtained (see below and also Reichart 2001).

The most likely explanation for the steep break observed is due to the presence of the Ly$\alpha$ break at a redshift of $5 < z < 6$. To provide a more robust estimate of the GRB 050814 redshift we fit the available photometry at different redshifts, allowing for a range in $\beta$ and $A_V$, modelled using the parametrization of Calzetti et al. (2000). The models of Madau (1995) provide the average hydrogen opacity as a function of redshift. Figure 2 shows the minimum $\chi^2$ for each redshift step plotted against redshift; the best fit is obtained for $z = 5.3 \pm 0.3$ and is shown in Fig. 1. However, we are only able to obtain weak constraints on $\beta$ and $A_V$. Fixing $\beta = 1.0$, a typical value for GRB afterglows, results in a best fit of a restframe $A_V = 0.9 \text{ mag}$ and an unchanged redshift. This $A_V$ is marginally higher than has been inferred from the SEDs of pre-Swift bursts with bright OAs ($A_V = 0.09 \text{ mag}$ in GRB 000301C; Jensen et al. 2001; $A_V = 0.18 \text{ mag}$ in GRB 000926; Fynbo et al. 2001; $A_V = 0.08 \text{ mag}$ in GRB 011211; Jakobsson et al. 2003; $A_V < 0.20 \text{ mag}$ in GRB 020124; Hjorth et al. 2003; $A_V = 0.26 \text{ mag}$ in GRB 021004; Holland et al. 2003; $A_V < 0.50 \text{ mag}$ in GRB 030323; Vreeswijk et al. 2003; $A_V = 0.34 \text{ mag}$ in GRB 030429; Jakobsson et al. 2004) but is a necessary consequence of the observed $I-K$ colour. The extrapolated $\beta = 1.0$ line, normalized for $A_V = 0.9 \text{ mag}$, slightly overestimates the predicted X-ray flux (inset of Fig. 1), indicating that $\beta$ is a bit steeper; $\beta = 1.1$ would make the X-ray data fall on the line. Since the best fit X-ray spectral index is consistent with the assumed optical/NIR one, a cooling break between the optical and X-rays can be ruled out.

We have also explored whether the observed SED could be explained by a lower redshift and a large extinction assuming the three extinction laws given by Pei (1992) for the Milky Way (MW), Large Magellanic Cloud (LMC) and Small Magellanic Cloud (SMC). This was done in the following way. We have calculated the observed $E(R-I) \equiv A_R - A_I = 2.41 \pm 0.10 \text{ mag}$ based on $\beta = 1.0$ (see above). By (blue)shifting the $R$ and $I$ filters along the aforementioned extinction laws, we can estimate which redshifts produce the observed $E(R-I)$. Using these redshifts we can then compute the predicted $E(I-K)$ and compare to the observed value of $0.88 \pm 0.29 \text{ mag}$. In every case the predicted values are $E(I-K) > 3.0 \text{ mag}$, implying that none of the extinction laws can give rise to the observed SED at a low redshift. In other words, the spectral break between the observed $R$- and $I$-bands combined with the shallower slope between $I$ and $K$ is inconsistent with the MW, SMC and LMC extinction laws at any lower redshift. Dust close to the GRB site might
Table 2. A list of all long-duration GRBs which have a Galactic extinction $A_{\text{V}}^\text{Gal} < 0.5$ mag, a declination between $-70^\circ$ and $+70^\circ$, and are localised with the Swift/XRT after 1 March 2005. Here $\theta_{\text{Sun}}$ is the Sun-to-field distance, $\theta_{\text{Moon}}$ the Moon-to-field distance and $I_{\text{Moon}}$, the Moon illumination at the time the burst occurred. For a burst detected in the optical but without a reported redshift, an upper redshift limit is estimated based on the filter it is detected in. $^a$ The OA was detected in $I$ but not in $V$, suggesting a high redshift (Cenko et al. 2005a).

not follow these extinction laws, for example due to dust being destroyed by the prompt radiation of the GRB itself (e.g. Perna et al. 2003). However, that would tend to produce greyer dust (small grains being preferentially removed), thus reducing rather than increasing the amount of reddening.

The X-ray limits on $N_{\text{H}}$ from the XRT also support a high-redshift origin for the red optical/NIR SED, by providing an upper limit on the possible absorbing extragalactic oxygen column density along the line of sight. The values of $N_{\text{H}}$ we derive from the fitting process are sensitive to the fit at low energies. We have used ancillary response files for the WT mode data, generated by xrtmkarf with “inarn=NONE”, which are better at reproducing the low energy continua. The $N_{\text{H}}$ limits using this response file are slightly higher than using the default ancillary response.

We can then obtain a limit on $A_{\text{V}}$ using a Galactic empirical relation stating that $A_{\text{V}} = 1$ mag corresponds to $N_{\text{H}} = 1.79 \times 10^{21}$ cm$^{-2}$ (Predehl & Schmitt 1995). This implies that for redshifts of $z = (0.5, 1.0, 2.0, 3.0)$ the respective 3σ upper limits on $A_{\text{V}}$ are (0.5, 0.8, 1.8, 3.6) mag. None of these are large enough to simultaneously reproduce the observed $R-I$ and $I-K$ colours at low redshifts.

4. The redshift distribution of Swift bursts

At the time of this writing (30 September 2005) Swift has been operating for approximately 9 months and has detected a total of 70 long-duration GRBs. In order to study the redshift distribution of GRBs, it is important to carefully select a sample containing bursts which have “observing conditions” favorable for redshift determination. Our first criteria is small error circles, hence the bursts have to be localised with the XRT (56 GRBs). In addition we require the Galactic extinction in the direction to the burst to be sufficiently small or $A_{\text{V}}^\text{Gal} < 0.5$ mag (38 GRBs). Thirdly, the XRT error circle should be distributed quickly for a relatively rapid follow-up. Although the automatic slewing of Swift was enabled in the middle of January 2005, part of the following month was dedicated to calibration which could not be interrupted. Therefore, we have only included bursts occurring after 1 March 2005 (31 GRBs). Finally, we have rejected (3) bursts with a declination unsuitable (above $+70^\circ$ or below $-70^\circ$) for follow-up observations.

The sample, containing 28 GRBs, is presented in Table 2. For each burst we have also listed the Sun-to-field distance ($\theta_{\text{Sun}}$), the Moon-to-field distance ($\theta_{\text{Moon}}$) and the Moon illumination at the time of the burst. This is done to examine if these parameters affect the redshift determination significantly, e.g. a full Moon close to a burst location. This is of course difficult to quantify as the OA brightness also plays a part. For example, GRB 050820A has a measured redshift even if it occurred during a full Moon and $\theta_{\text{Moon}} = 34^\circ$. Therefore, we decided not to limit the sample further. This relatively “clean” sample has a very high redshift recovery rate of almost 60% (16/28).

Figure A shows the redshift distribution of the 16 bursts with a reported redshift in our Swift sample. Both the mean and the median is $z \approx 2.75$, more than twice as large as the corresponding numbers for pre-Swift bursts (1.37 and 1.04, respectively).

Note that the sample contains all Swift bursts with a reported redshift except GRB 050126 ($z = 1.29$).
tively, calculated from a sample of 42 bursts). A natural explanation for this increase is the lower trigger threshold of *Swift* compared to previous missions, giving rise to fainter (*Swift* events are on average 1.7 mag fainter in the *R*-band at a similar epoch: Berger et al. 2005) and higher redshift bursts. This is complemented by the accurate positions provided by *Swift* and the rapid response of a variety of telescopes aimed at redshift determinations.

This *Swift* sample is the most uniform to date and it is of interest to compare its redshift distribution to models predicting the fraction of GRBs expected to occur at a given redshift. Natarajan et al. (2005; hereafter N05) have modelled the expected redshift distribution for GRBs, utilising several models including those which follow the globally averaged star formation rate (model II), and those which scale according to the average metallicity of the Universe at a given redshift (model IV; see e.g. Fynbo et al. 2003; Fryer & Heger 2005). Gorosabel et al. (2004; hereafter G04) have also carried out a similar exercise, where the GRB rate is assumed to be proportional to the star formation rate. These models are plotted in Fig. 3.

It is remarkable how similar the observed *Swift* redshift distribution is to the model predictions. Contrary to inferences that could be drawn from the pre-*Swift* redshift distribution, we can now reason that GRBs trace star formation (see also Jakobsson et al. 2005). However, with the available sample and the limited flux sensitivity of the *Swift* BAT for \( z > 5 \) bursts, it is currently not possible to determine if GRBs are unbiased tracers of star formation. For example, models II and IV from N05 are nearly indistinguishable when comparing to the relatively small sample of 16 bursts. Note that although model II from N05 and the G04 model both presuppose that the GRB rate is proportional to the star formation rate, they use different assumptions regarding the poorly determined GRB luminosity function and the intrinsic spectral shape, explaining their difference in Fig. 3.

By including all the bursts in Table 2 we are able to constrain the number of bursts above a specific redshift. For example, 7%–40% of the bursts are located at \( z > 5 \). The N05 and G04 predictions are 10% and 2%, respectively, suggesting that the GRB luminosity function parameters and/or the GRB spectral index assumed in N05 might be more appropriate. Bromm & Loeb (2005) also predict that 10% of the *Swift* GRBs should originate at \( z > 5 \).

5. Discussion & Conclusions

The mean redshift of our relatively unbiased *Swift* sample (\( z_{\text{mean}} = 2.8 \)) is larger than the mean redshift of sub-mm galaxies (\( z_{\text{mean}} = 2.4 \); Chapman et al. 2003) and is similar to that of Type 2 AGNs (\( z_{\text{mean}} \approx 3 \); Padovani et al. 2004). With two \( z > 5 \) GRBs discovered within a space of a month, and primarily due to the spectroscopic redshift of \( z = 6.29 \) for GRB 050904 (Kawai et al. 2005), we are finally accessing the GRB high-redshift regime. Are we starting to probe the era of Pop III stars? If the transition between the dark ages and the era of reionization occurred around \( z \approx 6–7 \) (see e.g. Miralda-Escudé 2003 for a review), the answer might be positive. However, Abel et al. (2002) have calculated that at most one massive metal-free star forms per pre-galactic halo, and since the GRB progenitor needs to be a member of a close binary system in the collapsar scenario (e.g. Fryer et al. 1999; MacFadyen & Woosley 1999; Zhang et al. 2004), it seems unlikely that Pop III stars could end their lives as GRBs. Woosley & Heger (2005) have proposed a non-binary possibility in the collapsar scenario, introducing unusually rapidly rotating massive stars. It is therefore conceivable that Pop III stars are GRB progenitors, although it is evident that the number of unknowns is currently too large to arrive at a concrete conclusion.

The number of GRBs without an OA in our sample, sets a strict upper limit on the fraction of heavily dust obscured afterglows as expected in ultraluminous infrared host galaxies (ULIRGs). At most 20% (6/28) of the GRB hosts in the sample can be of this nature. In fact, 5 of the non-detections only have a relatively shallow optical limit, typically \( \approx 19 \) mag (albeit early post-burst), suggesting that the fraction is possibly lower. This is consistent with results from sub-mm observations of pre-*Swift* burst (e.g. Tanvir et al. 2004).

The sample contains GRB 050814, whose OA was particularly faint in the *R*-band; the observed optical to X-ray spectral slope is flatter (\( \beta_{OX} = 0.36 \)) than expected for the fireball model. Hence, GRB 050814 is classified as a dark burst as defined by Jakobsson et al. (2004). We have argued that this is most likely due to the high-redshift nature (\( z = 5.3 \) of this burst; the \( R - I \) colour is extremely red which is impossible to explain by strong extinction given the observed \( I - K \) colour. Indeed, a similar conclusion was proposed for GRB 980329 (Fruchter 1999).

It is clear that GRBs have now opened up a window to the very high-redshift Universe. The emerging GRB redshift histogram (Fig. 3) strongly indicates that they can be used to trace...
the star formation in the Universe over a wide redshift range (0 ≤ z ≤ 7). Future instrumentation, such as the X-shooter (D’Odorico et al. 2004), will hopefully shed light on the end of the dark ages and the possible GRB/Pop III connection.
