Abstract
Objectives: Nonsyndromic hearing loss (NSHL) is the most frequent type of hereditary hearing impairment. Here, we explored the underlying genetic cause of NSHL in a three-generation family using whole-exome sequencing. The proband had concomitant NSHL and rare 48,XXYY Klinefelter syndrome. Material and Methods: Genomic DNA was extracted from the peripheral blood of the proband and their family members. Sanger sequencing and pedigree verification were performed on the pathogenic variants filtered by whole-exome sequencing. The function of the variants was analyzed using bioinformatics software. Results: The proband was digenic heterozygous for p.V37I in the GJB2 gene and p.L347I in the MYO7A gene. The proband’s mother had normal hearing and did not have any variant. The proband’s father and uncle both had NSHL and were compound for the GJB2 p.V37I and MYO7A p.L347I variants, thus indicating a possible GJB2/MYO7A digenic inheritance of NSHL. 48,XXYY Klinefelter syndrome was discovered in the proband after the karyotype analysis, while his parents both had normal karyotypes. Conclusions: Our findings reported a putative GJB2/MYO7A digenic inheritance form of hearing loss, expanding the genotype and phenotype spectrum of NSHL. In addition, this is the first report of concomitant NSHL and 48,XXYY syndrome.

Introduction
Hearing loss (HL) is one of the most common prevalent sensory defects in humans with a frequency of 1–3 per 1,000 newborns, and more than 50% of these cases are attributed to genetic factors [1]. HL has two major types: syndromic HL (SHL) and nonsyndromic HL (NSHL). NSHL is genetically heterogeneous and has various modes of transmission, including autosomal recessive, autosomal dominant, X-linked, and mitochondrial deafness [2]. Currently, more than 100 genes are associated with NSHL (see Hereditary Hearing Loss homepage at http://hereditaryhearingloss.org). Among them, the GJB2, SLC26A4, MYO7A, OTOF, and CDH23 genes are commonly found. With the increased access to next-generation sequencing, the simultaneous de-
tection of variants in two or more genes in patients with NSHL is being discovered, paving a way to the possibility of digenic/oligogenic inheritance of the disease.

48,XXYY Klinefelter syndrome is a rare type of Klinefelter syndrome, which was first described by Muldal et al. [3]. To date, more than 100 cases with 48,XXYY Klinefelter syndrome have been reported, with the incidence of 1/18,000–1/5,000 male births [3]. However, no study has reported on congenital HL combined with 48,XXYY Klinefelter syndrome. In this study, we identified a novel digenic GJB2/MYO7A inheritance of HL in a three-generation family affected by NSHL using whole-exome sequencing. The proband had concomitant NSHL and rare 48,XXYY Klinefelter syndrome.

**Patients and Methods**

**Family Enrollment and Clinical Evaluation**

We studied a three-generation Chinese family with four members affected by congenital HL (Fig. 1a). The proband had concomitant NSHL and 48,XXYY Klinefelter syndrome. Hearing status was determined by self-assessment or pure-tone audiometry (PTA). PTA was calculated as the average of the hearing level at 0.5, 1.0, 2.0, and 4.0 kHz. The level of HL, in terms of PTA, was described as follows: normal hearing, <25 dB; mild hearing impairment, 26–40 dB; moderate hearing impairment, 41–60 dB; severe hearing impairment, 61–80 dB; and profound hearing impairment, >81 dB. The Romberg test and tandem-walking test were performed to assess the vestibular function. Ocular examination included slit-lamp examination and stereoscopic fundoscopy.

**Ethical Statement**

Peripheral blood samples were collected from the family and from 100 unrelated healthy controls. DNA was isolated from the peripheral blood by phenol-chloroform procedures. The Institutional Ethics Committee of the Third Xiangya Hospital approved this study. Written informed consent was obtained from all subjects enrolled in this study. All procedures were performed according to the World Medical Association’s Declaration of Helsinki.

**Methods**

**Whole-Exome Sequencing**

Genomic DNA was isolated from the peripheral blood by standard phenol-chloroform procedures. The isolated DNA was sheared on a Bioruptor UCD-200 (Diagenode, Denville, NJ, USA). For all samples, shearing worked consistently, and the size distribution peak was approximately 200 bp. DNA libraries were prepared using the KAPA Library Preparation Kit (KR0453, Kapa Biosystems, Wilmington, MA, USA). The whole-exome sequencing was performed using SureSelectXT2 Target Enrichment System (Agilent Technologies, Santa Clara, CA, USA). Sample dilution, flow cell loading, and sequencing were performed according to Illumina’s specifications. DNA libraries were sequenced on the HiSeq2500 platform (Illumina, San Diego, CA, USA) as paired-end 200-bp reads. Raw data were filtered and aligned against the human reference genome (hg19) using BWA Aligner (http://bio-bwa.sourceforge.net/). Single-nucleotide polymorphisms were identified using Genome Analysis Toolkit (www.broadinstitute.org/gatk). Variants were annotated using ANNOVAR (annovar.openbioinformatics.org/en/latest/). We anticipated that a causative variant would be missense or gene-disrupting and would be rare in the overall population. Selected variants were checked in relevant variant frequency databases (ESP, dbSNP, 1000 Genomes, ClinVar, and HGMD). We applied filtering criteria that required a variant to have a frequency of <1% in the 1000 Genomes, ExAC, and gnomAD databases. In addition, variations that can cause clinical symptoms were further analyzed. All variants were interpreted according to the standards set out by the American College of Medical Genetics (ACMG) and categorized as pathogenic, likely to be pathogenic, variants of uncertain significance, likely to be benign, and benign.

**Sanger Sequencing**

The candidate variants identified by whole-exome sequencing were then confirmed by polymerase chain reaction (PCR). Primer sequences used for PCR amplification and DNA sequencing of the gap junction protein beta 2 (GJB2) gene (NM_004004) exon 2 were as follows: 5′-GAGCCTTGACAGCTGAGCA-3′ and 5′-TGCCATCCGAGAGCATGTA-3′; those of the myosin VIA (MYO7A) gene (NM_00112718) exon 10 were as follows: 5′-GACAGCATGTAATGGACTC-3′ and 5′-CACAGGAGCCTGCACTGTA-3′. Variants were identified by direct sequencing of PCR products bidirectionally using an ABI 3730xl automated sequencer (Applied Biosystems, USA). Segregation analysis of the respective MYO7A and GJB2 pathogenic variants was performed within the families.

**Results**

**Clinical Characteristics**

The proband (Fig. 1a: III-1) was a 27-year-old male who was referred to our hospital due to HL and the absence of pubertal development. Physical examination showed a height of 170 cm, a weight of 36 kg, and a Tanner developmental stage of G2P1. Laboratory tests showed low levels of testosterone (102.7 ng/dL; reference range [RR] 249–836 ng/dL) and high levels of follicle-stimulating hormone (97.53 mIU/mL; RR 1.7–8.6 mIU/mL) and luteinizing hormone (43.19 mIU/mL; RR 1.7–8.6). Ultrasound examination showed small testicular volumes (left, 15 × 7 mm; right, 15 × 8 mm). No dysmorphic facial abnormalities were observed, such as ocular hypertelorism.

**Fig. 1.** Illustration of the family with digenic GJB2/MYO7A variants. The pedigree shows mutations in GJB2/MYO7A genes (a). Chromosome analyses of the proband revealed 48,XXYY (b). The different hearing levels and the genotype-phenotype relation in the family members are summarized (c). Sequencing chromatograms of the GJB2 p.V37I and MYO7A p.L347I variants (d).

(Figure see next page.)
In silico Analysis

The GJB2 missense variant p.V37I has been reported previously and was predicted to be damaging using PolyPhen-2 and MutationTaster and tolerable using SIFT and PROVEAN. Amino acid alignment of GJB2 among different species revealed that the valine mutated at position 37 was conserved among all species examined (Fig. 2a). According to ACMG guidelines, the GJB2 p.V37I variant was interpreted as pathogenic since this variant has been reported as a pathogenic variant (PS1), with extremely low frequency (PM2), and was predicted to be damaging and disease-causing using PolyPhen-2 and MutationTaster (PP3). The missense MYO7A p.L347I variant was predicted to be disease-causing using SIFT, benign using PolyPhen-2, and tolerable using MutationTaster and PROVEAN. Amino acid alignment of MYO7A among different species revealed that the leucine mutated at position 347 was conserved among species examined (Fig. 2b). According to ACMG guidelines, the MYO7A p.L347I variant was interpreted as variant of uncertain significance since this variant has an extremely low frequency (PM2) and was predicted to be damaging and disease-causing using SIFT (PP3). The MYO7A p.L347I variant was not found in HGMD (http://www.hgmd.cf.ac.uk/), dbSNP (http://www.ncbi.nlm.nih.gov/snp), and ClinVar (http://www.ncbi.nlm.nih.gov/clinvar), indicating that it was a novel variant.

Discussion

Most NSHL forms are monogenic and have genetic heterogeneity. However, digenic/oligogenic inheritance has been reported recently [4–9]. Here, the novel compounds heterozygous for the GJB2 p.V37I variant and MYO7A p.L347I variant were found in the proband. The GJB2 gene accounts for approximately 50% of nonsyndromic autosomal recessive HL (DFNB2) in different populations [10, 11]. The GJB2 gene encodes the gap junction subunit protein connexin 26 (Cx26), which plays a crucial role in intracellular communication by forming the cochlear gap junction. In the inner ear, GJB2 plays a vital role in many auditory processes, including potassium recycling, energy supply, and maintenance of endolymphatic homeostasis [12, 13]. Currently, more than 300 GJB2 variants are associated with HL (HGMD, http://www.hgmd.cf.ac.uk/). The GJB2 p.V37I variant has a high allele frequency (up to 10%) in East Asians [10, 14, 15]. However, the pathogenicity of the p.V37I has yet to be elucidated. Early studies have shown the p.V37I variant as a benign polymorphism, as it was observed in unaffected heterozygous controls. How-
ever, an increasing body of evidence has indicated that both homozygotes and compound heterozygous for the p.V37I variant were associated with mild to moderate hearing impairment [16, 17].

The MYO7A gene encodes the actin-based motor protein myosin-VIIa, which is especially crucial for the function of cochlear hair cells and eye development [18]. The myosin VIIa protein contains a conserved N-terminal actin-binding and ATPase domain (motor domain), a neck region containing five isoleucine-glutamine (IQ) motifs, and a short predicted coiled-coil domain, followed closely by two myosin tail homology 4 (MyTH4) domains, two SH3 domain [18]. The MYO7A gene has long been associated with Usher syndrome type 1B (USH1B), which is characterized by sensorineural HL, retinitis pigmentosa, and vestibular dysfunction [18, 19]. In 1997, Weil et al. [20] and Liu et al. [21] have identified that MYO7A gene variants are associated with DFNB2. So far, most variants identified in MYO7A are associated with USH1B, whereas only approximately 17 MYO7A variants have been found to be responsible for DFNB2 [22, 23]. The novel MYO7A missense p.L347I variant located in the motor domain was predicted to be damaging using in silico analysis. The absence of vestibular and retinal defects in the affected patients suggests that this family has an isolated NSHL presentation, instead of USH1B.

It is estimated that 6–20% of GJB2 mutations in subjects with HL were monoallelic mutations [24]. Researchers have hypothesized that a single heterozygous GJB2 mutant was possibly contributing to deafness via digenic inheritance. In 2009, Liu et al. [5] have identified heterozygous GJB2 and GJB3 mutations in patients with NSHL. Since then, many other forms of digenic inheritance have been reported [4–9], such as GJB2/GJB3, GJB2/MITF, and GJB2/TMPRSS3 (Table 1). Although digenic inheritance has been increasingly described in NSHL, its prevalence is unknown. Chen et al. [4] have assessed the contributions of variants in GJB3 or GJB6 in a cohort of 100 patients with NSHL with likely pathogenic heterozygous GJB2 mutations. Putatively causative GJB3 variants were 1%, and no GJB6 mutation was found. Furthermore, Oldak et al. [25] have screened GJB2 variants in 42 patients with HL with at least one TMPRSS3 pathogenic variant and identified four individuals who were double heterozygous for pathogenic GJB2 and TMPRSS3 variants. They have proposed that the contributions of GJB2 digenic inheritance may not be predominant. In this study, the proband and his father and uncle were digenic heterozygous for the MYO7A p.L347I and GJB2 p.V37I variants. Based on the co-segregated analysis, we implied a possible novel GJB2/MYO7A digenic inheritance of NSHL in this family. However, this study has some limitations. First, it relies exclusively on data from only one family. Second, in vitro data demonstrating a functional link between these two genes are missing. Third, the dominant character of the identified GJB2 p.V37I variant with a possible incomplete penetrance in the family cannot be excluded. Further animal models or cell biology experiments and studies with a large sample size remain needed to clarify the role of the digenic mutations involved.

In this study, the proband had concomitant NSHL and rare 48,XXX Klinefelter syndrome. Compared with 47,XXX Klinefelter syndrome, 48,XXXY syndrome is associated with more severe neurodevelopmental and behavioral abnormalities [26–28]. Tartaglia et al. [26] have found that patients with 48,XXXY syndrome had some facial dysmorphic features, such as ocular hypertelorism, pes pla-

NSHL, nonsyndromic hearing loss.
nus, upward-slanting palpebral fissures, joint laxity, and dental problems. Other medical issues, including allergies and asthma, congenital heart defects, inguinal hernia, and cryptorchidism, were also more common in individuals with 48,XXYY syndrome. However, HL is rarely reported in patients with Klinefelter syndrome. In 1971, Anderson et al. [29] have studied the hearing ability of 26 men with different types of sex chromosome anomalies (usually 47,XXYY [Klinefelter syndrome]). They found that the number of hearing threshold impairments with a probably endogenous origin was unusually high (19%). However, genetic testing was not performed. In 2019, Li et al. [30] have reported a case of concomitant Usher syndrome and Klinefelter syndrome (47,XXYY). To the best of our knowledge, the case reported here is the first reported case of concomitant NSHL and 48,XXYY Klinefelter syndrome in the literature. Whether the NSHL is a new phenotypic feature of 48,XXYY Klinefelter syndrome or it happened by accident needs further investigation.

In conclusion, we reported a putative GJB2/MYO7A digenic inheritance form of HL in a three-generation family affected by NSHL using whole-exome sequencing, expanding the genotypic and phenotype spectrum of NSHL. In addition, this is the first report of a molecularly diagnosed case of concomitant NSHL and 48,XXYY Klinefelter syndrome.
