We present an experimental model system that enables quantitative assessment of intergranular exchange coupling in CoCrPt-oxide perpendicular magnetic recording media. A thin film structure consisting of a high coercivity CoPt unicrystal layer and a lower coercivity CoPt layer separated by a thin oxide interlayer is used to model perpendicularly magnetized grains separated by oxide grain boundaries. Exchange coupling energy between the CoPt layers was obtained for SiOx, TiOx, and CrOx interlayers by measuring field shifts from the lower coercivity layer. Cr segregation in CoCrPt grains to grain boundaries is also modeled experimentally and found to significantly suppress exchange coupling. © 2009 American Institute of Physics. [doi:10.1063/1.3226638]

The recording layer in present perpendicular thin film media consists of at least two magnetic layers: a CoCrPt-oxide granular layer comprising CoCrPt grains separated by oxide grain boundaries and a capping layer comprised of CoCrPt grains free of oxide grain boundaries. Ideally, the oxide grain boundaries would completely disrupt ferromagnetic exchange coupling between adjacent grains in the granular layer, while the capping layer provides spatially uniform intergranular exchange coupling. However, in practice, it is believed that significant intergranular exchange coupling does exist in the CoCrPt-oxide layer of present perpendicular thin film media, especially for media with very small grain sizes.2,3

In this paper, we present an experimental method that enables one to quantitatively determine the ferromagnetic exchange coupling through an oxide layer as a function of oxide layer thickness. The model system consists of two ferromagnetic layers of a Co84Pt16 alloy sandwiching an oxide interlayer. Films were prepared by rf sputtering using a Leybold Heraeus Z400 sputtering system maintained at a base pressure better than 2×10−7 Torr and an argon sputtering pressure fixed at 5 mTorr. A single crystal MgO[110] substrate is used to induce the desired epitaxial film growth [Fig. 1(a)].

The procedure described here closely follows other work done on epitaxial Co-alloy growth using MgO substrates.4,5 A 60 nm thick Cr underlayer is deposited on the MgO substrate. With the substrate heated to 400 °C during this deposition, the Cr layer grows with excellent (112) texture. After the substrate is cooled to room temperature, a 24 nm layer of Co84Pt16 is deposited on the Cr underlayer, which grows with (1010) texture. This layer is known as a “unicrystal” and has a hexagonal close-packed (HCP) structure with a single c-axis orientation variant lying in the plane of the film. The epitaxial relationships can be summarized as follows:

\[ \text{Co}(1\bar{1}0) \parallel \text{Cr}(112) \parallel \text{MgO}(110), \]
\[ \text{Co}(0001) \parallel \text{Cr}[\overline{1}10] \parallel \text{MgO}(001). \]

The x-ray diffraction pattern, shown in Fig. 1(b), and plan view electron diffraction pattern, shown in Fig. 2(a), demonstrate the excellent epitaxial growth of all the layers described above. This is also verified by the in-plane hysteresis loops measured along the MgO [001] (easy axis) and orthogonal MgO[110] (hard axis) directions in the film plane, as shown in Fig. 3(a). These loops were taken from a 50 nm unicrystal sample without a soft overlayer. The easy axis loop shows a coercivity of around 1000 Oe, even though the anisotropy field, as shown by the hard axis loop, is substantially higher.

After deposition of the unicrystal CoPt layer, a thin layer of oxide is deposited, followed by the deposition of another Co84Pt16 layer of 8 nm in thickness. The top CoPt layer does not show any particular texture. Figure 3(b) shows four measured hysteresis loops from this multilayer structure for a TiOx interlayer of different thicknesses with the field applied along the MgO(001) direction. The interlayer exchange field is obtained by measuring the field shift, \( \Delta H_{\text{shift}} \), of the hysteresis loop from the top CoPt layer. The interlayer coupling energy density is calculated according to

\[ \sigma = H_{\text{shift}} M_{s,\text{soft}} \delta_{\text{soft}}, \]  

where \( M_{s,\text{soft}} \) and \( \delta_{\text{soft}} \) are the saturation magnetization (1100 emu/cc) and the thickness (8 nm) of the softer top CoPt layer, respectively.

For each oxide, there is a particular thickness at which point the top and bottom layers have the same reversal field and measuring a shift in the minor loop becomes impossible [e.g., 11 Å; Fig. 3(b)]. However, the coupling energy density can still be estimated from an observed decrease in the reversal field of the major loop following the method of van

der Heijden et al. This decrease is a consequence of the exchange coupling felt by the unicrystal from the soft layer and is expressed as

$$\sigma = (H_{r,0} - H_{r}) M_{S,hard} \delta_{hard},$$

(2)

where $H_{r,0}$ is the intrinsic reversal field (i.e., the coercivity) of the unicrystal layer without interlayer coupling and $H_{r}$ is the reversal field with interlayer coupling.

Cross-section transmission electron microscope (TEM) micrographs show that the oxide interlayer is reasonably smooth and has no obvious discontinuities for the thicknesses studied. Figure 2(b) shows a representative cross-section for a SiO$_2$ interlayer of 1.5 nm thickness.

Figure 4 shows the interlayer coupling energy density as a function of the oxide layer thickness for three different oxides: CrO$_x$ (target composition: Cr$_2$O$_3$), TiO$_x$ (TiO$_2$), and SiO$_x$ (SiO$_2$). The symbols are the actual measurement data and the curves are fitting curves with the following thickness dependence:

$$\sigma = A \exp \left( -\frac{\delta_{oxide}}{B} \right) + C \cdot \delta_{oxide} + D,$$

(3)

where $\delta_{oxide}$ is the oxide layer thickness and $A$, $B$, $C$, and $D$ are all fitting parameters with typical values on the order of $10^2$ ergs/cm$^2$, 1 Å, $10^4$ ergs/cm$^3$, and 0.1 ergs/cm$^2$, respectively. For all three cases, the coupling is ferromagnetic in nature.

The nonzero offset of the coupling energy is likely due to magnetostatic “orange peel” coupling between the two ferromagnetic layers. However, the exponential increase at lower thickness cannot be explained by this magnetostatic coupling mechanism for any plausible interfacial roughness parameters. Therefore, it is reasonable to attribute the sharp increase in energy density to ferromagnetic exchange through the oxide interlayer. While the particular mechanism that explains this ferromagnetic exchange coupling remains unclear, a number of other reports have attributed similar trends in coupling energy to discontinuities, or “pinholes,” in the interlayer. Although detection of pinholes would require a more rigorous study of the oxide interlayer morphology, our preliminary TEM work does not show any obvious discontinuities. It is important to recognize that regardless of the mechanism, the trend is highly dependent on the type of oxide material that is used and is likely related to fundamental properties of the CoPt/oxide interface.

If we define the critical thickness to be the point at which the coupling energy density reaches 0.2 ergs/cm$^2$, the critical thickness for CrO$_x$ is at 1.2 nm, TiO$_x$ at 1.25 nm, and SiO$_x$ at 1.8 nm. The deposition conditions were maintained the same for each layer, including the oxide layers, within this set of presented data. In addition, the oxide deposition conditions were varied for a given oxide by changing the sputtering power, temperature, and deposition rate. It was found that the interlayer exchange coupling was largely independent of these parameters. We conclude that the coupling strength, as a function of oxide layer thickness, is very much a characteristic of the oxide material. It is interesting to note that significant exchange coupling can occur through a SiO$_x$ layer as thick as thick 1.8 nm, even though the layer appears to be continuous.

Magnetic grains in present perpendicular thin film media are actually composed of a CoCrPt alloy (rather than CoPt alloy used in our experiment), and experimental studies have found significant Cr segregation to grain boundaries. It has long been suggested that a Cr-rich CoCr grain boundary could result in a significant disruption of intergranular exchange coupling. To mimic such grain boundary conditions in today’s perpendicular thin film media, i.e., to study the impact of Cr segregation on intergranular exchange coupling, we performed the following addition to the experiments: very thin Cr layers, 1.0–1.5 Å, were deposited prior to, as well as after, the deposition of the oxide layer. Such interfacial “dusting” of pure Cr was performed for both TiO$_x$ and SiO$_x$ layers, the two most commonly used oxide materials in present commercial perpendicular media. Figures 5(a) and 5(b) show the measured interlayer coupling energy densities for the Cr dusting on SiO$_x$ and TiO$_x$ layers, respectively. In the case of a SiO$_x$ layer, with the Cr dusting, the coupling versus oxide layer thickness curve shifts by almost 8 Å. The thickness shift is significantly greater than the added Cr thickness. In the case of TiO$_x$, the shift is significantly smaller as compared with the SiO$_x$ interlayer. Note that the resulting critical thicknesses of the two oxide layers after the Cr dusting become very similar, even though they are very different without the Cr dusting.

The observed effect of interfacial Cr dusting could be due to Cr diffusion into the CoPt layers. Cr/CoPt interfacing
diffusion could very well lead to the formation of a thin CoCrPt layer with large enough Cr concentration to make
the layer paramagnetic instead. The formation of such a layer should result in significant reduction of the interlayer
echange coupling. The measurement data shown in Fig. 5 sug-
gest that an oxide grain boundary thicker than 1 nm could
significantly suppress ferromagnetic exchange coupling from
the adjacent grains. If the characteristic dependence between the exchange
coupling strength and the thickness of an oxide interlayer can
be applied to magnetic grains separated by grain boundaries
made of the same oxide, any adjacent magnetic grains with
grain boundaries thinner than the critical thickness would
experience significant intergranular exchange coupling. More
importantly, variation in grain boundary thickness below the
critical thickness will yield a substantial variation in the in-
tergranular coupling throughout the film. Such variation in
the intergranular exchange coupling over the media will un-
doubtedly lead to a transition noise increase since large spa-
tial fluctuations in the exchange fields will yield significant
shifts in transition boundaries locally. These spatial fluctua-
tions can only be eliminated if the oxide grain boundary
thickness distribution is beyond the critical thickness. The
optimum intergranular exchange coupling strength can be
achieved by tuning the thickness ratio between the CoCrPt-
oxide and the capping layers. Any distribution of oxide grain
boundary thickness below the critical thickness will make
spatially uniform intergranular exchange coupling impossible
within the CoCrPt-oxide layer itself.

In summary, we have developed an experimental model
system to quantitatively assess the intergranular exchange
coupling through oxide grain boundaries in present perpen-
dicular thin film recording media. For all the oxides studied
here, the ferromagnetic exchange coupling shows an expo-

nential dependence on the oxide layer thickness when the
thickness is below a critical value. It is found that this critical
thickness will yield a substantial variation in the inter-
granular coupling over the media. Such variation in
grain boundary thickness below the critical thickness should
also enable studies on various other types of inter-
granular materials in terms of their ability to exchange de-
couple independent of their capability to form well defined
grain boundaries for a given fabrication process.
